The country is split up into the two great natural divisions of the interior highlands or *Jebel*, and low-lying sandy deserts and plains of the seaboard. The latter are from 30 to 100 miles in breadth, skirting the highlands on the west and south, and are only broken where a spur from the mountains approaches the southern outlet of the Red Sea, forming the headland of Sidi Sheikh, exactly opposite to the island of Perim. There are many indications that this seaboard strip of desert was, until a geologically recent period, below sea-level. These plains of Yemen are called *Tehâma*. They are subject to drought, the rainfall being extremely small, but there are, nevertheless, scattered about them, oases where cereals can be reared with success, and water may be obtained in the nullah beds by sinking wells sufficient to supply the flocks and herds of the Beduin. It is in these arid plains that some of the best of Arabian camels are bred. The chief towns of the *Tehâma* are *Hodeida* and *Mokha* on the western coast, and *Aden* (*q.v.*) on the south. *Hodeida* lies on the north-east side of a large bay, sheltered by a promontory to the north-west. It is a large and flourishing town containing about 30,000 inhabitants, with a Turkish garrison. It possesses a climate which is inimical to European existence. At certain seasons of the year it is subject to frightful epidemics of fever. *Mokha* has lost its importance as a trade port since Aden has been occupied by the British. It owes its existence to the trade in coffee. Early in the

17th century English and Dutch established factories at *Mokha*, and a century later the French followed their example, so that for some two centuries *Mokha* became renowned for its wealth. On the British occupation of Aden in 1839 trade left *Mokha*, and since then the town has fallen into decay.

From Aden, northwards, a stretch of some 30 miles of desert separates the volcanic rocks and ridges of the coast from the green and fertile highlands of Yemen. These highlands present a most curious contrast to the arid sterility of the *Tehâma*. Ranges of mountains rise abruptly from the plains to great altitudes (estimated at 10,000 to 12,000 feet, or even higher, but there is no absolute determination of the height of any of the most prominent peaks) and assume a general formation of parallel ranges, with a strike from north-west to south-east, sheltering lateral valleys, which are wide and fertile, highly cultivated, and teeming with agricultural wealth. It is here that coffee and indigo are chiefly grown. Here, in Arabia Felix, English vegetables and many kinds of fruit reach perfection in a climate of which the average mean shade temperature may vary between 60° and 70° F. A line drawn from Aden northwards for 170 to 180 miles will pass not very far from the main water-parting of the plateau, of which the average level is 7000 or 8000 feet, and not far east of the great caravan road which connects *Sanaa*, the capital of Yemen, with the great southern port. It is on this route that the towns of *Kataba*, *Terim*, and *Damar* are situated, and it has probably been through all ages the great central trade-route of Yemen. It is remarkable that whilst the *Tehâma* is subject to a most uncertain rainfall, there should be two regular wet seasons in the highlands, corresponding to the spring and autumn "monsoons" of *Harrar* and the *Galla* country. Rain is said to fall daily during the recurrence of these wet seasons, but with intermittent periods of bright sunshine. Of the beauty of the scenery in the Yemen hill-country, Harris gives us a most vivid description. "Torn into all manner of fantastic peaks, the rocky crags add a wildness to the view that otherwise possesses the most peaceful charms. Rich green valleys, well timbered in places, and threaded by silvery streams of dancing water; sloping fields gay with crops and wild flowers; the terraced or jungle-covered slopes—all are so luxuriant, so verdant, that one's ideas as to the nature of Arabia are entirely upset." Colonel *Wahab*, who surveyed the hills north of *Lahej* in the Aden district, describes the wealth of green terraces, sloping in steps of graceful contour down the spurs of the mountains, as recalling the beauty of Himalayan scenery in the valleys of the *Jumna* and *Sutlej*. *Sanaa*, the capital of Yemen, lies at an elevation of nearly 7800 feet above sea-level, about 250 miles by road to the north of Aden, and 180 by road north-east of *Hodeida*, on the Red Sea coast. Between *Sanaa* and Aden are the three principal towns of *Damar*, *Terim*, and *Kataba*, the last marking the southern frontier of Turkish occupation in the highlands. *Damar*, 9300 feet above sea-level, is described by Harris as being an unwallied town, but protected by small mud forts placed at intervals—an obviously Turkish innovation denoting recent construction. Many of its houses are well built of stone, and decorated with considerable taste. A peculiarity in their construction is the use of slabs of alabaster for the windows, which, being carved in relief, admits of a peculiarly soft and varying light. There is an open square about the centre of the town, the bazaars and narrow streets around it being full of life and busy with trade. As usual, the Jews occupy a separate quarter. The effects of Turkish misrule are everywhere strongly marked in *Damar*. *Terim*, 80 miles from *Sanaa*, is comparatively a new, and essentially a poor, town, built chiefly of sun-dried bricks. It lies between 7000 and 8000 feet above sea-level.

Two notable examples of the engineering skill of the Sabæan and Himyaritic Arabs exist in Yemen; one at *Hirran*, near *Damar* (which Harris believes to be the *Haran* of Biblical record), and the other at *Mareb* or *Saba*. The storage tanks at *Hirran*, which are supplemented by deep wells, were obviously built for the purpose of providing water for the garrison of an ancient fortress which encloses them. Two spurs of a hill have been joined by an enormous wall, whereon there is space sufficient to drive "a carriage and pair." This wall is 150 yards long and 20 feet high, and is built with the peculiar cement which is typical of early Arab construction. Harris recognized in it many points of similarity to a gigantic wall, dating from early Arab times, which exists at *Mekinez* in Morocco. Within the wall is a well of which the lower part is sunk in the solid rock, and above the northern end are a series of three tanks reached by a stairway. *Hirran*, or *Hail Hirran*, as the hill is also called, is perforated with excavations, and abounds in sepulchral ruins and masses of broken pottery. The great dam of *Mareb* (*Sheba* or *Saba*) possibly dates from 1700 years B.C., for its construction is attributed to the father of *Himyar*, the founder of the Himyaritic dynasty. It is certainly of vast antiquity. M. d'Arnaud describes its ruins as comprising a gigantic wall 2 miles long and 175 paces wide, connecting two hills. The water which was stored by means of this enormous dam was

allowed to escape by dykes, or openings, at different levels, so that irrigation could be maintained, no matter at what level the water of the tank might stand. It is supposed to have been burst under exceptional pressure about A.D. 100.

The system of storing water in tanks, and the evidences of its antiquity, are abundant throughout South Arabia, and these evidences may supply a key to the mystery of those strange constructions in Southern Baluchistan and Makrán which for ages have presented an interesting problem to investigators. Throughout Makrán, but perhaps more especially in the districts of Panjgur and Kolwah, there are relics of walls of enormous thickness, and sometimes of considerable height, which are only known to the local inhabitants as Ghorbasta, or Ghabrbasta, the name indicating merely that they were built by a race of sun- or fire-worshippers. No modern Baluchi acknowledges any connexion with them. They possess, in fact, no history—no tradition even; but the peculiarities of their construction distinctly point to the same race of people for their origin as those who terraced the hillsides and reverted the fields round about them with similar masonry.

Those "Asiatic Ethiopians" whom Herodotus places in Southern Baluchistan 500 years B.C. have disappeared, and the Arab influences which now pervade the country from end to end are of later date and different origin; but there can be little doubt that the Sabæan or Himyaritic races of dusky Arabs who fenced round their gold mines in Africa with strange fortifications and built up the vast protective works for water storage in South Arabia, are responsible for many works designed on the same principles and of similar construction on the eastern side of the Persian Gulf. (See BALUCHISTAN.)

A certain amount of fresh light has been thrown on the ancient connexion between Ethiopia and South Arabia by the researches of Glaser. This connexion was evidently so close as to approach to the affinity of blood relationship. Egyptians, Syrians, and Greeks traded with Arabia for frankincense for more centuries before our era than we can clearly count. "In the most primitive times," says McCrindle, "the merchants of Arabia traded to Gaza and Egypt, and the producers of incense in Africa followed their example." What the Greeks called Ethiopia the Egyptians called Punt (or Pwent), Habash, and Kash. Punt certainly referred to both sides of the Red Sea, but the name never occurs in Himyaritic inscriptions. Habash (or Habashat) does occur, and, according to Glaser, the word means "collector"—i.e., collector of incense, and applied equally to Africans and Arabians—to Abyssinia and Somaliland as well as to Hadramut.

The condensed history of the Arab nation from the very earliest ages, which is to be found in the articles "Arabia" and "Yemen" of the ninth edition of the *Encyclopædia Britannica*, sufficiently illustrates the expansion of Arab trade and Arab colonization in those days when Ethiopia and Southern Arabia seem to have been united in the closest bonds of commercial affinity, and gold and frankincense and myrrh formed the chief articles of commercial quest. But whilst the spread of Arab (or Himyaritic) influence to the west and north can be more than faintly estimated from classical records and ancient inscriptions, there is very little said about eastern fields of enterprise, and it is only since the waste places of Baluchistan and the shores of Makrán have been brought under the close scrutiny of the Indian surveyor that evidence has been collected which proves that Arab enterprise, if not Arab empire, included a vast area of Asia to the east of the Persian Gulf, just as it included a vast area of Africa to the west of the Red Sea.

Herodotus refers to Asiatic Ethiopians, but makes no confusion between Africa and Asia as some modern historians suggest. The historians of Alexander's campaigns throw a casual light on the existence of a trade in incense which could only have been carried on by Arab merchants. In enumerating the inhabitants of Southern Gedrosia (Baluchistan), Ptolemy mentions Arbitæ, Parsidæ (or Parsiræ), and Rhamnæ, whose names are too suggestive of the Arab, Persian (or Tajak), and Dravidian ethnic occupation of the same nature that now exists to be altogether accidental. But it is to that invaluable anonymous record, the Periplus, and to the discovery of many relics of the ancient trade in Egyptian or Phœnician glass (the *Τάλοις ἀργή* of the Periplus), which are to be found in abundance on the coast of Makrán, that we are chiefly indebted for the identification of many of the trading ports of the Arabian Sea which would otherwise be subjects of conjecture.

Long before the rise of Mahommed, Semitic colonies had planted themselves in Asia to the east of the Persian Gulf, and from the days (early in the 1st century of our era) that the pilot Hippalus

worked out the problem of a regular passage between India to Africa by making use of the monsoon winds, Arabia competed with Egypt on the commercial highways of the ocean. The *Christian Topography of the Universe*, by Cosmas Indicopleustes (about A.D. 535-547), continues the story of the Periplus about 400 years later, and gives an account of the trade with Malabar and the Eastern Archipelago, which is taken up again by Arab geographers of the next seven centuries. A trading colony of Sabæan Arabs existed at Canton at the beginning of the 7th century. Arabian sciences influenced Chinese astrology, meteorology, and astronomical instruments, according to a learned Chinese authority. Colonies of Arabs and Jews settled early in our era on the southern coasts of Bombay, where their descendants are to be found to this day. When Mahommedan Arabs resorted thither in after ages they met with a friendly reception similar to that which their Sabæan predecessors had obtained, and they shared the honoured name of Moplah together with Christians.

With the rise of Mahommed and the universal acceptance of the creed of Islam, the second chapter in the history of Arabia opens. Hitherto Semitic instincts for trade and barter had been the moving spirit of an extension of Semitic, if not of Arab influence over the whole of the then known world. It was the enormous acquisition of geographical knowledge, supplemented by commercial wealth—the accumulation of centuries of trade, initiated no doubt by the southern or Himyaritic races, but gradually shared by the northern or more distinctly Semitic tribes—that paved the way for the unprecedented success of Arab arms in the cause of "Jehad" or holy war. The chief military movements directed against Europe, Northern Africa, and Persia, under the influence of Islamic religious fervour, and the almost unbroken success which attended these movements, are already briefly recorded. But in this record no note is made of that most remarkable episode in Arab history which culminated in the conquest of Sind, stamped out Greek influences on the Indus, and proved to be the one occasion in history when India was successfully invaded from the west. Very early in the Mahommedan era, if not before it, Arabs from the north—i.e., from Syria—had overrun and occupied Makrán and Sistán. Several attempts to invade India were made before the successful expedition of Mahommed Kasim in A.D. 710. According to latest history (Major Jarrett's translation of Az Siynti), Makrán was subjugated in 644, and in 663 Kirmán, Sistán, and the western mountain districts of Makrán were conquered. Two attempts to capture Debal, the port of Sind, were unsuccessful. In the Caliphate of Moawiah, Abdulla bin Suwad invaded Kaikanan (i.e., the Kalat highlands) and attempted to reach Sind that way; but the attempt failed, and there may still be seen near Kalat the traditional graveyard of the Arabs who fell in the attempt. Frequent Arab incursions were made Indiawards, but they were all by land following the Kirmán and Makrán route from Syria. Buddhism, which prevailed all through Sind and the mountainous districts to the west, had given place to Brahmanism about the middle of the 7th century, when the Brahman Chach usurped the throne of Sind. But it still held its own in Bela, between Sind and Makrán, and in the border province of Gandava (sometimes called Kandahar by Arab geographers), which was known as Budh at the beginning of the 8th century. There were great Arab cities and a flourishing trade between east and west before the Arabs conquered Sind. Kandabel (Gandava), Armail (Las Bela), Kanazbun (Panjgur), were certainly in existence before Sind was conquered, and it is probable that many of the other towns and cities of Makrán which subsequently rose to fame and opulence, when the great trade route to India passed through that country, were already founded, if not already famous.

The conquest of Sind originated in the efforts of Walid (sixth Caliph) to punish the Karak and Med pirates who had plundered vessels from Ceylon laden with presents for the Caliphate. These Karaks (who have left their name at Karachi) were of Scythic origin, and their ethnic affinities may be traced on the Euxine to this day. They have disappeared from the coasts of Baluchistan. The Meds are still there, a humble and starved race of fisher folk now, but once a powerful tribe in the Punjab and on the Indus. They, too, hailed originally from the north. Thus the expedition finally became partly military and partly naval; and it appears to be the first Arab naval expedition in the eastern seas, although they were about the same time occupied in the conquest of Spain from the shores of Africa. It was not until two unsuccessful attempts had been made to reach Debal that Hajjaj, the governor of Irak and Makrán, appointed his relative, the boy-general Mahommed Kasim, to the command of a fresh force, with the conquest of Sind in immediate view, but with the ulterior object of reaching China from the Indus. At the same time another general, Kutaiba, left the Oxus for the same goal, and the governorship of China was promised to whichever of the two reached that country first.

With a force of 6000 picked cavalry, 6000 camel-men, and 3000 baggage animals, Mahommed Kasim traversed Makrán, sending

*The Sind
Invasion.*

at the same time five catapults by sea for the purpose of reducing Debal. He passed through Makrán from west to east, destroying the Buddhist city of Armail (Las Bela) *en route*, and finally captured Debal on the 1st May 712. From that point his onward progress was triumphant. He enlisted Meds and Jats into his army, and by the time he had reduced Sadusan (Haidarabad) and reached Multán he had 50,000 men under him. He extended his conquests northward to the borders of Kashmir, and established an Arab dynasty in Sind which lasted for three centuries. The Caliph Walid died in 715 (after substituting Arabic for Greek as the language of the Indus provinces), and the tragic end of Mahommed Kasim is one of the epics of Arab history. These three centuries of Arab occupation of the Indus valley mark the zenith of Arab ascendancy in Asia. In 770 the governor of Sind became governor of Africa, and again in 800 there was a similar transfer. Amrán was perhaps the most famous governor. His control of Sind lasted from 833 to 841. Before the end of the 9th century Arab rule had commenced to decline; and then arose the cities of Multán and Mansura.

Throughout these centuries Sind maintained regular commercial communication with the rest of the Mahommedan empire; with the regions of the upper Oxus by way of Kabul and Bamian; with the Central Asian khanates through Zabulistan, Kandahar, and Herat; with Persia and Syria and Europe through Makrán; and a host of Arab geographers arose who have partly recounted their own experiences as travellers, and partly (as in the case of the best known of them, Edrisi) acted as geographical compilers. From them we learn the enormous extent of that vast network of commercial routes which was then spread over the face of Asia—a system of roads, caravanserais, and mercantile centres which has left its traces plainly written in spite of the sweeping waves of destruction poured across it by Moghul and Tatar. The skeletons of ancient towns and the dry channels of great irrigation works in the valley of the Helmund and the plains of Sistán witness to the former wealth of these regions under Arab rule; and from Quetta to Herat, and from Herat through Badghis and Afghan Turkestan to the Oxus, there are still to be encountered evidences of Arab occupation in acres of ancient ruins.

One or two of their more famous cities may be mentioned. Tiz, now a heap of ruins and a waste of graveyards on Chahbar bay, was once a great port of debarkation on the Makrán coast for India. It is well situated so as to avoid the full blast of the monsoon winds across the Arabian sea. From Tiz to the fertile valley of Kiz (or Kej), and from Kej to Kanazbun (Panjgur), Armail (Las Bela), Manhabari (Manja, or Mugger, Pir), and Debal, the ancient Indus port (the ruins of which are now far inland), the most frequented of these trade routes extended its length. Kiz and Kanazbun are described as large cities—as large as Multán; and the merchants of Kanazbun were famous for their wealth and their fair dealing. In the Indus valley such cities as Sadusan, Mansura, and Brahmanabad outrivalled the glories of any of our modern Indus towns.

It was doubtless during these three centuries that the Arabs developed their genius for shipbuilding and acquired that command of the eastern seas which was followed by the complete domination of the Mediterranean. As traders, Semitic races had held their own on the seas from the earliest dawn of history, and although they fell before the naval power of Rome, they reasserted themselves in full force, as Saracens, during the Middle Ages, even in the West. In the East they struggled long for supremacy with the Turks and finally lost it, but they were the first sea-power on the Indian Ocean and in the Persian Gulf. The lines they originally laid down for the construction of their sea-going vessels may be as distinctly traced in the early ocean sailing ships of Portugal, Spain, Holland, and England, as their nautical terms and astronomical nomenclature may be found in the mouth of the modern sailor. Many naval terms and nearly all the astronomical divisions of the heavens are of Arab origin. During the sovereignty of the early Caliphs an immense impetus was given in the Baghdad schools to the study of mathematics and the exact sciences. Borrowing their numerals from India and the compass (as well as gunpowder) from China, the Arabs had evolved for themselves systems of navigation and instruments for determining the value of latitude and longitude, before the close of the 12th century. About the time that Roger, king of Sicily, employed the geographer Edrisi in the compilation of a geographical map of the world, Abdul Hassan Ali of Morocco wrote a treatise on astronomy which included a detailed account of the use of instruments already well known and in the hands of Arab navigators. Amongst them was that ingenious instrument the astrolabe, by means of which observations for latitude could be obtained. Longitude was determined then, as now, by the differences between clock and sun time. It seems, indeed, almost incredible that the route to India *viâ* the Cape of Good Hope should have been left to Portuguese navigators to discover; for the Arabs certainly knew how to traverse the Indian Ocean centuries before the arrival of Vasco de Gama. It is possible that that great

Portuguese adventurer made use of Arab pilots in his voyages of discovery. With the rise of schismatics and the birth of those heresies which, under the name of Khariji, Khesaja, Shariite, Ismailite, Karmatian, &c., spread their roots afar from Syria to Mecca and from Mecca to the Indus, the power of the Arab in the East rapidly waned. Chief amongst these sects were the Karmatians. We hear of them first in the days when the power of the Caliphate was declining, ere the reign of Al Muktdar (908-932), by which time the Turks were already aggressive. By then the Karmatian heretics had brought themselves into prominence by plundering Kufa, Basra, and Samara, and even carried off the sacred stone from Mecca. They are not mentioned by Ibn Haukel as being in the Indus valley in the 10th century, but it could not have been long afterwards that they appeared as refugees from Bahrein and El Hasa. About 986 they founded new settlements on the Indus, and shortly afterwards were in possession of Multán and Mansura. Mahmud of Ghazni captured Mansura, about 1036, on his return from Somnat, being already in possession of Khozard (Kalat) and Multán, and thus practically closed the era of Arab ascendancy in Sind. He restored the old mosque at Multán, built by the Ummayyide Caliphs and destroyed by the Karmatians. There is a peculiar interest attaching to these "people of the veil," for they were in close communication with the mediæval schismatics of Syria, the Hashashin, the Ismailites, the Druses, and others of those mystical sects who were indebted to the East for their philosophy and theology and those mystic creeds which ended in pure atheism. The Ghazni rule did not last long. It was soon replaced by the Sumra dynasty of Mahommedan Rajputs, which lasted for three centuries. One of the Sumra rajahs at least was a Karmatian. Pure-bred Arabs had almost disappeared from Sind ere the rise of the Karmatians. It is said that the first Ghaznivide governor of Multán found but very few Arab families remaining; but Baluchistan still continued to attract them, and although the Arabic tongue has disappeared from the regions east of Persia, there is not a tribesman who boasts the title of "asl" or "pure" Baluch, who does not claim Arab descent and associate his ancestry with the tribe of Khoreish. In many cases this claim is obviously without foundation, but there is still a powerful confederation of tribes calling themselves Rind, whose appearance, manners, and traditions are undoubtedly Semitic. They exist in the lower parts of the Kej valley of Makrán, separated by the country of the Brahui from the Indus border Rinds, who occupy the highlands south and east of Quetta under the name of Marris, Bugtis, Bozdars, &c. The Arab tribes (or tribes of Arab extraction) on the Baluch borderland include the best and finest amongst the many peoples of varied origin who occupy positions of independence in the frontier hills.

There is but little to record of evidences in stone and brick of the Arab conquest of Sind. Long lines of tombs, stone-built and massive, are to be seen at Tatta, all of which are of Mahommedan design, but probably of later date than the days of Mansura and Brahmanabad. The best known and the most interesting relics are the curious double-chambered tombs (the two chambers forming a double storey), richly ornamented with geometric designs, and decorated with the true Saracenic arch, which exist in groups throughout southern Sind and the Las Bela borderland. They always exist apart from the visible remains of destroyed cities, being themselves often in a remarkable state of preservation, and conspicuous objects in the landscape by reason of the elevated sites which have been selected for their building. These are attributed to an Arab race called Kalmati, who are said to have originally migrated through Makrán from Oman and who, in the course of their migration, settled on the shores of the Kalmat Khaur, one of the harbours of the southern coast near Pasni. The name Kalmat is so old as to be recognized as the "Kalama" of Nearkos; so that it is probable that the comparatively recent tribe of southern Arabian origin, who, under that name, formed a powerful community in southern Sind within historic times, and have left behind them by far the most perfect Arab monuments to be found on the borders of India west of the Indus, adopted the name of their temporary resting-place in Makrán. Scattered remnants of the tribe are said still to be found in Sind.

Turkish sovereignty is now paramount through all Western Arabia, from Palestine to the strait of Babel-Mandeb, as well as through Eastern Arabia, from Basra, on the Euphrates, to the boundaries of Oman. The cultivated districts of the southern coast are divided between British occupation and that of independent tribes; the central deserts are still the home of the Beduin; and the highlands of Nejd are divided between two independent chiefships, each of which is of doubtful territorial extent, but considerable political significance.

The condition of Arabia about the middle of the 19th century,

Recent history.

when the Wahabi stretched his rule across the peninsula from the Red Sea to the Persian Gulf; when Hasa, Harik, the whole of Nejd, Kasim, Asir, and the provinces adjoining Yemen on the north were united under the sceptre of Feysul, has been well described by Palgrave. In 1870 Feysul, aged and blind, was assassinated, and dissensions arose which led immediately to the decline of Wahabi power, and gave opportunity to the Turk. A Turkish force was despatched into the province of Hasa on the east, and occupied its capital, Hofhuf; and about the same time Turkish interference asserted itself on the west in Asir (between Yemen and Hejaz), and in the inland provinces of Shammar. In 1871 a Turkish army from Syria tentatively established Ottoman sovereignty in Yemen, at the invitation of the Yemenis themselves; but Palgrave considered (with good reason at the time he wrote) that Yemen would not remain long under Turkish rule. The Turks have, however, not only retained their hold on Yemen, but they have rather consolidated than weakened their authority in the Shiah province of Asir, and extended it indefinitely into the hinterland which borders the central desert on the east of Yemen. In Hejaz their authority has never been doubtful, so that all the fertile and populous districts of Western Arabia bordering the Red Sea are now under Ottoman rule; and this rule is only limited on the south by the British occupation of Aden and the consequent extension of British influence into the adjoining districts. No definite boundaries exist; but the southern frontier of Turkish Arabia is placed by the most authoritative maps in a position a little to the south of Kataba. Kataba is about eighty miles due north of Aden, well within the limits of the mountain districts, which here attain to altitudes of 7400 and 7700 feet above sea, as determined by the latest Indian surveys. From a point south of Kataba, which roughly forms the apex of the triangular division of Southern Arabia included within Aden jurisdiction, the partition line between Turkish Arabia and the Aden districts runs irregularly past Tez (a town south of Ibb on the main northern caravan route) to a point on the coast line of the promontory of Sheikh Said, about seventy miles to the west of Aden. Here the Turks have constructed a fort and established a permanent military post at Turba. The guns of the fort do not command Perim, and the object of the occupation is doubtful. It is to this position that the French have advanced a shadowy claim. On the east the division between Aden and Yafi territory reaches from Kataba to the coast, near Shukra, about sixty miles east of Aden. From this point to the borderland of the fertile province of Oman, which occupies the south-eastern corner of the peninsula, the cultivated and habitable districts of the southern coast are under the independent rule of local chiefs who boast (according to Palgrave) an independence of barbarism and poverty which is in great contrast to the organized and progressive governments of the Arab sheikhs of Central Arabia. This hardly agrees with the latest illustration of the conditions of Arab existence in Hadramut afforded by the explorations of Bent. Hadramut is in direct touch with civilizing influences at Haidarabad in the Deccan of India; and in that city many of its chiefs are to be found serving the Nizam. Indigenous Arab government, undisturbed by Ottoman rapacity or by internal dissensions, invariably demands respect. In Southern Arabia, at the present time, it is probably to be found at its best. The province of Oman has always succeeded in maintaining its independence of Turkey, and is now under the rule of a member of the same Yemenite dynasty of Imams that has existed since the province was first delivered from the yoke of Persia, about the middle of the 18th century. The Turks are as firmly established in El Hasa, to the north of Oman, as they are in Hejaz, in Western Arabia. Hofhuf, the capital of El Hasa, is about 40 miles from Ajer, on the coast, and from 90 to 100 from Katif. Here, and at El Bidia, is a small garrison of regular Turkish troops. At Katif, where there is nothing but an old fort facing the sea, a force of *zaptieh* (Turkish gendarmerie) represents Ottoman authority. El Hasa is governed by a Turkish lieutenant-governor under the Wali of Basra. In 1886 the Turks commenced the construction of a fort at Fao, nearly opposite Mohamrah, on the lower Euphrates, which effectually dominated the channel of that river. This was in direct contravention of their treaty engagements with Persia. In consequence of representations made to the Porte by the British Government, the work was suspended some years ago, and guns were never placed in position; but the *enceinte* of the fort remains exactly as first constructed. In the Nejd or highlands of Central Arabia the political divisions of the country are represented by two independent Arab states, governed by the emirs of Jebel Shammar and Riad respectively. Ibn Rashid of Jebel Shammar, lately deceased, was reckoned to be the most important political personage amongst Arab chiefs of the present day. He was said to possess a bodyguard of 1000 mounted negroes, whose steeds are arrayed in silver harness. He is undoubtedly a strong and capable ruler. The two emirs or sheikhs are independent of each other; but both admit Turkish influence, whilst they repudiate Turkish sovereignty. The Turks themselves, for political reasons, still include all the Wahabi territory which they once dominated under the term Nejd in their official documents, and they maintain

their nominal rights as conquerors over the country. Practically, they do not interfere with the local Arab governments, which appear to be strong, progressive, and equitable.

Turkish authority in Yemen has never been established on the firm basis which supports it in El Hasa and Hejaz. Turkish misrule and oppression have, no doubt, much to answer for in promoting the rebellions and disturbances which, *The Yemen rebellion*, with but intermittent periods of rest from exhaustion, have harassed Yemen since 1891. But it must be remembered that the province of Asir, north of Yemen, in which these rebellions commenced, is a Shiah district, allied by religious principles to Yemen rather than to the orthodox province of Hejaz, and that there are some 600,000 Wahabis, as well as upwards of 2,000,000 Shiites in Yemen who do not recognize the Caliphate of the sultan in any way, and who will always dispute Ottoman sovereignty when an opportunity may arise which promises success. The easy and slack government of the Shiah Imam of Yemen had terminated in something approaching to general anarchy in the country in 1871, when the Yemenites rashly invited Turkish intervention. The Turks came from Hodeida, and, *more suo*, they came to stay. Although the Imam survived the Turkish occupation of Sanaa, the capital of Yemen, he existed only as a Turkish pensioner, and the Arab tribespeople soon found themselves little better than Turkish slaves. Acts of oppression and violence on the part of the Turkish authorities led to a revolt which commenced with resistance to tax-collecting on the part of an Asir tribe, the Beni Meruan, in 1891. Turkish rule had never been more than nominal in Asir, and so long as the Beduin rulers of Hejaz withheld their support it was of no great political significance. But the first reverse sustained by the Turkish troops (who took the field unprepared, and were defeated with a loss of 400 men in the early stages of the rebellion) set all Yemen aflame, and in a very short time the insurrection included all tribes south of Asir, excepting the Beduin of the Tehama. A Turkish force which landed at Hodeida under Ahmad Feizi Pasha—formerly governor of Mecca—checked its progress for a time. Manakha was retaken, Sanaa relieved, and Ismail Pasha was despatched to crush the rebellion in the south. Here a rapid collapse of the insurrection ensued, and, with 40,000 Turkish troops in Yemen, it appeared in 1893 as if resistance was at an end. The northern mountain districts, however, were but half subdued, and with but small provocation the flame has burst out again and again with intermittent persistency ever since. In May 1895 the British vice-consul was murdered. Early in 1896 fighting between the Ateyba and Harb tribes was reported; and the disturbances culminated with a partially successful assault upon Yambo (where the governor was wounded in the conflict) and in a mutiny at Jidda. It was decided to build forts at Jidda, and to despatch further reinforcements; but the record of the next two years still continued to be one of local disturbance throughout the country, and of more or less organized rebellion in certain parts of it. The plundering propensities of the Wali, and the unrest which is the invariable sequel of famine, led to another serious rising in 1899, and to the despatch of 22,000 troops and 7 batteries of artillery from Mecca. In May 1899 the Turks suffered a severe reverse at the hands of the Beduin, led by the Imam; but another hard-fought battle took place in June, in which the Turks were successful. In October of the same year 35 regiments, each 400 strong, left Constantinople for Upper Yemen; and since then, although, according to report, there have been intermittent fighting and active rebellion from time to time, it is clear that on the whole the Turks have not only maintained their position but have annexed new country and extended their occupation to the eastern hinterland of Yemen. Turkish occupation has doubtless favoured the interests of Great Britain in Yemen by affording some sort of guarantee for the safety of trade routes. The greater part of the Yemen trade now flows to Aden. The anarchy which preceded Turkish rule affected not only local trade but the importation of European goods from the Persian Gulf.

As might be expected from the close connexion which exists between commercial Arabia and India, trade prospects have suffered considerably from the influences of famine and plague of late years. The Jidda trade in 1897 showed a falling off *Trade* of nearly £51,780 (or 8 per cent.), reducing the total import value to about £645,000. On the other hand, trade with Egypt (which, curiously enough, includes the importation of a considerable amount of Brazilian coffee) is increasing rapidly. The chief imports are rice, wheat, and manufactured goods. The decrease in the value of the latter alone amounted to £35,740. Exports (chiefly hides, gum, and mother-of-pearl) also show a decrease, the total value only amounting to £19,250. Hodeida has suffered equally from the general depression of trade, although the want of a harbour must be reckoned as a permanent drawback to trade with this port. The total imports (piece goods, food stuffs, spices, and dates, chiefly) were valued in 1897 at £705,200, and the exports at £712,660. The latter are mostly coffee and hides, the value of the coffee export alone being over half a million. The products

of Yemen are almost exclusively agricultural. Coffee, dates, vegetables, and fruit from the hills, with rock-salt, iron, and coal from the Tehâma and lowlands, are the chief items in the trade reports, the lowland productions being inconsiderable. The Yemenis (estimated at 3,000,000 souls) weave a kind of coarse cloth, and they dye American cloth goods, and build ships; but they have apparently no other industries. Eastern Arabia contributes something to the trade of the Persian Gulf. Bahrein is answerable for an export of nearly half a million in value, and an import of £550,000. The former includes dates, rice, pearls, and specie as the principal items, the value of the pearl export in 1898 being nearly £300,000. The imports include coffee, dates, piece-goods, rice (in large quantities from India, and of the very best quality, much of which is exported to the mainland), pearls, and metals. Of the total export value of £387,000 from the Arab coast ports in 1898, £357,700 worth went to Persia, and of that amount £343,750 is included under the head "pearls." This indicates that Linja, on the Persian coast, is the great trade mart for pearls of the Gulf; and that Arab trade, independently of this valuable item, is inconsiderable. The rice trade with India is that which figures most largely in the general commercial record of trade with ports outside the Gulf, and this, no doubt, is important. (For Aden trade see ADEN.)

Arabistan, formerly known as Khúzistân, a province of Persia, bounded on the S. by the Persian Gulf, on the W. by Turkish territory, on the N. by Luristân, and on the E. by the Bakhtiari district and Fars. It is now subdivided into the districts of Muhamrah (*q.v.*), Fellahíyeh (the old Dorák), Rám-Hormuz (popularly known as Rámiz), Havízeh, Shushtar, and Dizfúl, has a population of about 200,000 (mostly Arabs), and pays a yearly revenue of about £30,000. The soil is very fertile; but since the dam over the Karun at Ahvaz was swept away, and the numerous canals which diverted the waters of the Karun and other rivers for irrigation were neglected and became useless, a great part of the province is uncultivated, and most of the crops depend for water on rainfall or the overflowing of the rivers.

The district of SHUSHTAR, with the city of same name, 22 villages, and about 3700 families of the Kunduzú, Sád, Anaffjeh, and Al-i-Kethír tribes, has a population of about 40,000, and pays a yearly revenue of about £6000. The city, with a population of about 15,000, is situated at an elevation of 400 feet at the point where the Karun river bifurcates into the Ab-i-Gerger and Shutait, in 32° 3' N. lat. and 48° 53' E. long.

The district of DIZFÚL, with the city of same name, 12 villages, and 1000 families of the Al-i-Kethír tribe, has a population of about 40,000, and pays a yearly revenue of about £6000. The city has a population of about 25,000, and is situated on the left bank of the Ab-i-Diz at an elevation of 600 feet in 32° 25' N. lat. and 48° 28' E. long. (A. H. S.)

Arabkir, a prosperous town of Asia Minor, in the Memuret el-Aziz, or Kharpút viláyet, situated on an elevated plateau, near a small tributary of the Euphrates. Its large Armenian population suffered severely during the massacres of 1895. Population, before 1895, 20,000 (Moslems, 11,000; Christians, 9000).

Aracaju, a city and port of Brazil, capital of the state of Sergipe. The town was founded in 1855, and has now a population of about 10,000. It has a hospital, high school, normal school, a number of churches, and other public buildings.

Aracaty, a town and port of Brazil, in the state of Ceara, with a population of 18,000. It is an important commercial centre, visited by several lines of coastwise steamers.

ARACHNIDA.

ARACHNIDA is the name given in 1815 by Lamarck (Greek, ἀράχνη, a spider) to a class which he instituted for the reception of the spiders, scorpions, and mites previously classified by Linnæus in the order Aptera of his great group Insecta. Lamarck at the same time founded the class Crustacea for the lobsters, crabs, and water-fleas, also until then included in the order Aptera of Linnæus. Lamarck included the Thysanura and the Myriapoda in his class Arachnida. The Insecta of Linnæus was a group exactly equivalent to the Arthropoda founded a hundred years later by Siebold and Stannius. It was thus reduced by Lamarck in area, and made to comprise only the six-legged, wing-bearing "Insecta." For these Lamarck proposed the name Hexapoda; but that name has been little used, and they have retained to this day the title of the much larger Linnæan group, viz., Insecta. The position of the Arachnida in the great sub-

phylum Arthropoda, according to recent anatomical and embryological researches, is explained in another article (ARTHROPODA). The Arachnida form a distinct class or line of descent in the grade Euarthropoda, diverging (perhaps in common at the start with the Crustacea) from primitive Euarthropods, which gave rise also to the separate lines of descent known as the classes Diplopoda, Crustacea, Chilopoda, and Hexapoda.

Limulus an Arachnid.—Modern views as to the classification and affinities of the Arachnida have been determined by the demonstration that *Limulus* and the extinct Eurypterines (Pterygotus, &c.) are Arachnida; that is to say, are identical in the structure and relation of so many important parts with *Scorpio*, whilst differing in those respects from other Arthropoda that it is impossible to suppose that the identity is due to homoplasy or convergence, and the conclusion must be accepted that the resemblances arise from

close genetic relationship. The view that *Limulus*, the king-crab, is an Arachnid was maintained as long ago as 1829 by Straus-Durkheim (1), on the ground of its possession of an internal cartilaginous sternum—also possessed by the Arachnida (see Figs. 1, 2, 3, 4, 5, and 6)—and of the similarity of the disposition of the six leg-like appendages around the mouth in the two cases (see Figs. 45 and 63). The evidence of the exact equivalence of the segmentation and appendages of *Limulus* and *Scorpio*, and of a number of remarkable points of agreement in their

FIG. 1.—Entosternum, entosternita or plastron of *Limulus polyphemus*, Latr. Dorsal surface. LAR, left anterior process; RAP, right anterior process; Ph.N., pharyngeal notch; ALR, anterior lateral rod or tendon; PLR, posterior lateral rod or tendon; PLP, posterior lateral process. structure, was furnished by Lankester in an article published in 1881 ("Limulus and Arachnid," *Quart. Journ. Mic. Sci.* vol. xxi. N.S.), and in a series of subsequent memoirs, in which the structure of the entosternum, of the coxal glands, of the eyes, of the veno-pericardiac muscles, of the respiratory lamellæ, and of other parts, was for the first time described, and in which the new facts discovered were shown uniformly to support the hypothesis that *Limulus* is an Arachnid. A list of these memoirs is given at the close of this article (2, 3, 4, 5, and

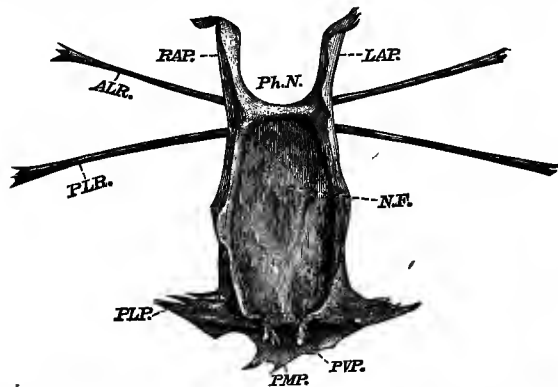

FIG. 2.—Ventral surface of the entosternum of *Limulus polyphemus*, Latr. Letters as in Fig. 1 with the addition of N.F., neural fossa protecting the aggregated ganglia of the central nervous system; PVP, left posterior ventral process; PMP, posterior median process. Natural size. (From Lankester.)

13). The Eurypterines (Gigantostroma) were included in the identification, although at that time they were supposed to possess only five pairs of anterior or prosomatic appendages. They have now been shown to possess six pairs (Fig. 47), as do *Limulus* and *Scorpio*.

The various comparisons previously made between the structure of *Limulus* and the Eurypterines on the one hand, and that of a typical Arachnid, such as *Scorpio*, on the other, had been vitiated by erroneous notions as to the origin of the nerves supplying the anterior appendages of

Limulus (which were finally removed by Alphonse Milne-Edwards in his beautiful memoir (6) on the structure of that animal), and secondly by the erroneous identification of the double sternal plates of *Limulus*, called "chilaria," by Owen, with a pair of appendages (7). Once the identity of the chilaria with the pentagonal sternal plate of the scorpion is recognized—an identification first insisted on by Lankester—the whole series of segments and appendages in the two animals, *Limulus* and *Scorpio*, are seen to correspond most closely, segment for segment, with one another (see Figs. 7 and 8).

The structure of the prosomatic appendages or legs is also seen to present many significant points of agreement (see figures), but a curious discrepancy existed in the six-jointed structure of the limb in *Limulus*, which differed from the seven-jointed limb of *Scorpio* by the defect of one joint. Mr R. I. Pocock of the British Museum has lately observed that in *Limulus* a marking exists on the fourth joint, which apparently indicates a previous division of this segment into two, and thus establishes the agreement of *Limulus* and *Scorpio* in this small feature of the number of segments in the legs (see Fig. 11).

It is not desirable to occupy the limited space of this article by a full description of the limbs and segments of *Limulus* and *Scorpio*. The reader is referred to the complete series of figures here given, with their explanatory legends (Figs. 12, 13, 14, 15). Certain matters, however, require comment and explanation to render the comparison intelligible.¹ The tergites, or chitinized dorsal halves of the body rings, are fused to form a "prosomatic carapace," or carapace of the prosoma, in both *Limulus* and *Scorpio* (see Figs. 7 and 8).

This region corresponds in both cases to six somites, as indicated by the presence of six pairs of limbs. On the surface of the carapace there are in both animals a pair of central eyes with simple lens and a pair of lateral eye-tracts, which in *Limulus* consist of closely-aggregated simple eyes, forming a "compound" eye, whilst in *Scorpio* they present

FIG. 3.—Entosternum of *Scorpio* (*Palamnaeus indus*, De Geer; dorsal surface. *asp*, paired anterior process of the sub-neural arch; *ap*, anterior lateral process (same as RAP and LAR in Fig. 1); *tmp*, lateral median process (same as ALR and PLR of Fig. 1); *pp*, posterior process (same as PLP in Fig. 1); *pf*, posterior flap or diaphragm of Newport; *m*¹ and *m*², perforations of the diaphragm for the passage of muscles; *DR*, the paired dorsal ridges; *GC*, gastric canal or foramen; *AC*, arterial canal or foramen. Magnified five times linear. (After Lankester, *loc. cit.*)

FIG. 4.—Ventral surface of the same entosternum as that drawn in Fig. 3. Letters as in Fig. 3 with the addition of N.C., neural canal or foramen. (After Lankester, *loc. cit.*)

¹ The discussion of the segmentation or metamerism of the Arachnida in this article should be read after a perusal of the article ARTHROPODA by the same author.

several separate small eyes. The microscopic structure of the central and the lateral eyes has been shown by Lankester and Bourne (5) to differ; but the lateral eyes

Following the prosoma is a region consisting of six segments (Figs. 14 and 15), each carrying a pair of plate-like appendages in both *Limulus* and *Scorpio*. This region is called the mesosoma. The tergites of this region and those of the following region, the metasoma, are fused to form a second or posterior carapace in *Limulus*, whilst remaining free in *Scorpio*. The first pair of foliaceous appendages in each animal is the genital operculum; beneath it are found the openings of the genital ducts. The second pair of mesosomatic appendages in *Scorpio* are known as the "pectens." Each consists of an axis, bearing numerous blunt tooth-like processes arranged in a series. This is represented in *Limulus* by the first gill-bearing appendage. The leaves (some 150 in number) of the gill-book (see figure) correspond to the tooth-like processes of the pectens of *Scorpio*. The next four pairs of appendages (completing the mesosomatic series of six) consist, in both *Scorpio* and *Limulus*, of a base carrying each 130 to 150 blood-holding, leaf-like plates, lying on one another like the leaves of a book. Their minute structure is closely similar in the two cases; the leaf-like plates receive blood from the great sternal sinus, and serve as respiratory organs. The difference between the gill-books of *Limulus* and the lung-books of *Scorpio* depends on the fact that the latter are adapted to aerial respiration, while the former serve for aquatic respiration. The appendage carrying the gill-book stands out on the surface of the body in *Limulus*, and has other portions developed

FIG. 5.—Entosternum of one of the mygalomorphous spiders; dorsal surface. Ph.N., pharyngeal notch. The three pairs of rod-like tendons correspond to the two similar pairs in *Limulus*, and the posterior median process with its repetition of triangular segments closely resembles the same process in *Limulus*. Magnified five times linear. (From Lankester, *loc. cit.*)

FIG. 6.—Ventral surface of the same entosternum as that drawn in Fig. 5. Ph.N., pharyngeal notch. Behind it on the body of the entosternum is seen the neural fossa, as in Fig. 2. (After Lankester, *loc. cit.*)

of *Scorpio* were shown by them to be similar in structure to the lateral eyes of *Limulus* and the central eyes of *Scorpio* to be identical in structure with the central eyes of *Limulus* (see below).

FIG. 7.—Diagram of the dorsal surface of *Limulus polyphemus*. oc, lateral compound eyes; central monomelic eyes; PA, post-anal spine; I to VI, the six appendage-bearing somites of the prosoma; VII, usually considered to be the tergum of the genital somite, but suggested by Mr Pocock to be that of the otherwise suppressed pre-genital somite; VIII to XIII, the six somites of the mesosoma, each with a movable pleural spine and a pair of dorsal entopophysis or muscle-attaching ingrowths; XIV to XVIII, the confluent or unexpressed six somites of the metasoma. (From Lankester, *Q. J. Micro. Sci.* vol. xxi. 1891.) According to the system of numbering explained in the text, if VII is the tergum of the pre-genital somite (as is probable) it should be labelled Prg without any number, and the somites VIII to XIII should be lettered 1 to 6, indicating that they are the six normal somites of the mesosoma; whilst XV to XVIII should be replaced by the numbers 7 to 12—an additional suppressed segment (masking up the typical six) being reckoned to the mesosomatic fusion.

FIG. 8.—Diagram of the dorsal surface of a *Scorpio* to compare with Fig. 7. Letters and Roman numerals as in Fig. 7, excepting that VII is here certainly the tergum of the first somite of the mesosoma—the genital somite—and is not a survival of the embryonic pre-genital somite. (From Lankester, *loc. cit.*) The anus (not seen) is on the sternal surface.

FIG. 9.—Ventral view of the posterior carapace or meso-meta-somitic (opisthosomatic) fusion of *Limulus polyphemus*. The soft integument and limbs of the mesosoma have been removed as well as all the viscera and muscles, so that the inner surface of the terga of these somites with their entopophyses are seen. The unsegmented dense chitinous sternal plate of the mesosoma (XIII to XVIII) is not removed. Letters as in Fig. 7. (After Lankester, *loc. cit.*)

besides the gill-book and its base; it is fused with its fellow of the opposite side. On the other hand, in *Scorpio*, the gill-book-bearing appendage has sunk below the surface, forming a recess or chamber for itself, which communicates with the exterior by an oval or circular "stigma" (Fig. 10, *stg*).

FIG. 10.—Ventral view of a Scorpion, *Palamnoeus indus*, De Gear, to show the arrangement of the coxae of the limbs, the sternal elements, genital plate and pectens. M, mouth behind the oval median camerostome; I, the chelicera; II, the chele; III to VI, the four pairs of walking legs; VIIgo, the genital somite or first somite of the mesosoma with the genital operonum (a fused pair of limbs); VIIIp, the pectiniferous somite; IXstg to XIIstg, the four pulmonary somites; met, the pentagonal metasternite of the prosoma behind all the coxae; α , the sternum of the pectiniferous somite; y, the broad first somite of the metasoma.

of the mesosoma (Fig. 49), would throw light on this matter; but the specimen recently carefully studied by the writer and Mr Pocock reveals neither gill-bearing limbs nor stigmata. The probability appears to be against an actual introversion of the appendage and its lamellæ, as was at one time suggested by Lankester. It is probable that

such an in-sinking as is shown in the accompanying diagram has taken place (Fig. 15); but we are yet in need of evidence as to the exact equivalence of margins, axis, &c., obtaining between the lung-book of *Scorpio* and the gill-book of *Limulus*. Zoologists are

FIG. 11.—Third leg of *Limulus polyphemus*, showing the division of the fourth segment of the leg by a groove S into two, thus giving seven segments to the leg as in *Scorpio*. (From a drawing by Mr Pocock.)

familiar with many instances (fishes, crustaceans) in which the protective walls of a water-breathing organ or gill-apparatus become converted into an air-breathing organ or lung, but there is no other case known of the conversion of gill processes themselves into air-breathing plates.

The identification of the lung-books of *Scorpio* with the gill-books of *Limulus* is practically settled by the existence of the pectens in *Scorpio* (Fig. 14, VIII.)

on the second mesosomatic somite. There is no doubt that these are parapodial or limb appendages, carrying numerous imbricated secondary processes, and therefore comparable in essential structure to the leaf-bearing plates of the second mesosomatic somite of *Limulus*. They have remained unenclosed and projecting on the surface of the body, as once were the appendages of the

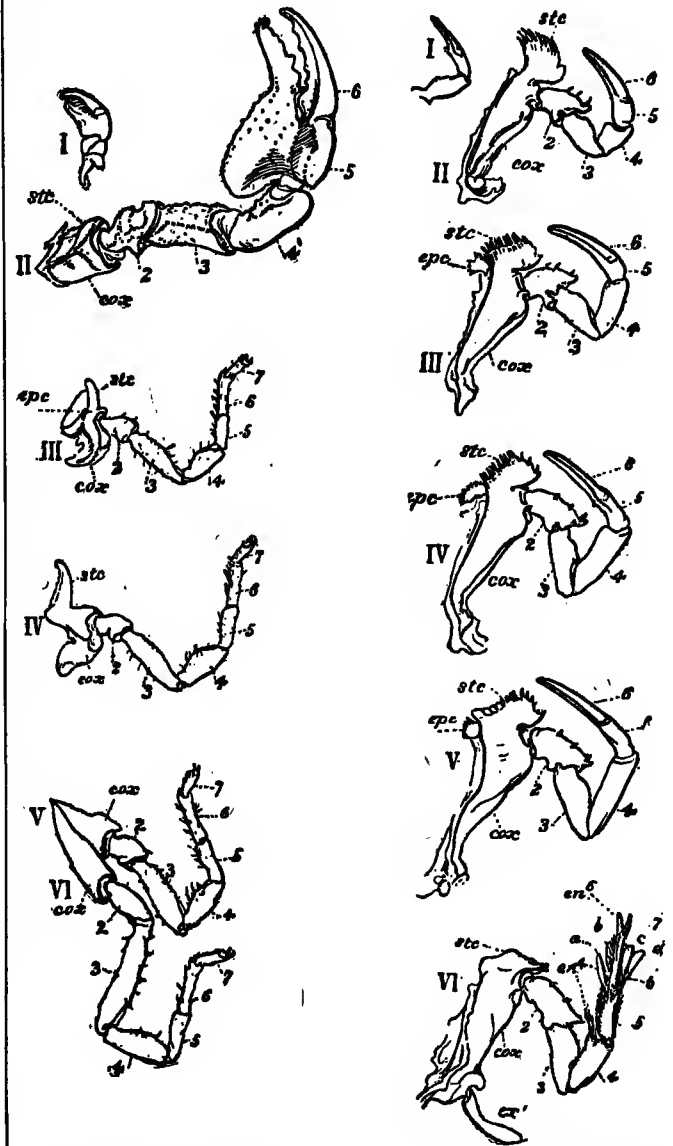

FIG. 12.—The prosomatic appendages of *Limulus polyphemus* (right) and *Scorpio* (left), *Palamnoeus indus* compared. The corresponding appendages are marked with the same Roman numerals. The Arabic numerals indicate the segments of the legs. cox, coxa or basal segment of the legs; stc, the sterno-coxal process or jaw-like up-growth of the coxa; epo, the articulated movable outgrowth of the coxa, called the epi-coxite (present only in III of the *Scorpio* and III, IV, and V of *Limulus*); α , the exopodite of the sixth limb of *Limulus*; a, b, c, d, movable processes on the same leg (see for some suggestions on the morphology of this leg, Pocock in *Quart. Journ. Micr. Sci.*, March 1901; see also Fig. 50 below and explanation.) (From Lankester, *loc. cit.*)

four following somites. But they have lost their respiratory function. In non-aquatic life such an unprotected organ cannot subservise respiration. The "pectens" have become more firmly chitinized and probably somewhat altered in shape as compared with their condition in the aquatic ancestral scorpions. Their present function in scorpions is not ascertained. They are not specially sensitive under ordinary conditions, and may be touched or even pinched without causing any discomfort to the scorpion. It is probable that they acquire special

sensibility at the breeding season and serve as "guides" in copulation. The shape of the legs and the absence of paired terminal claws in the Silurian Palæophonus (see Figs. 48 and 49) as compared with living scorpions

soft tissues of the sternal region so that the lamellæ cannot be detached and presented as standing out from it. The apparent axis or basal support of the scorpion's lung-books shown in the figures, is a false or secondary axis and merely a part of the infolded surface which forms the air-chamber. The maceration of the soft parts of a scorpion preserved in weak spirit and the cleaning of the chitinized ingrown cuticle give rise to the false

FIG. 13.—Diagrams of the meta-sternite *st*, with genital operculum *op*, and the first lamelligerous pair of appendages *ga*, with uniting sternal element *st* of Scorpio (left) and *Limulus* (right). (From Lankester, *loc. cit.*)

(see Fig. 10) show that the early scorpions were aquatic, and we may hope some day in better-preserved specimens than the two as yet discovered, to find the respiratory organs of those creatures in the condition of projecting appendages serving aquatic respiration somewhat as in *Limulus*, though not necessarily repeating the exact form of the broad plates of *Limulus*.

It is important to note that the series of lamellæ of the lung-book and the gill-book correspond *exactly* in structure, the narrow, flat, blood-space in the lamellæ being interrupted by pillar-like junctions of the two surfaces in both cases (see Lankester (4)), and the free surfaces of the adjacent lamellæ being covered with a very delicate chitinous cuticle which is drawn out into delicate hairs and processes. The elongated axis which

FIG. 15.—The remaining three pairs of mesoecomatic appendages of *Scorpio* and *Limulus*. Letters as in Fig. 14. 130 indicates that there are 130 lamellæ in the Scorpion's lung-book, whilst 150 indicates that 150 similar lamellæ are counted in the gill of *Limulus*. (After Lankester, *loc. cit.*)

appearance of a limb axis carrying the lamellæ. The margins of the lamellæ of the scorpion's lung-book which are *lowermost* in the figures (Fig. 15) and appear to be free are really those which are attached to the blood-holding axis. The true free ends are those nearest the stigma.

FIG. 14.—The first three pairs of mesoecomatic appendages of *Scorpio* and *Limulus* compared. VII, the genital operculum; VIII, the postens of *Scorpio* and the first branchial plate of *Limulus*; IX, the first pair of lung-books of *Scorpio* and the second branchial plate of *Limulus*; *gp*, genital pore; *epst*, epistigmatic sclerite; *stg*, stigma or orifice of the hollow tendons of the branchial plates of *Limulus*. (After Lankester, *loc. cit.*)

opens at the stigma in *Scorpio* and which can be cleared of soft, surrounding tissues and coagulated blood so as to present the appearance of a limb axis carrying the book-like leaves of the lung is not really, as it would seem to be at first sight, the limb axis. That is necessarily a blood-holding structure and is obliterated and fused with

Passing on now from the mesosoma we come in *Scorpio* to the metasoma of six segments, the first of which is broad whilst the rest are cylindrical. The last is perforated by the anus and carries the post-anal spine or sting. The somites of the metasoma carry no parapodia. In *Limulus* the metasoma is practically suppressed. In the allied extinct Eurypterines it is well developed, and resembles that of *Scorpio*. In the embryo-*Limulus* (Fig. 42) the six somites of the mesosoma are not fused to form a carapace at an early stage, and they are followed by three separately marked metasomatic somites; the other three somites of the metasoma have disappeared in *Limulus*, but are represented by the unsegmented præ-anal region. It is probable that we have in the metasoma of *Limulus* a case of the disappearance of once clearly demarcated somites. It would be possible to suppose, on the other hand, that new somites are only beginning to make their appearance here. The balance of various considerations is against the latter hypothesis. Following the metasoma. In *Limulus*, we have as in *Scorpio* the post-anal spine—in this case not a sting, but a powerful and important organ of locomotion, serving to turn the animal over when it has fallen upon its back. The nature of the post-anal spine has been strangely misinterpreted by some writers. Owen (7) maintained that it represented a number of coalesced

somites, regardless of its post-anal position and mode of development! The agreement of the grouping of the somites, of the form of the parapodia (appendages, limbs)

FIG. 16.—Diagram to show the way in which an outgrowing gill-process bearing blood-holding lamellae, may give rise, if the sternal body wall sinks inwards, to a lung-chamber with air-holding lamellae. I is the embryonic condition; *bs*, blood sinus; L is the condition of outgrowth with *gl*, gill lamellae; A is the condition of in-sinking of the sternal surface and consequent enclosure of the lamelliferous surface of the appendage in a chamber with narrow orifice—the pulmonary air-holding chamber; *pl*, pulmonary lamellae; *bs*, blood sinus. (After Kingsley.)

pendages, and the metasoma being destitute of appendages.

In 1893, some years after the identification of the somites of *Limulus* with those of *Scorpio*, thus indicated, had been published, zoologists were startled by the discovery by a Japanese zoologist, Mr Kishinouye (8) of a seventh prosomatic somite in the embryo of *Limulus longispina*. This was seen in longitudinal sections, as shown in Fig. 19. The simple identification of somite with somite in *Limulus* and *Scorpio* seemed to be threatened by this discovery. But in 1896 Dr August Brauer of Marburg (9) discovered in the embryo of *Scorpio* a seventh prosomatic somite (see VII. PrG, Figs. 17 and 18), or, if we please so to term it, a *præ-genital* somite, hitherto unrecognized. In the case of *Scorpio* this segment is indicated in the embryo by the presence of a pair of rudimentary appendages, carried by a well-marked somite. As in *Limulus*, so in *Scorpio*, this unexpected somite and its appendages disappear in the course of development. In fact, more or less complete "excalation" of the somite takes

place. Owing to its position it is convenient to term the somite which is excalated in *Limulus* and *Scorpio* "the *præ-genital* somite." It appears not improbable that the sternal plates wedged in between the last pair of legs in both *Scorpio* and *Limulus*, viz., the pentagonal sternite of *Scorpio* (Fig. 10) and the chilaria of *Limulus* (see Figs. 13 and 20), may in part represent in the adult the sternum of the excalated *præ-genital* somite. This has not been demonstrated by an actual following out of the development, but the position of these pieces and the fact that they are (in *Limulus*) supplied by an independent segmental nerve, favours the view that they may comprise the sternal area of the vanished *præ-genital* somite. This interpretation, however, of the "metasternites" of *Limulus* and *Scorpio* is opposed by the coexistence in *Thelyphonus* (Figs. 55, 57, and 58) of a similar metasternite with a complete *præ-genital* somite. Hansen (10) has recognized that the "præ-genital somite" persists in a rudimentary condition, forming a "waist" to the series of somites in the Pedipalpi and Araneæ. The present writer is of opinion that it will be found most convenient to treat this evanescent somite as something special, and not to attempt to reckon it to either the prosoma or the mesosoma. These will then remain as typically composed each of six appendage-bearing somites—the prosoma comprising in addition the ocular prosthomere.¹ When the *præ-genital* somite or traces of it are present it should not be called "the seventh prosomatic" or the "first mesosomatic," but simply the "*præ-genital* somite." The first segment of the mesosoma of *Scorpio* and *Limulus*

thus remains the first segment, and can be identified as such throughout the Euarachnida, carrying as it always does the genital apertures. But it is necessary to remember, in the light of recent discoveries, that the sixth prosomatic pair of appendages is carried on the seventh somite of the whole series, there being two prosthomeres or somites in front of the mouth, the first carrying the eyes, the second the chelicerae; also that the first mesosomatic or genital somite is not the seventh or even the eighth of the whole series of somites which have been historically present, but is the ninth, owing to the presence or to the excalation of a *præ-genital* somite. It seems that confusion and trouble will be best avoided by abstaining from the introduction of the non-evident somites, the ocular and the *præ-genital*, into the numerical nomenclature of the component somites of the three great body regions. We shall, therefore, ignoring the ocular somite, speak of the first, second, third, fourth, fifth, and

FIG. 18.—Portion of a similar embryo at a later stage of growth. The *præ-genital* somite, VII PrG, is still present, but has lost its rudimentary appendages; *go*, the genital operculum, left half; *Km*, the left pecten; *abp4* to *abp7*, the rudimentary appendages of the lung-sacs. (After Brauer, loc. cit.)

FIG. 17.—Embryo of *Scorpio*, ventral view showing somites and appendages. *ego*, frontal groove; *sa*, rudiment of lateral eyes; *obl*, canerostome (upper lip); *so*, sense-organ of Fåsten. PrG, rudiment of the appendage of the *præ-genital* somite which disappears; *abp1*, rudiment of the right half of the genital operculum; *abp2*, rudiment of the right pecten; *abp3* to *abp7*, rudiments of the four appendages which carry the pulmonary lamellae; I to VI, rudiments of the six limbs of the prosoma; VII PrG, the evanescent *præ-genital* somite; VIII, the first mesosomatic somite or genital somite; IX, the second mesosomatic somite or pectiniferous somite; X to XIII, the four pulmoniferous somites; XIV, the first metasomatic somite. (After Brauer, *Zeitsch. wiss. Zool.*, vol. lix, 1895.)

FIG. 19.—Section through an early embryo of *Limulus longispina*, showing seven transverse divisions in the region of the unsegmented anterior carapace. The seventh, VII, is anterior to the genital operculum, *op*, and is the cavity of the *præ-genital* somite which is more or less completely suppressed in subsequent development, possibly indicated by the area marked VII in Fig. 7 and by the great entopophyses of the prosomatic carapace. (After Kishinouye, *Journ. Sci. Coll. Japan*, vol. v, 1892.)

of the whole series of somites which have been historically present, but is the ninth, owing to the presence or to the excalation of a *præ-genital* somite. It seems that confusion and trouble will be best avoided by abstaining from the introduction of the non-evident somites, the ocular and the *præ-genital*, into the numerical nomenclature of the component somites of the three great body regions. We shall, therefore, ignoring the ocular somite, speak of the first, second, third, fourth, fifth, and

¹ See the article ARTHROPODA for the use of the term "prosthomere."

sixth leg-bearing somites of the prosoma and indicate the appendages by the Roman numerals, I., II., III., IV., V., VI., and whilst ignoring the præ-genital somite we shall speak of the first, second, third, &c. somite of the mesosoma or opisthosoma (united mesosoma and metasoma) and indicate them by the Arabic numerals.

There are a number of other important points of structure besides those referring to the somites and appendages in which *Limulus* agrees with *Scorpio* or other Arachnida and differs from other Arthropoda. The chief of these are as follows:—

FIG. 20.—View of the ventral surface of the mid-line of the prosomatic region of *Limulus polyphemus*. The coxae of the five pairs of limbs following the chelicerae were arranged in a series on each side between the mouth, M, and the metasternites, meta. sf, The sub-frontal median sclerite; Ch, the chelicerae; cam, the camerostome or upper lip; M, the mouth; pmat, the promesosternal sclerite or chitinous plate, unpaired; meta, the right and left metasternites (corresponding to the similarly placed pentagonal sternite of *Scorpio*). Natural size. (After Lankester.)

limbs which in all living Arachnids is either chelate or retrovert (as in spiders), and is known as the chelicerae. It is possible, as maintained by some writers (Patten and others), that the lobes of the cerebral nervous mass in Arachnids indicate a larger number of prosthomeres as having fused in this region, but there is no embryological evidence at present which justifies us in assuming the existence in Arachnids of more than two prosthomeres. The position of the chelicerae of *Limulus* and of the ganglionic nerve-masses from which they receive their nerve-supply, is closely similar to

FIG. 21.—Development of the lateral eyes of a *Scorpio*. h, epidermic cell-layer; mea, mesoblastic connective tissue; n, nerves; I, II, III, IV, V, depressions of the epidermis in each of which a cuticular lens will be formed. (From Korschelt and Heider, after Laurie.)

that of the same structures in *Scorpio*. The cerebral mass is in *Limulus* more easily separated by dissection as a median lobe distinct from the laterally-placed ganglia of the cheliceral somite than is the case in *Scorpio*, but the relations are practically the same in the two forms. Formerly it was supposed that in *Limulus* both the chelicerae and the next following pair of appendages were prosthomerous, as in Crustacea, but the dissections of Alphonse Milne-Edwards (6) demonstrated the true

limitations of the cerebrum, whilst embryological researches have done as much for *Scorpio*. *Limulus* thus agrees with *Scorpio* and differs from the Crustacea, in which there are three prosthomeres—one ocular and two carrying palpiform appendages. It is true that in the lower Crustacea (*Apus*, &c.) we have evidence of the gradual movement forward of the nerve-ganglia belonging to these palpiform appendages. But although in such lower Crustacea the nerve-ganglia of the third prosthomere have not fused with the anterior nerve-mass, there is no question as to the præ-oral position of two appendage-bearing somites in addition to the ocular prosthomere. The Crustacea have, in fact, three prosthomeres in the head and the Arachnida only two, and *Limulus* agrees with the Arachnida in this respect and differs from the Crustacea. The central nervous systems of *Limulus* and of *Scorpio* present

FIG. 22.—Section through the lateral eye of *Euscorpis italicus*. lens, Cuticular lens; nerve, retinal cells (nerve-end cells); rhabd, rhabdomes; nerve, nerve fibres of the optic nerve; int, intermediate cells (lying between the bases of the retinal cells). (After Lankester and Bourne from Parker and Haswell's *Text-book of Zoology*, Macmillan and Co.)

closer agreement in structure than can be found when a Crustacean is compared with either. The wide divarication of the lateral cords in the prosoma and their connexion by transverse commissures, together with the "attraction" of ganglia to the prosomatic ganglion group which properly belong to hinder segments, are very nearly identical in the two animals. The form and disposition of the ganglion cells are also peculiar and closely similar in the two. (See Patten (42) for important observations on the neuromeres, &c., of *Limulus* and *Scorpio*.)

FIG. 23.—Section through a portion of the lateral eye of *Limulus*, showing three ommatidia—A, B, and C. hyp, The epidermic cell-layer (so-called hypodermis), the cells of which increase in volume below each lens, l, and become nerve-end cells or retinal cells, rt; in A the letters rh point to a rhabdomere secreted by the cell rt; c, the peculiar central spherical cell; n, nerve fibres; mes, mesoblastic skeletal tissue; ch, chitinous cuticle. (From Korschelt and Heider after Watase.)

2. *The Minute Structure of the Central Eyes and of the Lateral Eyes.*—*Limulus* agrees with *Scorpio* not only in having a pair of central eyes and also lateral eyes, but in the microscopic structure of those organs which differs in

the central and lateral eyes respectively. The central eyes are "simple eyes," that is to say, have a single lens, and are hence called "monomeniscous." The lateral eyes are in *Limulus* "compound eyes," that is to say, consist of many lenses placed closed together; beneath each lens

lens of a central eye is called an "ommatœum." It shows in *Scorpio* and *Limulus* a tendency to segregate into minor groups or "ommatidia." It is found that in embryological growth the retinal layer of the central eyes forms as a separate pouch, which is pushed in

laterally beneath the corneagen layer from the epidermic cell layer. Hence it is in origin double, and consists of a true retinal layer and a post-retinal layer (Fig. 24, B), though these are not separated by a membrane. Accordingly the diplostichous ommatœum or soft tissue of the Arachnid's central eye should strictly be called "triplostichous," since the deep layer is itself doubled or folded. The retinal cells of both the lateral and central eyes of *Limulus* and *Scorpio* produce cuticular structures on their sides; each such piece is a rhabdomere and a number (five or ten) uniting form a rhabdom (Fig. 26). In the specialized ommatidia of the compound eyes of Crustacea and Hexapods the rhabdom is an important structure.¹ It is a very significant fact that the lateral and central eyes of *Limulus* and *Scorpio* not only agree each with each in regard to their monostichous and diplostichous structure but also in the formation in both classes of eyes of rhabdomeres and rhabdoms in which the component pieces are five or a multiple of five (Fig. 26). Whilst each unit of

FIG. 24.—Diagrams of the development and adult structure of one of the paired central eyes of a Scorpion. A, early condition before the lens is deposited, showing the folding of the epidermic cell-layer into three; B, diagram showing the nature of this infolding; C, section through the fully formed eye; *gl.*, epidermic cell-layer; *r.*, the retinal portion of the same which, owing to the infolding, lies between *gl.*, the corneagen or lens-forming portion, and *pr.*, the post-retinal or capsular portion or fold; *l.*, cuticular lens; *g.*, line separating lens from the lens-forming or corneagen cells of the epidermis; *n.*, nerve fibres; *rh.*, rhabdomeres. (From Korschelt and Heider.) How the inversion of the nerve-end cells and their connexion with the nerve-fibres is to be reconciled with the condition found in the adult, or with that of the monostichous eye, has not hitherto been explained.

is a complex of protoplasmic cells, in which the optic nerve terminates. Each such unit is termed an "ommatidium." The lateral eyes of *Scorpio* consist of groups of separate small lenses each with its ommatidium, but they do not form a continuous compound eye as in *Limulus*. The ommatidium (soft structure beneath the lens-unit of a compound eye) is very simple in both *Scorpio* and *Limulus*. It consists of a single layer of cells, continuous with those which secrete the general chitinous covering of the prosoma. The cells of the ommatidium are a good deal larger than the neighbouring common cells of the epidermis. They secrete the knob-like lens (Fig. 22). But they also receive the nerve fibres of the optic nerve. They are at the same time both optic nerve-end cells, that is to say, retina cells and corneagen cells or secretors of the chitinous lens-like cornea. In *Limulus* (Fig. 23) each ommatidium has a peculiar ganglion cell developed in a central position, whilst the ommatidium of the lateral eyelets of *Scorpio* shows small intermediate cells between the larger nerve-end cells. The structure of the lateral eye of *Limulus* was first described by Grenacher, and further and more accurately by Lankester and Bourne (5) and by Watase; that of *Scorpio* by Lankester and Bourne, who showed that the statements of von Graber were erroneous, and that the lateral eyes of *Scorpio* have a single cell-layered or "monostichous" ommatidium like that of *Limulus*. Watase has shown, in a very convincing way, how by deepening the pit-like set of cells beneath a simple lens the more complex ommatidia of the compound eyes of Crustacea and Hexapoda may be derived from such a condition as that presented in the lateral eyes of *Limulus* and *Scorpio*. (For details the reader is referred to Watase (11) and to Lankester and Bourne (5).) The structure of the central eyes of *Scorpio* and Spiders and also of *Limulus* differs essentially from that of the lateral eyes in having two layers of cells (hence called diplostichous) beneath the lens, separated from one another by a membrane (Figs. 24 and 25). The upper layer is the corneagen and secretes the lens, the lower is the retinal layer. The mass of soft cell-structures beneath a large

the lateral eye of *Limulus* has a rhabdom of ten² pieces

FIG. 25.—Section through one of the central eyes of a young *Limulus*. L, cuticular or corneous lens; *hy.*, epidermic cell-layer; *corn.*, its corneagen portion immediately underlying the lens; *ret.*, retinula cells; *n.f.*, nerve fibres; *con. tiss.*, connective tissue (mesoblastic skeletal tissue). (After Lankester and Bourne, *Q. J. Mic. Sc.* 1883.)

the lateral eye of *Limulus* has a rhabdom of ten² pieces

¹ See Fig. 11 in the article ARTHROPODA.

² Though ten is the prevailing number of retinula cells and rhabdomeres in the lateral eye of *Limulus*, Watase states that they may be as few as nine and as many as eighteen.

forming a star-like chitinous centre in section, each lateral eye of *Scorpio* has several rhabdoms of five or less rhabdomeres, indicating that the *Limulus* lateral eye-unit is more specialized than the detached lateral eyelet of *Scorpio*, so as to present a coincidence of one lens with one rhabdom. Numerous rhabdomeres (grouped as rhabdoms in *Limulus*) are found in the retinal layer of the central eyes also.

Whilst *Limulus* agrees thus closely with *Scorpio* in regard to the eyes, it is to be noted that no Crustacean has structures corresponding to the peculiar diplostichous central eyes, though these occur again (with differences in detail) in Hexapoda. Possibly, however, an investigation of the development of the median eyes of some Crustacea (*Apus*, *Palæmon*) may prove them to be diplostichous in origin.

3. *The so-called "Coxal Glands."*—In 1882 (*Proc. Roy. Soc. No. 221*) Lankester described under the name "coxal

FIG. 26.—A, diagram of a retinula of the central eye of a Scorpion consisting of five retina-cells (*ret.*), with adherent branched pigment cells (*pig.*); B, rhabdom of the same, consisting of five confluent rhabdomeres; C, transverse section of the rhabdom of a retinula of the Scorpion's central eye, showing its five constituent rhabdomeres as rays of a star; D, transverse section of a retinula of the lateral eye of *Limulus*, showing ten retinula cells, *ret.*, each bearing a rhabdomere, *rhab.* (After Lankester.)

same in essentials as that of the coxal glands of *Scorpio* (13). Coxal glands have since been recognized and described in other Arachnida. It has lately (1900) been shown that the coxal gland of *Limulus* is provided with a very delicate thin-walled coiled duct which opens, even in the adult condition, by a minute pore on the coxa of the fifth leg (Patten and Hazen, 13A). Previously to this, Lankester's pupil Gulland had shown (1885) that in the embryo the coxal gland is a comparatively simple tube, which opens to the exterior in this position and by its other extremity into a coelomic space. Similar observations were made by Laurie (17) in Lankester's laboratory (1890) with regard to the early condition of the coxal gland of *Scorpio*, and by Bertkau (41) as to that of the spider *Atypus*. H. M. Bernard (13B) showed that the opening remains in the adult *Scorpio*. In all the embryonic or permanent opening is on the coxa of the fifth pair of prosomatic limbs. Thus an organ newly discovered in *Scorpio* was found to have its counterpart in *Limulus*.

The name "coxal gland" needs to be carefully distinguished from "crural gland," with which it is apt to be confused. The crural glands, which occur in many terrestrial Arthropods, are epidermal in origin and totally distinct from the coxal glands. The coxal glands of the Arachnida are structures of the same nature as the green glands of the higher Crustacea and the so-called "shell glands" of the Entomostraca. The latter open at the base of the fifth pair of limbs of the Crustacean, just as the coxal glands open on the coxal joint of the fifth pair of limbs of the Arachnid. Both belong to the category of "coelomoducts," namely, tubular or funnel-like portions of the coelom opening to the exterior in pairs in each somite (potentially), and usually persisting in only a few somites as either "urocoels" (renal organs) or "gonocoels" (genital tubes).

FIG. 27.—Diagram showing the position of the coxal glands of a Scorpion, *Buturus australis*, Lin., in relation to the legs, disphragm, entosternal flap, and the gastric caeca. 1 to 6, The bases of the six prosomatic limbs; A, prosomatic gastric gland (sometimes called salivary); B, coxal gland; C, disphragm of Newport—fibrous flap of the entosternum; D, mesosomatic gastric caeca (so-called liver); E, alimentary canal. (From Lankester, *Q. J. Micro. Sci.* vol. xxiv. N.S. p. 152.)

In Peripatus they occur in every somite of the body. They have till recently been very generally identified with the nephridia of Chaetopod worms, but there is good reason for considering the true nephridia (typified by the nephridia of the Earthworm) as a distinct class of organs (see Lankester in vol. ii. chap. iii. of *A Treatise on Zoology*, 1900). The genital ducts of Arthropoda are like the green glands, shell glands, and coxal glands, to be regarded as coelomoducts (gonocoels). The coxal glands do not establish any special connexion between *Limulus* and *Scorpio*, since they also occur in the same somite in the lower Crustacea, but it is to be noted that the coxal glands of *Limulus* are in minute structure and probably in function more like those of Arachnids than those of Crustacea.

4. *The Entosternites and their Minute Structure.*—Straus-Durkheim (1) was the first to insist on the affinity between *Limulus* and the Arachnids, indicated by the presence of a free suspended entosternum or plastron or entosternite in both. We have figured here (Figs. 1 to 6) the entosternites of *Limulus*, *Scorpio*, and *Mygale*. Lankester some years ago made a special study of the histology

glands" a pair of brilliantly white oviform bodies lying in the Scorpion's prosoma immediately above the coxae of the fifth and sixth pairs of legs (Fig. 27). These bodies had been erroneously supposed by Newport (12) and other observers to be glandular outgrowths of the alimentary canal. They are really excretory glands, and communicate with the exterior by a very minute aperture on the posterior face of the coxa of the fifth limb on each side. When examined with the microscope by means of the usual section method, they are seen to consist of a labyrinthine tube lined with peculiar cells, each cell having a deep vertically striated border on the surface farthest from the lumen, as is seen in the cells of some renal organs. The coils and branches of the tube are packed by connective tissue and blood spaces. A similar pair of coxal glands, lobate instead of ovoid in shape, was described by Lankester in *Mygale*, and it was also shown by him that the structures in *Limulus* called "brick-red glands" by Packard have the same structure and position as the coxal glands of *Scorpio* and *Mygale*. In *Limulus* these organs consist each of four horizontal lobes lying on the coxal margin of the second, third, fourth, and fifth prosomatic limbs, the four lobes being connected to one another by a transverse piece or stem (Fig. 28). Microscopically their structure is the

(3) of these entosternites for the purpose of comparison, and also ascertained the relations of the very numerous muscles which are inserted into them (4). The entosternites are cartilaginous in texture, but they have neither the chemical character nor the microscopic structure of the hyaline cartilage of Vertebrates. They yield chitin in place of chondrin or gelatin—as does also the cartilage of the Cephalopod's endoskeleton. In microscopic structure they all present the closest agreement with one another. We find a firm, homogeneous or sparsely fibrillated matrix in which are embedded nucleated cells (corpuscles of protoplasm) arranged in rows of three, six, or eight, parallel with the adjacent lines of fibrillation.

A minute entosternite having the above-described structure is found in the Crustacean *Apus* between the bases of the mandibles, and also in the Decapoda in a similar position, but in no Crustacean does it attain to any size or importance. On the other hand, the entosternite of the Arachnida is a very large and important feature in the structure of the prosoma, and must play an important part in the economy of these organisms. In *Limulus* (Figs. 1 and 2) it has as many as twenty-five pairs of

FIG. 28.—The right coxal gland of *Limulus polyphemus*, Latr. a^2 to a^5 , Posterior borders of the chitinous bases of the coxae of the second, third, fourth, and fifth prosomatic limbs; b , longitudinal lobe or stolon of the coxal gland; c , its four transverse lobes or outgrowths corresponding to the four coxae. (From Lankester, *loc. cit.*, after Packard.)

muscles attached to it, coming to it from the bases of the surrounding limbs and from the dorsal carapace and from the pharynx. It consists of an oblong plate two inches in length and one in breadth, with a pair of tendinous outgrowths standing out from it at right angles on each side. It "floats" between the prosomatic nerve centres and the alimentary canal. In each somite of the mesosoma is a small, free entosternite having a similar position, but below or ventrad of the nerve cords, and having a smaller number of muscles attached to it. The entosternite was probably in origin part of the fibrous connective tissue lying close to the integument of the sternal surface—giving attachment to muscles corresponding more or less to those at present attached to it. It became isolated and detached, why or with what advantage to the organism it is difficult to say, and at that period of Arachnid development the great ventral nerve cords occupied a more lateral position than they do at present. We know that such a lateral position of the nerve cords preceded the median position in both Arthropoda and Chætopoda. Subsequently to the floating off of the entosternite the approximation of the nerve cords took place in the prosoma, and thus they were able to take up a position below the entosternite. In the mesosoma the approximation had occurred before the entosternites were formed.

In the Scorpion (Figs. 3 and 4) the entosternite has tough membrane-like outgrowths which connect it with the body-wall, both dorsally and ventrally forming an oblique diaphragm, cutting off the cavity of the prosoma from that of the mesosoma. It was described by Newport as "the diaphragm." Only the central and horizontal parts of this structure correspond precisely to the entosternite of *Limulus*: the right and left anterior processes (marked *ap* in Figs 3 and 4, and *RAP*, *LAP*, in Figs. 1 and 2) correspond in the two animals, and the

median lateral process *Imp* of the Scorpion represents the tendinous outgrowths *ALR*, *PLR*, of *Limulus*. The Scorpion's entosternite gives rise to outgrowths, besides the great posterior flaps, *pf*, which form the diaphragm, unrepresented in *Limulus*. These are a ventral arch forming a neural canal through which the great nerve cords pass (Figs. 3 and 4, *snp*), and further a dorsal gastric canal and arterial canal which transmit the alimentary tract and the dorsal artery respectively (Figs. 3 and 4, *GC*, *DR*).

In *Limulus* small entosternites are found in each somite of the appendage-bearing mesosoma, and we find in Scorpion, in the only somite of the mesosoma which has a well-developed pair of appendages, that of the pectens, a small entosternite with ten pairs of muscles inserted into it. The supra-pectinal entosternite lies ventrad of the nerve cords.

In *Mygale* (Figs. 5 and 6) the form of the entosternite is more like that of *Limulus* than is that of Scorpion. The anterior notch *Ph.N.* is similar to that in *Limulus*, and the three pairs of upstanding tendons on the dorsal surface correspond to the two similar pairs in *Limulus*, whilst the imbricate triangular pieces of the posterior median region resemble the similarly-placed structures of *Limulus* in a striking manner.

It must be confessed that we are singularly ignorant as to the functional significance of these remarkable organs—the entosternites. Their movement in an upward or downward direction in *Limulus* and *Mygale* must exert a pumping action on the blood contained in the dorsal arteries and the ventral veins respectively. In Scorpion the completion of the horizontal plate by oblique flaps, so as to form an actual diaphragm shutting off the cavity of the prosoma from the rest of the body, possibly gives to the organs contained in the anterior chamber a physiological advantage in respect of the supply of arterial blood and its separation from the venous blood of the mesosoma. Possibly the movement of the diaphragm may determine the passage of air into or out of the lung-sacs. Muscular fibres connected with the suctorial pharynx are in *Limulus* inserted into the entosternite, and the activity of the two organs may be correlated.

5. *The Blood and the Blood-vascular System.*—The blood fluids of *Limulus* and Scorpion are very similar. Not only are the blood corpuscles of *Limulus* more like in form and granulation to those of Scorpion than to those of any Crustacean, but the fluid is in both animals strongly impregnated with the blue-coloured tint.

The great dorsal contractile vessel or "heart" of *Limulus* is closely similar to that of Scorpion; its ostia or incurrent orifices are placed in the same somites as those

FIG. 29.—Diagram of the arterial system of A, Scorpion, and B, *Limulus*. The Roman numerals indicate the body somites and the two figures are adjusted for comparison. *ca*, Cerebral arteries; *sp*, supra-spinal or medullary artery; *c*, caudal artery; *l*, lateral anastomotic artery of *Limulus*. The figure B also shows the peculiar neural investiture formed by the cerebral arteries in *Limulus* and the derivation from this of the arteries to the limbs, III, IV, VI, whereas in Scorpion the latter have a separate origin from the anterior aorta. (From Lankester, "Limulus an Arachnid.")

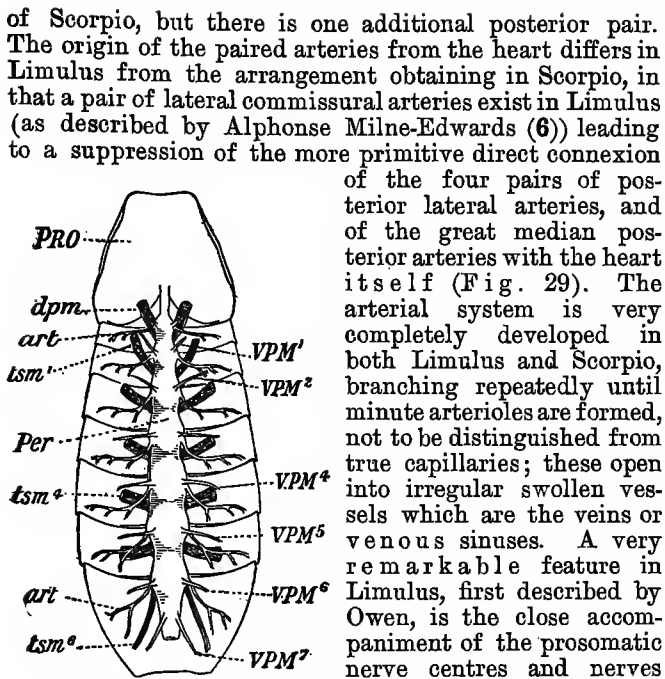

Fig. 80.—View from below of a Scorpio (*B. occitanus*) opened and dissected so as to show the pericardium with its muscles, the lateral arteries, and the tergo-sternal muscles. PRO, prosoma; *dpm*, dorso-plastral muscle; *art*, lateral artery; *tsm*¹, tergo-sternal muscle (labelled *av* in Fig. 81) of the second (pectiniferous) mesosomatic somite; this is the most anterior pair of the series of six, none are present in the genital somite; *tsm*⁴ tergo-sternal muscle of the fifth mesosomatic somite; *tsm*⁵, tergo-sternal muscle of the enlarged first metasomatic somite; *Per*, pericardium; *VPM*¹ to *VPM*⁷, the series of seven pairs of veno-pericardiac muscles (labelled *pv* in Fig. 81). There is some reason to admit the existence of another more anterior pair of these muscles in Scorpio; this would make the number exactly correspond with the number in Limulus. (After Lankester, *Trans. Zool. Soc.* vol. xi. 1888.)

Arthropoda for the arteries to accompany the nerve cords, and a "supra-spinal" artery—that is to say, an artery in close relation to the ventral nerve cords—has been described in several cases. On the other hand, in many Arthropods, especially those which possess tracheæ, the arteries do not have a long course, but soon open into wide blood sinuses. Scorpio certainly comes nearer to Limulus in the high development of its arterial system, and the intimate relation of the anterior aorta and its branches to the nerve centres and great nerves, than does any other Arthropod.

An arrangement of great functional importance in regard to the venous system must now be described, which was shown in 1883 by Lankester to be common to Limulus and Scorpio. This arrangement has not hitherto been detected in any other class than the Arachnida, and if it should ultimately prove to be peculiar to that group, would have considerable weight as a proof of the close genetic affinity of Limulus and Scorpio.

The great pericardial sinus is strongly developed in both animals. Its walls are fibrous and complete, and it holds a considerable volume of blood when the heart itself is contracted. Opening in pairs in each somite, right and left into the pericardial sinus are large veins, which bring the blood respectively from the gill-books and the lung-books to that chamber, whence it passes by the ostia into the heart. The blood

is brought to the respiratory organs in both cases by a great venous-collecting sinus having a ventral median position. In both animals the wall of the pericardial sinus is connected by vertical muscular bands to the wall of the ventral venous sinus (its lateral expansions around the lung-books in Scorpio) in each somite through which the pericardium passes. There are seven pairs of these veno-pericardiac vertical muscles in Scorpio, and eight in Limulus (see Figs. 30, 31, 32). It is obvious that the contraction of these muscles must cause a depression of the floor of the pericardium and a rising of the roof of the ventral blood sinus, and a consequent increase of volume and flow of blood to each. Whether the pericardium and the ventral sinus are made to expand simultaneously or all the movement is made by one only

of the surfaces concerned, must depend on conditions of tension. In any case it is clear that we have in these muscles an apparatus for causing the blood to flow differentially in increased volume into either the pericardium, through the veins leading from the respiratory organs, or from the body generally into the great sinuses which bring the blood to the respiratory organs. These muscles act so as to pump the blood through the respiratory organs.

Fig. 81.—Diagram of a lateral view of a longitudinal section of a Scorpio. *d*, chelicers; *ch*, chela; *cam*, camerostome; *m*, mouth; *ent*, entosternum; *p*, pecten; *stig*¹, first pulmonary aperture; *stig*², fourth pulmonary aperture; *dam*, muscle from carapace to a præoral entosclerite; *ad*, muscle from carapace to entosternum; *md*, muscle from tergite of genital somite to entosternum (same as *dpm* in Fig. 80); *dv*¹ to *dv*⁶, dorso-ventral muscles (same as the series labelled *tsm* in Fig. 80); *pv*¹ to *pv*⁷, the seven veno-pericardiac muscles of the right side (labelled *VPM* in Fig. 80). (After Beck, *Trans. Zool. Soc.* vol. xi. 1888.)

of the surfaces concerned, must depend on conditions of tension. In any case it is clear that we have in these muscles an apparatus for causing the blood to flow differentially in increased volume into either the pericardium, through the veins leading from the respiratory organs, or from the body generally into the great sinuses which bring the blood to the respiratory organs. These muscles act so as to pump the blood through the respiratory organs.

It is not surprising that with so highly developed an arterial system Limulus and Scorpio should have a highly developed mechanism for determining the flow of blood to the respiratory organs. That this is, so to speak, a need of animals with localized respiratory organs is seen by the existence of provisions serving a similar purpose in other animals, e.g., the branchial hearts of the Cephalopoda.

The veno-pericardiac muscles of Scorpio were seen and

Fig. 82.—Diagram of a lateral view of a longitudinal section of Limulus. *Suc*, suctorial pharynx; *al*, alimentary canal; *Ph*, pharynx; *M*, mouth; *Est*, entosternum; *VS*, ventral venous sinus; *chi*, chilaria; *go*, genital operculum; *br*¹ to *br*⁵, branchial appendages; *met*, unsegmented metasoma; *Entap*⁴, fourth dorsal entostaphylis of left side; *tsm*, tergo-sternal muscles, six pairs as in Scorpio (labelled *av* in Fig. 81); *VPM*¹ to *VPM*⁸, the eight pairs of veno-pericardiac muscles (labelled *pv* in Fig. 81). *VPM*¹ is probably represented in Scorpio, though not marked in Figs. 80 and 81. (After Benham, *Trans. Zool. Soc.* vol. xi. 1888.)

figured by Newport but not described by him. Those of Limulus were described and figured by Alphonse Milne-Edwards, but he called them merely "transparent ligaments," and did not discover their muscular structure. They are figured and their importance for the first time

recognized in the memoir on the muscular and skeletal systems of *Limulus* and *Scorpio* by Lankester, Beck, and Bourne (4).

6. *Alimentary Canal and Gastric Glands.*—The alimentary canal in *Scorpio*, as in *Limulus*, is provided with a powerful suctorial pharynx, in the working of which extrinsic muscles take a part. The mouth is relatively smaller in *Scorpio* than in *Limulus*—in fact is minute, as it is in all the terrestrial Arachnida which suck the juices of either animals or plants. In both, the alimentary canal takes a straight course from the pharynx (which bends under it downwards and backwards towards the mouth in

FIG. 33.—The alimentary canal and gastric glands of a Scorpion (A) and of *Limulus* (B). *ps*, Muscular suctorial enlargement of the pharynx; *sal*, prosomatic pair of gastric caeca in Scorpion, called salivary glands by some writers; *c*¹ and *c*², the anterior two pairs of gastric caeca and ducts of the mesosomatic region; *c*³, *c*⁴, and *c*⁵, caeca and ducts of Scorpion not represented in *Limulus*; *M*, the Malpighian or renal caecal diverticula of Scorpion; *pro*, the proctodæum or portion of gut leading to anus and formed embryologically by an invagination of the epiblast at that orifice. (From Lankester, "Limulus and Arachnid.")

double pair of renal excretory tubes, which have been identified by earlier authors with the Malpighian tubes of the Hexapod and Myriapod insects. *Limulus* is devoid of any such tubes. We shall revert to this subject below.

7. *Ovaries and Spermaries: Gonocœls and Gonoducts.*—The scorpion is remarkable for having the specialized portion of coelom from the walls of which egg-cells or sperm-cells are developed according to sex, in the form of a simple but extensive network. It is not a pair of simple tubes, nor of dendriform tubes, but a closed network. The same fact is true of *Limulus*, as was shown by Owen (7) in regard to the ovary, and by Benham (14) in regard to the testis. This is a very definite and remarkable agreement, since such a reticular gonocœl is not found in Crustacea (except in the male *Apus*). Moreover, there is a significant agreement in the character of the spermatozoa of *Limulus* and *Scorpio*. The Crustacea are—with the exception of the Cirrhipedia—remarkable for having stiff,

motionless spermatozooids. In *Limulus* Lankester found (15) the spermatozoa to possess active flagelliform "tails," and to resemble very closely those of *Scorpio* which, as are those of most terrestrial Arthropoda, are actively motile. This is a microscopic point of agreement, but is none the less significant.

In regard to the important structures concerned with the fertilization of the egg, *Limulus* and *Scorpio* differ entirely from one another. The eggs of *Limulus* are fertilized in the sea after they have been laid. *Scorpio*, being a terrestrial animal, fertilizes by copulation. The male possesses elaborate copulatory structures of a chitinous nature, and the eggs are fertilized in the female without even quitting the place where they are formed on the wall of the reticular gonocœl. The female scorpion is viviparous, and the young are produced in a highly developed condition as fully formed scorpions.

Differences between Limulus and Scorpio.—We have now passed in review the principal structural features in which *Limulus* agrees with *Scorpio* and differs from other Arthropoda. There remains for consideration the one important structural difference between the two animals. *Limulus* agrees with the majority of the Crustacea in being destitute of renal excretory caeca or tubes opening into the hinder part of the gut. *Scorpio*, on the other hand, in common with all air-breathing Arthropoda except *Peripatus*, possesses these tubules, which are often called Malpighian tubes. A great deal has been made of this difference by some writers. It has been considered by them as proving that *Limulus*, in spite of all its special agreements with *Scorpio* (which, however, have scarcely been appreciated by the writers in question), really belongs to the Crustacean line of descent, whilst *Scorpio*, by possessing Malpighian tubes, is declared to be unmistakably tied together with the other Arachnida to the tracheate Arthropods, the Hexapods, Diplopods, and Chilopods, which all possess Malpighian tubes.

It must be pointed out that the presence or absence of such renal excretory tubes opening into the intestine appears to be a question of adaptation to the changed physiological conditions of respiration, and not of morphological significance, since a pair of renal excretory tubes of this nature is found in certain Amphipod Crustacea (*Talorchestia*, &c.) which have abandoned a purely aquatic life. This view has been accepted and supported by Professors Korschelt and Heider (16). An important fact in its favour was discovered by Laurie (17), who investigated the embryology of two species of *Scorpio* under Lankester's direction. It appears that the Malpighian tubes of *Scorpio* are developed from the mesenteron, viz., that portion of the gut which is formed by the hypoblast, whereas in Hexapod insects the similar caecal tubes are developed from the proctodæum or in-pushed portion of the gut which is formed from epiblast. In fact it is not possible to maintain that the renal excretory tubes of the gut are of one common origin in the Arthropoda. They have appeared independently in connexion with a change in the excretion of nitrogenous waste in Arachnids, Crustacea, and the other classes of Arthropoda when aerial, as opposed to aquatic, respiration has been established—and they have been formed in some cases from the mesenteron, in other cases from the proctodæum. Their appearance in the air-breathing Arachnids does not separate those forms from the water-breathing Arachnids which are devoid of them, any more than does their appearance in certain Amphipoda separate those Crustaceans from the other members of the class.

Further, it is pointed out by Korschelt and Heider that the hinder portion of the gut frequently acts in Arthropoda as an organ of nitrogenous excretion in the absence

of any special excretory tubules, and that the production of such cæca from its surface in separate lines of descent does not involve any elaborate or unlikely process of growth. In other words, the Malpighian tubes of the terrestrial Arachnida are *homoplastic* with those of Hexapoda and Myriapoda, and not *homogenetic* with them. We are compelled to take a similar view of the agreement between the tracheal air-tubes of Arachnida and other tracheate Arthropods. They are homoplasts (see 18) one of another, and do not owe their existence in the various classes compared to a common inheritance of an ancestral tracheal system.

Conclusions arising from the Close Affinity of Limulus and Scorpio.—When we consider the relationships of the various classes of Arthropoda, having accepted and established the fact of the close genetic affinity of Limulus and Scorpio, we are led to important conclusions. In such a consideration we have to make use not only of the fact just mentioned, but of three important generalizations which serve as it were as implements for the proper estimation of the relationships of any series of organic forms. First of all there is the generalization that the relationships of the various forms of animals (or of plants) to one another is that of the ultimate twigs of a much-branching genealogical tree. Secondly, identity of structure in two organisms does not necessarily indicate that the identical structure has been inherited from an ancestor common to the two organisms compared (homogeny), but may be due to independent development of a like structure in two different lines of descent (homoplasia). Thirdly, those members of a group which, whilst exhibiting undoubted structural characters indicative of their proper assignment to that group, yet are simpler than and inferior in elaboration of their organization to other members of the group, are not necessarily representatives of the earlier and primitive phases in the development of the group—but are very often examples of retrogressive change or degeneration. The second and third implements of analysis above cited are of the nature of cautions or checks. Agreements are not necessarily due to common inheritance; simplicity is not necessarily primitive and ancestral.

On the other hand, we must not rashly set down agreements as due to "homoplasia" or "convergence of development" if we find two or three or more concurrent agreements. The probability is against agreement being due to homoplasia when the agreement involves a number of really separate (not correlated) coincidences. Whilst the chances are in favour of some *one* homoplastic coincidence or structural agreement occurring between some member or other of a large group *a* and some member or other of a large group *b*, the matter is very different when by such an initial coincidence the two members have been particularized. The chances against these two selected members exhibiting *another* really independent homoplastic agreement are enormous; let us say 10,000 to 1. The chances against yet another coincidence are a hundred million to one, and against yet one more "coincidence" they are the square of a hundred million to one. Homoplasia can only be assumed where the coincidence is of a simple nature, and is such as may be reasonably supposed to have arisen by the action of like selective conditions upon like material in two separate lines of descent.¹

So, too, degeneration is not to be lightly assumed as the explanation of a simplicity of structure. There is a very definite criterion of the simplicity due to degeneration which can in most cases be applied. Degenerative simplicity is never uniformly distributed over all the structures of the organism. It affects many or nearly all the structures of the body, but leaves some, it may be only one, at a high level of elaboration and complexity. Ancestral simplicity is more uniform, and does not coexist with specialization and elaboration of a single organ. Further: degeneration cannot be inferred safely by the examination of an isolated case; usually we obtain a series of forms indicating the steps of a change in structure—and what we have to decide is whether the movement has been from the simple to the more complex, or from the more complex to the simple. The feathers of a peacock afford a convenient example of primitive and degenerative simplicity. The highest point of elaboration in colour, pattern, and form is shown by the great eye-painted tail feathers. From these we can pass by gradual transitions in two directions, viz., either to the simple lateral tail feathers with a few rami only, developed only on one side of the shaft and of uniform metallic coloration—or to the simple contour feathers of small size, with the usual symmetrical series of numerous rami right and left of the shaft and no remarkable colouring. The one-sided specialization and the peculiar metallic colouring of the lateral tail feathers mark them as the extreme terms of a degenerative series, whilst the symmetry, likeness of constituent parts *inter se*, and absence of specialized pigment, as well as the fact that they differ little from any average feather of birds in general, mark the contour feather as primitively simple, and as the starting-point from which the highly-elaborated eye-painted tail feather has gradually evolved.

Applying these principles to the consideration of the Arachnida, we arrive at the conclusion that the smaller and simpler Arachnids are not the more primitive, but that the Acari or Mites are in fact a degenerate group. This was maintained by Lankester in 1878 (19), again in 1881 (20); it was subsequently announced as a novelty by Claus in 1885 (21). Though the aquatic members of a class of animals are in some instances derived from terrestrial forms, the usual transition is from an aquatic ancestry to more recent land-living forms. There is no doubt, from a consideration of the facts of structure, that the aquatic water-breathing Arachnids, represented in the past by the Eurypterines and to-day by the sole survivor Limulus, have preceded the terrestrial air-breathing forms of that group. Hence we see at once that the better-known Arachnida form a series, leading from Limulus-like aquatic creatures through Scorpions, Spiders, and Harvestmen to the degenerate Acari or Mites. The spiders are specialized and reduced in apparent complexity, as compared with the Scorpions, but they cannot be regarded as degenerate, since the concentration of structure which occurs in them results in greater efficiency and power than are exhibited by the Scorpion. The determination of the relative degree of perfection of organization attained by two animals compared is difficult when we introduce, as seems inevitable, the question of efficiency and power, and do not confine the question to the perfection of morphological development. We have no measure of the degree of power manifested by various animals—though it would be possible to arrive at some conclusions as to how that "power" should be estimated. It is not possible here to discuss that matter further. We must

¹ A great deal of superfluous hypothesis has lately been put forward in the name of "the principle of convergence of characters" by a certain school of palæontologists. The horse is supposed by these writers to have originated by separate lines of descent in the Old World and the New, from five-toed ancestors! And the important consequences following from the demonstration of the identity in structure of Limulus and Scorpio are evaded by arbitrary and even phantastic

invocations of a mysterious transcendental force which brings about "convergence" irrespective of heredity and selection. Morphology becomes a farce when such assumptions are made.

be content to point out that it seems that the Spiders, the Pedipalps, and other large Arachnids have not been derived from the Scorpions directly, but have independently developed from aquatic ancestors, and from one of these independent groups—probably through the Harvestmen from the Spiders—the Acari have finally resulted.

Leaving that question for consideration in connexion with the systematic statement of the characters of the various groups of Arachnida which follows below, it is well now to consider the following question, viz., seeing that *Limulus* and *Scorpio* are such highly developed and specialized forms, and that they seem to constitute as it were the first and second steps in the series of recognized Arachnida—what do we know, or what are we led to suppose with regard to the more primitive Arachnida from which the Eurypterines and *Limulus* and *Scorpio* have sprung? Do we know in the recent or fossil condition any such primitive Arachnids? Such a question is not only legitimate, but prompted by the analogy of at least one other great class of Arthropods. The great Arthropod class, the Crustacea, presents to the zoologist at the present day an immense range of forms, comprising the primitive Phyllopods, the minute Copepods, the parasitic Cirrhipedes and the powerful Crabs and Lobsters, and the highly-elaborated Sand-hoppers and Slaters. It has been insisted, by those who accepted Lankester's original doctrine of the direct or genetic affinity of the Chætopoda and Arthropoda, that *Apus* and *Branchipus* really come very near to the ancestral forms which connected those two great branches of Appendiculate (Parapodiate) animals. On the other hand, the Land Crabs are at an immense distance from these simple forms. The record of the Crustacean family-tree is in fact a fairly complete one—the lower primitive members of the group are still represented by living forms in great abundance. In the case of the Arachnida, if we have to start their genealogical history with *Limulus* and *Scorpio*, we are much in the same position as we should be in dealing with the Crustacea, were the whole of the Entomostraca and the whole of the Arthrostraca wiped out of existence and record. There is no possibility of doubt that the series of forms corresponding in the Arachnid line of descent to the forms distinguished in the Crustacean line of descent as the lower grade—the Entomostraca—have ceased to exist, and not only so, but have left little evidence in the form of fossils as to their former existence and nature. It must, however, be admitted as probable that we should find some evidence, in ancient rocks or in the deep sea, of the early more primitive Arachnids. And it must be remembered that such forms must be expected to exhibit, when found, differences from *Limulus* and *Scorpio* as great as those which separate *Apus* and *Cancer*. The existing Arachnida, like the higher Crustacea, are "nomomeristic," that is to say, have a fixed typical number of somites to the body. Further, they are, like the higher Crustacea, "somatogamic," that is to say, they have this limited set of somites grouped in three (or more) "tagmata" or regions of a fixed number of similarly modified somites—each tagma differing in the modification of its fixed number of somites from that characterizing a neighbouring "tagma." The most primitive among the lower Crustacea, on the other hand, for example the Phyllopoda, have not a fixed number of somites, some genera—even allied species—have more, some less, within wide limits; they are "anomomeristic." They also, as is generally the case with anomomeristic animals, do not exhibit any conformity to a fixed plan of "tagmatism" or division of the somites of the body into regions sharply marked off from one another; the head or prosomatic tagma is followed by a trunk consisting of somites which either graduate in character as we

pass along the series or exhibit a large variety, in different genera, families, and orders, of grouping of the somites. They are anomotagmic, as well as anomomeristic.

When it is admitted—as seems to be reasonable—that the primitive Arachnida would, like the primitive Crustacea, be anomomeristic and anomotagmic, we shall not demand of claimants for the rank of primitive Arachnids agreement with *Limulus* and *Scorpio* in respect of the exact number of their somites and the exact grouping of those somites; and when we see how diverse are the modifications of the branches of the appendages both in Arachnida and in other classes of Arthropoda (*q.v.*), we shall not over-estimate a difference in the form of this or that appendage exhibited by the claimant as compared with the higher Arachnids. With those considerations in mind, the claim of the extinct group of the Trilobites to be considered as representatives of the lower and more primitive steps in the Arachnid genealogy must, it seems, receive a favourable judgment. They differ from the Crustacea in that they have only a single pair of præ-oral appendages, the second pair being definitely developed as mandibles. This fact renders their association with the Crustacea impossible, if classification is to be the expression of genetic affinity inferred from structural coincidence. On the contrary, this particular point is one in which they agree with the higher Arachnida. But little is known of the structure of these extinct animals; we are therefore compelled to deal with such special points of resemblance and difference as their remains still exhibit. They had lateral eyes¹ which resemble no known eyes so closely as the lateral eyes of *Limulus*. The general form and structure of their prosomatic carapace are in many striking features identical with that of *Limulus*. The trilobation of the head and body—due to the expansion and flattening of the sides or "pleura" of the tegumentary skeleton—is so closely repeated in the young of *Limulus* that the latter has been called "the Trilobite stage" of *Limulus* (Fig. 42 compared with Fig. 41). No Crustacean exhibits this trilobite form. But most important of the evidences presented by the Trilobites of affinity with *Limulus*, and therefore with the Arachnida, is the tendency less marked in some, strongly carried out in others, to form a pygidial or telsonic shield—a fusion of the posterior somites of the body, which is precisely identical in character with the metasomatic carapace of *Limulus*. When to this is added the fact that a post-anal spine is developed to a large size in some Trilobites (Fig. 38), like that of *Limulus* and *Scorpio*, and that lateral spines on the pleura of the somites are frequent as in *Limulus*, and that neither metasomatic fusion of somites nor post-anal spine, nor lateral pleural spines are found in any Crustacean, nor all three together in any Arthropod besides the Trilobites and *Limulus*—the claim of the Trilobites to be considered as representing one order of a lower grade of Arachnida, comparable to the grade Entomostraca of the Crustacea, seems to be established.

The fact that the single pair of præ-oral appendages of Trilobites, known only as yet in one genus, is in that particular case a pair of uni-ramose antennæ—does not render the association of Trilobites and Arachnids improbable. Although the præ-oral pair of appendages in the higher Arachnida is usually chelate, it is not always so; in Spiders it is not so; nor in many Acari. The bi-ramose structure of the post-oral limbs, demonstrated by Beecher in the Trilobite *Triarthrus*, is no more inconsistent with its claim to be a primitive Arachnid than is the foliaceous modifica-

¹ A pair of round tubercles on the labrum (camerostome or hypostoma) of several species of Trilobites has been described and held to be a pair of eyes quite recently (22). Sense-organs in a similar position were discovered in *Limulus* by Patten (42) in 1894.

tion of the limbs in Phyllopods inconsistent with their relationship to the Arthrostracous Crustaceans such as Gammarus and Oniscus.

Thus, then, it seems that we have in the Trilobites the representatives of the lower phases of the Arachnidan pedigree. The simple Anomomeristic Trilobite, with its equi-formal somites and equi-formal appendages, is one term of the series which ends in the even more simple but degenerate Acari. Between the two and at the highest point of the arc, so far as morphological differentiation is concerned, stands the Scorpion; near to it in the Trilobite's direction (that is on the ascending side) are Limulus and the Eurypterines—with a long gap, due to obliteration of the record, separating them from the Trilobite. On the other side—tending downwards from the Scorpion towards the Acari—are the Pedipalpi, the Spiders, the Book-Scorpions, the Harvest-men, and the Water-Mites.

The strange Nobody-Crabs or Pycnogonids occupy a place on the ascending half of the arc below the Eurypterines and Limulus. They are strangely modified and degenerate, but seem to be (as explained in the systematic review) the remnant of an Arachnidan group holding the same relation to the Scorpions which the Læmopoda hold to the Podophthalmate Crustacea.

We have now to offer a classification of the Arachnida and to pass in review the larger groups, with a brief statement of their structural characteristics.

In the bibliography at the close of this article (referred to by leaded arabic numerals in brackets throughout these pages), the titles of works are given which contain detailed information as to the genera and species of each order or sub-order, their geographical distribution, and their habits and economy so far as they have been ascertained. The limits of space do not permit of a fuller treatment of those matters here.

TABULAR CLASSIFICATION¹ OF THE ARACHNIDA.

CLASS. ARACHNIDA

Grade A. ANOMOMERISTICA.

Sub-Class. TRILOBITÆ.

Orders. Not satisfactorily determined.

Grade B. NOMOMERISTICA.

Sub-Class I. PANTOPODA.

Order 1. Nymphonomorpha.

" 2. Ascorhynchomorpha.

" 3. Pycnogonomorpha.

Sub-Class II. EU-ARACHNIDA.

Grade a. DELOBRANCHIA, Lankester (*vel.* HYDRO-PNEUSTEA, Pocock).

Order 1. Xiphosura.

" 2. Gigantostrea.

Grade b. EMBOLBRANCHIA, Lankester (*vel.* AEROPNEUSTEA, Pocock).

Section a. Pectinifera.

Order 1. Scorpionidea.

Sub-order a. Apoxypoda.

" b. Dionychopoda.

¹The writer is indebted to Mr R. I. Pocock, assistant in the Natural History departments of the British Museum, for valuable assistance in the preparation of this article and for the classification and definition of the groups of Eu-arachnida here given. The general scheme and some of the details have been brought by the writer into agreement with the views maintained in this article. Mr Pocock accepts those views in all essential points and has, as a special student of the Arachnida, given to them valuable expansion and confirmation. The writer also desires to express his thanks to Messrs Macmillan for permission to use Figs. 22, 43, 44, and 45, which are taken from Parker and Haswell's *Text-book of Zoology*; and to Messrs Swan Sonnenschein and Co. for the loan of several figures from the translations published by them of the admirable treatise on *Embryology* by Professors Korschelt and Heider; also to the publishers of the treatise on *Palæontology* by Professor Zittel, Herr Oldenbourg and Macmillan and Co. of New York for several cuts of extinct forms.

Section β. Epectinata.

Order 2. Pedipalpi.

Sub-order a. Uropygi.

Tribe 1. Urotricha.

" 2. Tartarides.

Sub-order b. Amblypygi.

Order 3. Aranæ.

Sub-order a. Mesothelæ.

" b. Opisthothelæ.

Tribe 1. Mygalomorpha.

" 2. Arachnomorpha.

Order 4. Palpigradi (= Microthelyphonida).

Order 5. Solifugæ (= Mycetophoræ).

Order 6. Pseudoscorpiones (= Chelonethi).

Sub-order a. Panctenodactyli.

" b. Hemictenodactyli.

Order 7. Podogona (= Meridogastra).

Order 8. Opiliones.

Sub-order a. Laniatores.

" b. Palpatores.

" c. Anepignathi.

Order 9. Rhynchostomi (= Acari).

Sub-order a. Cryptostigmata.

" b. Metastigmata.

" c. Prostigmata.

" d. Astigmata.

" e. Vermiformia.

" f. Tetrapoda.

CLASS. ARACHNIDA.—Euarthropoda having two prothomeres (somites which have passed from a post-oral to a præ-oral position), the appendages of the first represented by eyes, of the second by solitary rami which are rarely antenniform, more usually chelate. A tendency is exhibited to the formation of a metasomatic as well as a prosomatic carapace by fusion of the tergal surfaces of the somites. Intermediate somites forming a mesosoma occur, but tend to fuse superficially with the metasomatic carapace or to become co-ordinated with the somites of the metasoma, whether fused or distinct to form one region, the opisthosoma (abdomen of authors). In the most highly-developed forms the two anterior divisions (tagmata) of the body, prosoma and mesosoma, each exhibit six pairs of limbs, pediform and plate-like respectively, whilst the metasoma consists of six limbless somites and a post-anal spine. The genital apertures are placed in the first somite following the prosoma, excepting where a pragenital somite, usually suppressed, is retained. Little is known of the form of the appendages in the lowest archaic Arachnida, but the tendency of those of the prosomatic somites has been (as in the Crustacea) to pass from a generalized bi-ramose or multi-ramose form to that of uni-ramose antennæ, chelæ, and walking-legs.

The Arachnida are divisible into two grades of structure—according to the fixity or non-fixity of the number of somites building up the body:—

Grade A (of the Arachnida). ANOMOMERISTICA.—Extinct archaic Arachnida, in which (as in the Entomostracous Crustacea) the number of well-developed somites may be more or less than eighteen and may be grouped only as head (prosoma) and trunk or may be further differentiated. A telsonic tergal shield of greater or less size is always present, which may be imperfectly divided into well-marked but immovable tergites indicating incompletely differentiated somites. The single pair of palpiform appendages in front of the mouth has been found in one instance to be antenniform, whilst the numerous post-oral appendages in the same genus were bi-ramose. The position of the genital apertures is not known. Compound lateral eyes present; median eyes wanting. The body and head have the two pleural regions of each somite flattened and expanded on either side of the true gut-holding body-axis. Hence the name of the sub-class signifying tri-lobed, a condition realized also in the Xiphosurous Arachnids. The members of this group, whilst resembling the lower Crustacea (as all lower groups of a branching genealogical tree must do), differ from them essentially in that the head exhibits only one prothomere (in addition to the eye-bearing prothomere) with palpiform appendages (as in all Arachnida) instead of two. The Anomomeristic Arachnida form a single sub-class, of which only imperfect fossil remains are known.

Sub-class (of the Anomomeristica). TRILOBITÆ.—The single sub-class Trilobitæ constitutes the grade Anomomeristica. It has been variously divided into orders by a number of writers. The greater or less evolution and specialization of the metasomatic carapace appears to be the most important basis for classification—but this has not been made use of in the latest attempts at drawing up a system of the Trilobites. The form of the middle and lateral regions of the prosomatic shield has been used, and an excessive importance attached to the demarcation of certain areas in that structure. Sutures are stated to mark off some of these pieces, but in the proper sense of that term as applied to the skeletal structures

of the Vertebrata, no sutures exist in the chitinous cuticle of Arthropoda. That any partial fusion of originally distinct chitinous plates takes place in the cephalic shield of Trilobites, comparable to the partial fusion of bony pieces by suture in Vertebrata, is a suggestion contrary to fact.

The Trilobites are known only as fossils, mostly Silurian and

appearance to the free somites. The genus *Agnostus*, which belongs to the last category, occurs abundantly in Cambrian strata and is one of the earliest forms known. This would lead to the supposition that the great development of metasomatic carapace is a primitive and not a late character, were it not for the fact that *Paradoxides* and *Atops*, with an inconspicuous telsonic carapace

FIG. 34.—Restoration of *Triarthrus Becki*, Green, as determined by Mr Beecher from specimens obtained from the Utica Slates (Ordovician), New York. A, dorsal; B, ventral surface. In the latter the single pair of antennae springing up from each side of the camerostome or hypostome or upper lip-lobe are seen. Four pairs of appendages besides these are seen to belong to the cephalic tergum. All the appendages are pediform and bi-ramose; all have prominent gnathobase, and in all the exopodite carries a comb-like series of secondary processes. (After Beecher, from Zittel.)

præ-Silurian; a few are found in Carboniferous and Permian strata. As many as two thousand species are known. Genera with small metasomatic carapace consisting of three to six fused segments distinctly marked though not separated by soft membrane, are *Harpee*, *Paradoxides*, and *Triarthrus* (Fig. 34). In *Calymene*, *Homalonotus*, and *Phacops* (Fig. 38) from six to sixteen segments are clearly marked by ridges and grooves in the metasomatic tagma, whilst in *Ilænus* the shield so formed is large but no somites are marked out on its surface. In this genus ten free somites (mesosoma) occur between the prosomatic and metasomatic carapaces.

FIG. 35.—*Triarthrus Becki*, Green. a, Restored thoracic limbs in transverse section of the animal; b, section across a posterior somite; c, section across one of the sub-terminal somites. (After Beecher.)

paces. *Asaphus* and *Megalaspis* (Fig. 39) are similarly constituted. In *Agnostus* (Fig. 40) the anterior and posterior carapaces constitute almost the entire body, the two carapaces being connected by a mid-region of only two free somites. It has been held that the forms with a small number of somites marked in the posterior carapace and numerous free somites between the anterior and posterior carapace, must be considered as anterior to those in which a great number of posterior somites are traceable in the metasomatic carapace, and that those in which the traces of distinct somites in the posterior or metasomatic carapace are most completely absent must be regarded as derived from those in which somites are well marked in the posterior carapace and similar in

and numerous free somites, are also Cambrian in age, the latter indeed anterior in horizon to *Agnostus*.

On the other hand, it may well be doubted whether the pygidial or posterior carapace is primarily due to a fusion of the

FIG. 38.—*Dalmanites limulurus*, Green. One of the Phacopidae, from the Silurian, New York. (From Zittel.)

FIG. 39.—*Megalaspis extenuatus*. One of the Asephidae allied to *Ilænus*, from the Ordovician of East Gothland, Sweden. (From Zittel.)

tergites of somites which were previously movable and well developed. The posterior carapace of the Trilobites and of *Limulus* is probably enough in origin a telsonic carapace—that is to say is the tergum of the last segment of the body which carries the anus. From the front of this region new segments are produced in the first instance, and are added during growth to the existing

FIG. 36.—*Triarthrus Becki*, Green. Dorsal view of second thoracic leg with and without setae. en, Inner ramus; ex, outer ramus. (After Beecher.)

FIG. 37.—*Delphon Forbessii*, Barr. One of the Cheiruridae, Silurian Bohemia. (From Zittel's Palaeontology.)

series. This telson may enlarge, it may possibly even become internally and sternally developed as partially separate somites, and the tergum may remain without trace of somite formation, or, as appears to be the case in *Limulus*, the telson gives rise to a few well-marked somites (mesosoma and two others) and then enlarges without further trace of segmentation, whilst the chitinous integument which develops in increasing thickness on the terga as growth advances welds together the unsegmented telson and the somites in front of it, which were previously marked by separate tergal thickenings. It must always be remembered that we are liable (especially in the case of fossilized integuments) to attach an unwarranted interpretation to the mere discontinuity or continuity of the thickened plates of chitinous cuticle on the back of an Arthropod. These plates may fuse, and yet the somites to which they belong may remain distinct, and each have its pair of appendages well de-

veloped by dislocation of important segmental structures (such as appendages and nerve-ganglia), may lead to highly-developed specialization (individuation, H. Spencer), as in the Araneæ and Opiliones, and, on the other hand, may terminate in simplification and degeneration, as in the Acari.

The most important general change which has affected the structure of the nomomeristic Arachnida in the course of their historic development is the transition from an aquatic to a terrestrial life. This has been accompanied by the conversion of the lamelliform

FIG. 40.—Four stages in the development of the trilobite *Agnostus nudus*. A, youngest stage with no mesosomatic somites; B and C, stages with two mesosomatic somites between the prosomatic and telsonic carapaces; D, adult condition, still with only two free mesosomatic somites. (From Korschelt and Heider.)

veloped. On the other hand, an unusually large tergal plate, whether terminal or in the series, is not always due to fusion of the dorsal plates of once-separate somites, but is often a case of growth and enlargement of a single somite without formation of any trace of a new somite. For the literature of Trilobites see (22*).

Grade B (of the Arachnida) NOMOMERISTICA.—Arachnida in which, excluding from consideration the eye-bearing prosthomere, the somites are primarily (that is to say, in the common ancestor of the grade) grouped in three regions of six—(a) the "prosoma" with palpiform appendages, (b) the "mesosoma" with plate-like appendages, and (c) the "metasoma" with suppressed appendages. A somite placed between the prosoma and mesosoma—the præ-genital somite—appears to have belonged originally to the prosomatic series (which with its ocular prosthomere and palpiform limbs [Pantopoda] would thus consist of eight somites), but to have been gradually reduced. In living Arachnida, excepting the Pantopoda, it is either fused (with loss of its appendages) with the prosoma (*Limulus*,¹ *Scorpio*), after embryonic appearance, or is retained as a rudimentary, separate, detached somite in front of the mesosoma, or disappears altogether (excalation).

FIG. 42.—So-called "trilobite stage" of *Limulus polyphemus*. A, dorsal, B, ventral view. (From Korschelt and Heider, after Leuckart.)

gill-plates into lamelliform lung-plates, and later the development from the lung-chambers, and at independent sites, of tracheæ or air-tubes (by adaptation of the vasifactive tissue of the blood-vessels) similar to those independently developed in Peripatus, Diplopoda, Hexapoda, and Chilopoda. Probably tracheæ have developed independently by the same process in several groups of tracheate Arachnida. The nomomeristic Arachnida comprise two subclasses—one a very small degenerate offshoot from early ancestors; the other, the great bulk of the class.

Sub-class I (of the Nomomeristica). PANTOPODA.—Nomomeristic Arachnida, in which the somites corresponding to mesosoma and metasoma have entirely aborted. The seventh leg-bearing somite (the præ-genital rudimentary somite of Eu-arachnida) is present and has its leg-like appendages fully developed. Mononiscous eyes with a double (really triple) cell-layer formed by invagination, as in the Eu-arachnida, are present. The Pantopoda stand in the same relation to *Limulus* and *Scorpio* that *Cyamus* holds to the thoracostracous Crustacea. The reduction of the organism to seven leg-bearing somites, of which the first pair, as in so many Eu-arachnida, are chelate, is a form of degeneration connected with a peculiar quasi-parasitic habit resembling that of the crustacean Læmidipoda. The genital pores are situate at the base

FIG. 41.—Five stages in the development of the trilobite *Sao hirsuta*. A, youngest stage; B, older stage with distinct pygidial carapace; C, stage with two free mesosomatic somites between the prosomatic and telsonic carapaces; D, stage with seven free intermediate somites; E, stage with twelve free somites; the telsonic carapace has not increased in size; a, lateral eye; g, so-called facial "suture" (not really a suture); p, telsonic carapace. (From Korschelt and Heider, after Barrode.)

The atrophy and total disappearance of ancestrally well-marked somites frequently take place (as in all Arthropoda) at the posterior extremity of the body, whilst excalation of somites may occur at the constricted areas which often separate adjacent "regions," though there are very few instances in which it has been recognized. Concentration of the organ-systems by fusion of neighbouring regions (prosoma, mesosoma, metasoma), previously distinct, has frequently occurred, together with obliteration of the muscular and chitinous structures indicative of distinct somites. This concentration and obliteration of somites, often accompanied

FIG. 43.—One of the Nymphonomorphous Pantopods, *Nymphon hirsutum*, showing the seven pairs of appendages 1 to 7; ab, the rudimentary opisthosoms; s, the mouth-bearing proboscis. (From Parker and Haswell's *Text-book of Zoology*, after Hoek.)

of the 7th pair of limbs, and may be repeated on the 4th, 5th, and 6th. In all known Pantopoda the size of the body is quite minute as compared with that of the limbs: the alimentary canal sends a long cæcum into each leg (cf. the Araneæ) and the genital products are developed in gonocœls also placed in the legs.

The Pantopoda are divided into three orders, the characters of which are dependent on variation in the presence of the full number of legs.

Order 1 (of the Pantopoda). Nymphomorpha, Pocock (nov.) (Fig. 43).—In primitive forms belonging to the family Nymphonidæ the full complement of appendages is retained—the 1st (mandibular), the 2nd (palpiform), and the 3rd (ovigerous) pairs being well developed in both sexes. In certain derivative forms constituting the family Pallenidæ, however, the appendages of the 2nd pair are either rudimentary or atrophied altogether.

Two families: 1. Nymphonidæ (genus *Nymphon*), and 2. Pallenidæ (genus *Pallene*).

¹ Mr Pocock suggests that the area marked vii. in the outline figure of the dorsal view of *Limulus* (Fig. 7) may be the tergum of the suppressed præ-genital somite. Embryological evidence must settle whether this is so or not.

Order 2. Ascorhynchomorpha, Pocock (nov.).—Appendages of the 2nd and 3rd pairs retained and developed, as in the more primitive types of Nymphonomorpha; but those of the 1st pair are either rudimentary, as in the Ascorhynchidæ, or atrophied, as in the Colossendeidæ. In the latter a further specialization is shown in the fusion of the body segments.

Two families: 1. Ascorhynchidæ (genera *Ascorhynchus* and *Ammonothea*); 2. Colossendeidæ (genera *Colossendeis* and *Discorachne*).

Order 3. Pycnogonomorpha, Pocock (nov.).—Derivative forms in which the reduction in number of the anterior appendages is carried farther than in the other orders, reaching its extreme in the Pycnogonidæ, where the 1st and 2nd pairs are absent in both sexes and the 3rd pair also are absent in the female. In the Hannoniidæ, however, which resemble the Pycnogonida in the absence of the 3rd pair in the female and of the 2nd pair in both sexes, the 1st pair are retained in both sexes.

Two families: 1. Hannoniidæ (genus *Hannonia*); 2. Pycnogonidæ (genera *Pycnogonum* and *Phoxichilus*).

Remarks.—The Pantopoda are not known in the fossil condition. They are entirely marine, and are not uncommon in the coralline zone of the sea-coast. The species are few, not more than fifty (23). Some large species of peculiar genera are taken at great depths. Their movements are extremely sluggish. They are especially remarkable for the small size of the body and the extension of viscera into the legs. Their structure is eminently that of degenerate forms. Many frequent growths of coralling Algæ and Hydroid polyps, upon the juices of which they feed, and in some cases a species of gall is produced in Hydroids by the penetration of the larval Pantopod into the tissues of the polyp.

Sub-Class II (of the Nomomeristic Arachnida). EU-ARACHNIDA.—These start from highly developed and specialized aquatic branchiferous forms, exhibiting prosoma with six pediform pairs of appendages, an intermediate præ-genital somite, a mesosoma of six somites bearing lamelliform pairs of appendages, and a metasoma of six somites devoid of appendages, and the last provided with a post-anal spine. Median eyes are present, which are monomeric, with distinct retinal and corneagenous cell-layers, and placed centrally on the prosoma. Lateral eyes also may be present, arranged in lateral groups, and having a single or double cell-layer beneath the lens. The first pair of limbs is often chelate or prehensile, rarely antenniform; whilst the second, third, and fourth may also be chelate, or may be simple palps or walking legs.

An internal skeletal plate, the so-called "entosternite" of fibro-cartilaginous tissue, to which many muscles are attached, is placed between the nerve-cords and the alimentary tract in the prosoma of the larger forms (*Limulus*, *Scorpio*, *Mygale*). In the same and other leading forms a pair of much-coiled glandular tubes, the coxal glands (coelomocœls in origin), is found with a duct opening on the coxa of the fifth pair of appendages of the prosoma. The vascular system is highly developed (in the non-degenerate forms); large arterial branches closely accompany or envelop the chief nerves; capillaries are well developed. The blood-corpuscles are large amœbiform cells, and the blood-plasma is coloured blue by hæmocyanin.

The alimentary canal is uncoiled and cylindrical, and gives rise laterally to large gastric glands, which are more than a single pair in number (two to six pairs), and may assume the form of simple cœca. The mouth is minute and the pharynx is always suctorial, never gizzard-like. The gonadial tubes (gonocœls or gonadial coelom) are originally reticular and paired, though they may be reduced to a simpler condition. They open on the first somite of the mesosoma. In the numerous degenerate forms simplification occurs by obliteration of the demarcations of somites and the fusion of body-regions, together with a gradual suppression of the lamelliferous respiratory organs and the substitution for them of tracheæ, which, in their turn, in the smaller and most reduced members of the group, may also disappear.

The Eu-arachnida are divided into two grades with reference to the condition of the respiratory organs as adapted to aquatic or terrestrial life.

Grade *a* (of the Eu-arachnida). DELOBRANCHIA (Hydropneustea).

Mesosomatic segments furnished with large plate-like appendages, the 1st pair acting as the genital operculum, the remaining pairs being provided with branchial lamellæ fitted for breathing oxygen dissolved in water. The præ-genital somite partially or wholly obliterated in the adult. The mouth lying far back, so that the basal segments of all the prosomatic appendages, excepting those of the 1st pair, are capable of acting as masticatory organs. Lateral eyes consisting of a densely-packed group of eye-units ("compound" eyes).

Order 1. Xiphosura.—The præ-genital somite fuses in the embryo with the prosoma and disappears (see Fig. 19). Not free-swimming,

none of the prosomatic appendages modified to act as paddles; segments of the mesosoma and metasoma (=opisthosoma) not more than ten in number, distinct or coalesced.

Family—Limulidæ (*Limulus*)

„ Belinuridæ (*Belinurus*, *Aglaspis*, *Prestwichia*).

„ Hemiaspidæ (*Hemiaspis*, *Bunodes*).

Remarks.—The Xiphosura are marine in habit, frequenting the shore. They are represented at the present day by the single genus *Limulus* (Figs. 44 and 45; also Figs. 7, 9, 11, to 15 and 20), which

FIG. 44.—Dorsal view of *Limulus polyphemus*, Latr. One-fourth the natural size, linear. (From Parker and Haswell, *Text-book of Zoology*, after Leuckart.)

FIG. 45.—Ventral view of *Limulus polyphemus*, one-fourth the natural size, linear. 1 to 6, the six prosomatic pairs of appendages; *abd*, the solid opisthosomatic carapace; *tels*, the post-anal spine (not the telson as the lettering would seem to imply, but only its post-anal portion); *operc*, the fused first pair of mesosomatic appendages forming the genital operculum. (From Parker and Haswell, *Text-book of Zoology*, after Leuckart.)

occurs on the American coast of the Atlantic Ocean, but not on its eastern coasts, and on the Asiatic coast of the Pacific. The Atlantic

species (*L. polyphemus*) is common on the coasts of the United States, and is known as the King-crab or Horse-shoe Crab. A single specimen was found in the harbour of Copenhagen in the 18th century, having presumably been carried over by a ship to which it clung.

A species of *Limulus* is found in the Buntersandstein of the Vosges; *L. Walchi* is abundant in the Oolitic lithographic slates of Bavaria.

The genera *Belinurus*, *Aglaspis*, *Prestwichia*, *Hemiaspis*, and *Bunodes* consist of small forms which occur in Palæozoic rocks. In none of them are the appendages known, but in the form of the two carapaces and the presence of free somites they are distinctly intermediate between *Limulus* and the *Trilobitæ*. The young form of *Limulus* itself (Fig. 40) is also similar to a *Trilobite* so far as its segmentation and trilobation are concerned. The lateral eyes of *Limulus* appear to be identical in structure and position with those of certain *Trilobitæ*.

Order 2. Gigantostraca (Figs. 46, 47).—Free-swimming forms, with the appendages of the 6th or 5th and 6th pairs flattened or

ledge as to such appendages, and further evidence with regard to them is much to be desired. (For literature see Zittel, 22*.)

FIG. 46.—*Eurypterus Fischeri*, Eichwald. Silurian of Rootzkiel. Restoration after Schmidt, half the size of nature. The dorsal aspect is presented showing the prosomatic shield with paired compound eyes and the prosomatic appendages II to VI. The small first pair of appendages is concealed from view by the carapace. 1 to 12 are the somites of the opisthosoma; 13, the post-anal spine. (From Zittel's *Text-book of Palæontology*. Macmillan, New York, 1896.)

lengthened to act as oars; segments of mesosoma and metasoma (=opisthosoma), twelve in number.

Appendages of anterior pair very large and chelate.

Sub-order Pterygotomorpha, Pterygotidæ (*Pterygotus*).

Appendages of anterior pair minute and chelate.

Sub-order Eurypteromorpha { *Stylonuridæ* (*Stylonurus*).
Eurypteridæ (*Eurypterus*,
Stimonia).

Remarks.—The Gigantostraca are frequently spoken of as “the Eurypterine.” Not more than thirty species are known. They became extinct in Palæozoic times, and are chiefly found in the Upper Silurian, though extending upwards as far as the Carboniferous. They may be regarded as “macrourous” Xiphosura; that is to say, Xiphosura in which the nomomeristic number of eighteen well-developed somites is present and the posterior ones form a long tail-like region of the body. There still appears to be some doubt whether in the sub-order Eurypteromorpha the first pair of prosomatic appendages (Fig. 46) is atrophied, or whether, if present, it has the form of a pair of tactile palps or of minute chelæ. Though there are indications of lamelliform respiratory appendages on mesosomatic somites following that bearing the genital operculum, we cannot be said to have any proper know-

FIG. 47.—*Pterygotus osiliensis*, Schmidt. Silurian of Rootzkiel. Restoration of the ventral surface, one-third the natural size, after Schmidt. *a*, camarostome or epistoma; *m*, chilarium or metasternite of the prosoma (so-called metastoma); *oo*, the compound eyes; 1 to 8, segments of the sixth prosomatic appendage; I' to V', first five opisthosomatic somites; 7', sixth opisthosomatic somite. Observe the powerful gnathobases of the sixth pair of prosomatic limbs and the median plates behind *m*. The dotted line on somite I indicates the position of the genital operculum which was probably provided with branchial lamellæ. (From Zittel's *Palæontology*.)

Grade *b* (of the Eu-arachnida). EMOLOBRANCHIA
 (Aeropneustea).

In primitive forms the respiratory lamellæ of the appendages of the 3rd, 4th, 5th, and 6th, or of the 1st and 2nd mesosomatic somites are sunk beneath the surface of the body, and become adapted to breathe atmospheric oxygen, forming the leaves of the

FIG. 48.—Dorsal view of a restoration of *Palæophonus nunctus*, Thorell. The Silurian Scorpion from Gothland. (Restored after Thorell's indications by Mr R. I. Pocock.)

so-called lung-books. In specialized forms these pulmonary sacs are wholly or partly replaced by tracheal tubes. The appendages of the mesosoma generally suppressed; in the more primitive forms one or two pairs may be retained as organs subservient to reproduction or silk-spinning. Mouth situated more forwards than in Delobranchia, no share in mastication being taken by the basal

segments of the 5th and 6th pairs of prosomatic appendages. Lateral eyes, when present, represented by separate ocelli.

The præ-genital somite, after appearing in the embryo, either is obliterated (Scorpio, Galeodes, Opilio, and others) or is retained as a reduced narrow region of the body, the "waist," between prosoma and mesosoma. It is represented by a full-sized tergal plate in the Pseudo-scorpiones.

Section a. *Pectinifera*.—The primitive distinction between the mesosoma and the metasoma retained, the latter consisting of six somites and the former of six somites in the adult, each of which is furnished during growth with a pair of appendages. Including the præ-genital somite (Fig. 16), which is suppressed in the adult, there are thirteen somites behind the prosoma. The appendages of the 1st and 2nd mesosomatic somites persisting as the genital operculum and pectones respectively, those of the 3rd, 4th, 5th, and 6th somites (? in *Palæophonus*) sinking below the surface during growth in connexion with the formation of the four pairs of pulmonary sacs (see Fig. 17). Lateral eyes monostichous.

Order i. *Scorpionidea*.—Prosoma covered by a single dorsal shield, bearing typically median and lateral eyes; its sternal elements reduced to a single plate lodged between or behind the basal segments of the 5th and 6th pairs of appendages. Appendages of 1st pair tri-segmented, chelate; of 2nd pair chelate, with their basal segments subserving mastication; of 3rd, 4th, 5th, and 6th pairs similar in form and function, except that in recent

FIG. 49.—Ventral view of a restoration of *Palæophonus Hunters*, Pocock, the Silurian Scorpion from Lesmahago, Scotland. Restored by Mr R. L. Pocock. The meeting of the coxæ of all the prosomatic limbs in front of the pentagonal sternum; the space for a genital operculum; the pair of pectens, and the absence of any evidence of pulmonary stigmata are noticeable in this specimen. (See Pocock, *Quart. Jour. Micr. Sci.* 1901.)

and Carboniferous forms the basal segments of the 3rd and 4th are provided with sterno-coxal (maxillary) lobes, those of the 4th pair meeting in the middle line and underlying the mouth. The five posterior somites of the metasoma constricted to form a "tail," the post-anal sclerite persisting as a weapon of offence and provided with a pair of poison glands (see Figs. 8, 10, 12, 13, 14, 15, 21, and 22).

Sub-order Apoxypoda.—The 3rd, 4th, 5th, and 6th pairs of appendages short, stout, tapering, the segments about as wide as long, except the apical, which is distally slender, pointed, slightly curved, and without distinct movable claws.

Family—*Palæophonidæ*, *Palæophonus* (Figs. 48 and 49).

Sub-order Dionychopoda.—The 3rd, 4th, 5th, and 6th pairs of appendages slender, not evenly tapering, the segments longer than wide; the apical segment short, distally truncate, and provided with a pair of movable claws. Basal segments of the 5th and 6th pairs of appendages abutting against the sternum of the prosoma (see Fig. 10 and Figs. 51, 52, and 53).

Family—*Pandinidæ* (*Pandinus*, *Opisthophthalmus*, *Urodacus*).
 ,, *Vejoïdæ* (*Væjovis*, *Jurus*, *Euscorpis*, *Broteas*).
 ,, *Bothriuridæ* (*Bothriurus*, *Cercophonius*).
 ,, *Buthidæ* (*Buthus*, *Centrurus*).
 ,, **Cyclophthalmidæ* (*Cyclophthalmus*) } Carbon-
 ,, **Eoscorpuidæ* (*Eoscorpis*, *Centromachus*) } iferous.

Remarks on the Order Scorpionidea.—The Scorpion is one of the great animals of ancient lore and tradition. It and the crab are the only two invertebrates which had impressed the minds of early men sufficiently to be raised to the dignity of astronomical representation. It is all the more remarkable that the scorpion proves to be the oldest animal form of high elaboration which has persisted to the present day. In the Upper Silurian two specimens of a scorpion have been found (Figs. 48, 49), one in Gothland and one in Scotland, which would be recognized at once as true

scorpions by a child or a savage. The Silurian scorpion, *Palæophonus*, differs, so far as obvious points are concerned, from a modern scorpion only in the thickness of its legs and in their terminating in strong spike-like joints, instead of being slight and provided with a pair of terminal claws. The legs of the modern scorpion (Fig. 10 : Fig. 51) are those of a terrestrial Arthropod, such as a beetle; whilst those of the Silurian scorpion are the legs of an aquatic Arthropod, such as a crab or lobster. It is probable that

FIG. 50.—Comparison of the sixth prosomatic limb of a recent Scorpion (B), of *Palæophonus* (C), and of *Limulus* (A), showing their agreement in the number of segments; in the existence of a movable spine, Sp, at the distal border of the fifth segment; in the correspondence of the two claws at the free end of the limb of Scorpio with two spines similarly placed in *Limulus*; and lastly, in the correspondence of the three talon-like spines carried on the distal margin of segment six of recent Scorpions with the four larger but similarly situated spines on the leg of *Limulus*; s, groove dividing the ankylosed segments 4 and 5 of the *Limulus* leg into two. (After Pocock, *Q. J. Mic. Sci.* 1901.)

the Silurian scorpion was an aquatic animal, and that its respiratory lamellæ were still projecting from the surface of the body to serve as branchiæ. No trace of "stigmata," the orifices of the lung-chambers of modern scorpions, can be found in the Scottish specimen of *Palæophonus*, which presents the ventral surface of the animal to view. On the other hand, no trace of respiratory appendages excepting the pectens can be detected in the specimen (see Fig. 49).

Fossil scorpions of the modern type are found in the Coal Measures. At the present day scorpions of various genera are found in all the warm regions of the world. In Europe they occur as far north as Bavaria and the south of France. The largest species measure

FIG. 51.—Drawing from life of the desert Scorpion, *Buthus australis*, Lin., from Biskra, N. Africa. (From Lankester, *Journ. Linn. Soc. Zool.* vol. xvi. 1881.)

9 inches from the front of the head to the end of the sting; and occur in tropical India and Africa. Between 200 and 300 species are known. The scorpions use their large chelæ for seizing prey and for fighting with one another. They never use the sting when (as frequently happens) they attack another scorpion, because, as was ascertained by A. G. Bourne (24), the poison exuded by the sting has no injurious effect on another scorpion nor on the scorpion itself. The stories of a scorpion stinging itself to death when placed in a circle of burning coals are due to erroneous observation. When placed in such a position the scorpion faints and becomes inert. It is found (Bourne, 24) that some species of scorpion faint at a temperature of 40° cent. They recover on being removed to cooler conditions. A scorpion having seized its prey (usually a large insect, or small reptile or

mammal) with the large chelæ brings its tail over its head, and deliberately punctures the struggling victim twice with its sting (Fig. 52). The poison of the sting is similar to snake-poison (Calmette), and rapidly paralyzes animals which are not immune to it. It is probably only sickly adults or young children of the human race who can be actually killed by a scorpion's sting. When the scorpion has paralyzed its prey in this way, the two short chelicerae are brought into play (Fig. 53). By the crushing action of their pincers, and an alternate backward and forward movement, they bring the soft blood-holding tissues of the victim close to the minute pin-hole aperture which is the scorpion's mouth. The muscles acting on the bulb-like pharynx now set up a pumping action (see Huxley, 26); and the juices—but no solid matter, excepting such as is reduced to powder—are sucked into the scorpion's alimentary canal. A scorpion appears to prefer for its food another scorpion, and will suck out the juices of an individual as large as itself. When this has taken place, the gorged scorpion becomes distended and tense in the mesosomatic region. It is certain that the absorbed juices do not occupy the alimentary canal alone, but pass also into its caecal off-sets, which are the ducts of the gastric glands (see Fig. 33).

FIG. 52.—Drawing from life of the Italian Scorpion *Euscorpion italicus*, Herbst, holding a blue-bottle fly with its left chela, and carefully piercing it between head and thorax with its sting. Two insertions of the sting are effected and the fly is instantly paralysed by the poison so introduced into its body. (From Lankester, *Journ. Linn. Soc.*)

All Arachnida, including Limulus, feed by suctorial action in essentially the same way as Scorpio. Scorpions of various species have been observed to make a hissing noise when disturbed, or even when not disturbed. The sound is produced by stridulating organs developed on the basal joints of the limbs, which differ in position and character in different genera (see Pocock, 27). Scorpions copulate with the ventral surfaces in contact. The eggs are fertilized, practically in the ovary, and develop *in situ*. The young are born fully formed and are carried by the mother on her back. As many as thirty have been counted in a brood. For information as to the embryology of scorpions, the reader is referred to the works named in the bibliography below. Scorpions do not possess spinning organs nor form either snares or nests, so far as is known. But some species inhabiting sandy deserts form extensive burrows. The fifth pair of prosomatic appendages is used by these scorpions when burrowing, to kick back the sand as the burrow is excavated by the great chelæ.

References to works dealing with the taxonomy and geographical distribution of scorpions are given at the end of this article (28). Section β . *Epectinata*.—The primitive distinction between the mesosoma and the metasoma wholly or almost wholly obliterated, the two regions uniting to form an opisthosoma, which never consists of more than twelve somites and never bears appendages or breathing-organs behind the 4th somite. The breathing-organs of the opisthosoma, when present, represented by two pairs of stigmata, opening either upon the 1st and 2nd (Pedipalpi) or the 2nd and 3rd somites (Solifugæ, Pseudo-scorpiones), or by a single pair upon the 3rd (? 2nd) somite (Opiliones) of the opisthosoma, there being rarely an additional stigma on the 4th (some Solifugæ). The appendages of the 2nd somite of the opisthosoma absent, rarely minute and bud-like (some Amblypygi), never pectiniform. A præ-genital somite is often present either in a reduced condition forming a waist (Pedipalpi, Araneæ, Palpigradi) or as a full-sized tergal plate (Pseudo-scorpiones); in some it is entirely atrophied (Solifugæ, Holosomata, and Rhynchostomi). Lateral eyes when present diplostichous.

Remarks.—The Epectinate Arachnids do not stand so close to the aquatic ancestors of the Embolobranchia as do the Pectiniferous scorpions. At the same time we are not justified in supposing that the scorpions stand in any way as an intermediate grade between any of the existing Epectinata and the Delobranchia. It is probable that the Pedipalpi, Araneæ, and Podogona have been separately evolved as distinct lines of descent from the ancient aquatic Arachnida. The Holosomata and Rhynchostomi are probably off-shoots from the stem of the Araneæ, and it is not unlikely (in view of the

FIG. 53.—The same Scorpion carrying the now paralyzed fly held in its chelicerae, the chelæ liberated for attack and defence. Drawn from life. (From Lankester, *Journ. Linn. Soc.*)

structure of the prosomatic somites of the Tartarides) that the Solifugæ are connected in origin with the Pedipalpi. The appearance of tracheæ in place of lung-sacs cannot be regarded as a starting-point for a new line of descent comprising all the tracheate forms; tracheæ seem to have developed independently in different lines of descent. On the whole, the Epectinata are highly specialized and degenerate forms, though there are few, if any, animals which surpass the spiders in rapidity of movement, deadliness of attack, and constructive instincts.

Order 2. Pedipalpi (Figures 54 to 59).—Appendages of 1st pair bisegmented, without poison gland; of 2nd pair prehensile, their basal segments underlying the proboscis, and furnished with

FIG. 54.—*Thelyphonus*, one of the Pedipalpi. A, ventral view; I, chelicera (detached); II, chelæ; III, palpiform limb; IV to VI, the walking legs; stc, sterno-coxal process (gnathobase) of the chelæ; st', anterior sternal plate of the prosoma; st'', posterior sternal plate of the prosoma; pregen, position of the præ-genital somite (not seen); l, l, position of the two pulmonary sacs of the right side; 1 to 11, somites of the opisthosoma (mesosoma plus metasoma); msg, stigmata of the tergo-sternal muscles; an, anus. B, dorsal view of the opisthosoma of the same; pregen, the præ-genital somite; st, the tergal stigmata of the tergo-sternal muscles; paf, post-anal segmented filament corresponding to the post-anal spine of *Limulus*. (From Lankester, *Q. J. Mic. Sci.* N.S. vol. xxi. 1881.)

sterno-coxal (maxillary) process, the apical segment tipped with a single movable or immovable claw; appendages of 3rd pair different from the remainder, tactile in function, with at least the apical segment many-jointed and clawless. The ventral surface of the prosoma bears prosternal, metasternal, and usually mesosternal chitine-plates (Fig. 55). A narrow præ-genital somite is present between opisthosoma and prosoma (Figs. 55, 57). Opisthosoma consisting of eleven somites, almost wholly without visible appendages. Intromittent organ of male beneath the genital operculum (=sternum of the 1st somite of opisthosoma).

FIG. 55.—*Thelyphonus* sp. Ventral view of the anterior portion of the body to show the three prosomatic sternal plates a, b, c, and the rudimentary sternal element of the præ-genital somite; opisth 1, first somite of the opisthosoma. (From a drawing made by Mr Pickard - Cambridge, under the direction of Mr R. I. Pocock.)

Note.—The possibility of another interpretation of the anterior somites of the mesosoma and the præ-genital somite must be borne in mind. Possibly, though not probably, the somites carrying the two lung-sacs correspond to the first two lung-bearing somites of Scorpio, and it is the genital opening which has shifted. The same caution applies in the case of the Araneæ. Excalation of one or of two anterior mesosomatic somites, besides the præ-

genital somite, would then have to be supposed to have occurred also.

Sub-order *a*. Uropygi.—Prosoma longer than wide, its sternal area very narrow, furnished with a large prosternal and metasternal plate, and often with a small mesosternal sclerite. Appendages of 2nd pair with their basal segments united in the middle line and incapable of lateral movement; appendages of 3rd pair with only the apical segment many-jointed. Opisthosoma without trace of appendages; its posterior somites narrowed to form

FIG. 56.—*Thelyphonus assamensis* ♂. Ventral surface of the anterior region of the opisthosoma, the first somite being pushed upwards and forwards so as to expose the subjacent structures. *opistho 1*, 1st somite of the opisthosoma; *opistho 2*, second do.; *g*, genital aperture; *l*, edges of the lamellae of the lung-books; *m*, stigmata of tergo-sternal muscles. (Original drawing by Mr Pocock.)

a movable tail for the support of the post-anal sclerite, which has no poison glands.

Tribe 1. Urotricha.—Dorsal area of prosoma covered with a single shield (? two in *Geralinura*), bearing median and lateral eyes. Post-anal sclerite modified as a long, many-jointed feeler. Appendages of 2nd pair folding in a horizontal plane, completely chelate, the claw immovably united to the sixth segment. Respiratory organs present in the form of pulmonary sacs.

Family—Thelyphonidæ (*Thelyphonus* (Fig. 54), *Hypoctonus*, **Geralinura*).

Tribe 2. Tartarides.—Small degenerate forms with the dorsal area of the prosoma furnished with two shields, a larger in front

FIG. 57.—*Schizomus crassicaudatus*, one of the Tartarid Pedipalpi. Ventral view of a female with the appendages cut short near the base. *a*, Prosternum of prosoma; *b*, metasternum of prosoma; *præ-gen*, the præ-genital somite; *1 opisth*, first somite of the opisthosoma; *11 opisth*, eleventh somite of the opisthosoma; *pa*, post-anal lobe of the female (compare the jointed filament in *Thelyphonus*, Fig. 54). (Original drawing by Mr Pickard-Cambridge, directed by Mr Pocock.)

FIG. 58.—*Schizomus crassicaudatus*, a Tartarid Pedipalp. Dorsal view of a male with the appendages cut short. I to VI, the proso-matic appendages; *a*, anterior plate, and *b*, posterior plate of the proso-matic cœspace; *præ-gen*, tergum of the præ-genital somite; *11*, the eleventh somite of the opisthosoma; *pa*, post-anal lobe of the male—a conical body with narrow basal stalk. (Original as above.)

covering the anterior four somites, and a smaller behind covering the 5th and 6th somites; the latter generally subdivided into a right and left portion; rarely there is a pair of narrow sclerites interposed between the anterior and posterior shields. Eyes evanescent or absent. Appendages of 2nd pair folding in a vertical plane, not chelate, the claw long and movable. Post-anal sclerite short and undivided. No distinct respiratory stigmata behind the sterna of the 1st and 2nd somites of the opisthosoma.

Family—Hubbardiidæ (*Schizomus*, *Hubbardia*) (Figs. 57-59).

Sub-order *b*. Amblypygi.—Prosoma wider than long, covered

above by a single shield bearing median and lateral eyes, which have diplostichous ommata. Sternal area broad, with prosternal, two mesosternal, and metasternal plates, the prosternum projecting forwards beneath the coxæ of the 2nd pair of appendages. Appendages of 2nd pair folding in a horizontal plane; their basal segments freely movable; claw free or fused; basal segments of 4th and 5th pairs widely separated by the sternal area; appendages of 3rd pair with all the segments except the proximal three, forming a many-jointed flagellum. Opisthosoma without post-anal

FIG. 59.—*Schizomus crassicaudatus*, one of the Pedipalpi. Lateral view of a male. II to VI, the proso-matic appendages, the first being concealed (see Fig. 58); 5, the fifth, and 11, the eleventh tergites of the opisthosoma; *pa*, the conical post-anal lobe. (Original as above.)

sclerite and posterior caudal elongation: with frequently a pair of small lobate appendages on the sternum of the 3rd somite. Respiratory organs, as in Urotricha.

Family—Phrynichidæ (*Phrynichus*, *Damon*).

„ Admetidæ (*Admetus*, *Heterophrynus*).

„ Charontidæ (*Charon*, *Sarax*).

(Family ?)—*Geraphrynus.

Remarks.—The Pedipalpi are confined to the tropics and warmer temperate regions of both hemispheres. Fossil forms occur in the Carboniferous. The small forms known as *Schizomus* and *Hubbardia* are of special interest from a morphological point of view. The Pedipalpi have no poison glands. (Reference to literature (29).)

Order 3. Araneæ (Figs. 60 to 64).—Prosoma covered with a single shield and typically furnished with median and lateral eyes of diplostichous structure, as in the Amblypygi. Its sternal surface wide, continuously chitinized, but with prosternal and

FIG. 60.—*Liphistius desultor*, Schiödte, one of the Araneæ Mesothela. Dorsal view. I to VI, the proso-matic appendages; 4, 5, 6, the fourth, fifth, and sixth tergites of the opisthosoma. Between the bases of the sixth pair of limbs and behind the proso-matic cœspace is seen the tergite of the small præ-genital somite. (Original by Pickard-Cambridge and Pocock.)

metasternal elements generally distinguishable at the anterior and posterior ends respectively of the large mesosternum. Prosternum underlying the proboscis. Appendages of 1st pair have two segments, as in Pedipalpi, but are furnished with poison gland, and are retroverts. Appendages of 2nd pair not underlying the mouth, but freely movable and, except in primitive forms, furnished with a maxillary lobe; the rest of the limb like the legs, tipped with a single claw and quite unmodified (except in ♂).

Remaining pairs of appendages similar in form and function, each tipped with two or three claws. Opisthosoma when segmented showing the same number of somites as in the Pedipalpi; usually unsegmented, the præ-genital somite constricted to form the waist; the appendages of its 3rd and 4th somites retained as spinning mammillæ. Respiratory organs (see Fig. 63, *stg*), as in the Amblypygi, or with the posterior pair, rarely the anterior pair as well, replaced by tracheal tubes. Intromittent organ of male in the apical segment of the 2nd prosomatic appendage.

Sub-order *a*. Mesothelæ (see Figs. 60 to 62).—Opisthosoma distinctly segmented, furnished with 11 tergal plates, as in the Amblypygi; the ventral surface of the 1st and 2nd somites with large sternal

FIG. 61.—*Liphistius desultor*. Ventral view with the prosomatic appendages cut off, excepting the chelicera (1) whose sharp retroverts are seen. Between the bases of the prosomatic limbs an anterior and a posterior sternal plate (black) are seen. 1, the sternum of the first opisthosomatic or genital somite covering the genital aperture and the first pair of lung-sacs. In front of it the narrow waist is formed by the soft sternal area of the præ-genital somite; 2, the sternite of the second opisthosomatic somite covering the posterior pair of lung-sacs; 3 and 4, the spinning appendages (limbs) of the opisthosoma; a, inner, b, outer ramus of the appendage; 11, sternite of the eleventh somite of the opisthosoma; in front of it other rudimentary sternites; an, anus. (Original as above.)

plates, covering the genital apertures and the two pairs of pulmonary sacs, the sternal plates from the 6th to the 11th somites represented by integumental ridges, weakly chitinized in the middle. The two pairs of spinning appendages retain their primitive position in the middle of the lower surface of the opisthosoma far in advance of the anus on the 3rd and 4th somites, each appendage consisting of a stout, many-jointed outer branch and a slender, unsegmented inner branch. Prosoma as in the Mygalomorphæ, except that the mesosternal area is long and narrow.

Family—Liphistiidæ (*Liphistius*, **Arthrolycosa*).

Sub-order *b*. Opisthothelæ (see Fig. 63).—Opisthosoma without trace of separate terga and sterna, the segmentation merely represented posteriorly by slight integumental folds and the sterna of the 1st and 2nd somites by the opercular plates of the pulmonary sacs. The spinning appendages migrate to the posterior end of the opisthosoma and take up a position close to the anus; the inner branches of the anterior pair either atrophy or are represented homogenetically by a plate, the cribellum, or by an undivided membranous lobe, the colulus.

Tribe 1. Mygalomorphæ.—The plane of the articulation of the appendages of the 1st pair to the prosoma (the retrovert) vertical, the basal segment projecting straight forwards at its proximal end, the distal segment or fang closing backwards in a direction sub-parallel to the long axis of the body. Two pairs of pulmonary sacs.

FIG. 62.—*Liphistius desultor*. Lateral view. I to VI, appendages of the prosoma cut off at the base; o, ocular tubercle; præ-gen, the præ-genital somite; 1 and 2, sternites of the first and second opisthosomatic somites; 3 and 4, appendages of the third and fourth opisthosomatic somites, which are the spinning organs, and in this genus occupy their primitive position instead of migrating to the anal region as in other spiders; 5, tergite of the fifth opisthosomatic somite; 11, eleventh opisthosomatic somite; an, anus. (Original.)

Families—Theraphosidæ (*Avicularia*, *Pæcilotheria*). Barychelidæ (*Barychelus*, *Plagiobothrus*). Dipluridæ (*Diplura*, *Macrothela*). Ctenizidæ (*Cteniza*, *Nemestia*). Atypidæ (*Atypus*, *Calommata*).

Tribe 2. Arachnomorphæ.—The plane of the articulation of the appendages of the 1st pair to the prosoma horizontal, the basal segment projecting vertically downwards, at least at its proximal end, the distal segment or fang closing inwards nearly or quite at right angles to the long axis of the body. The posterior pulmonary sacs (except in *Hypochilus*) replaced by tracheal tubes; the anterior and posterior pairs replaced by tracheal tubes in the Caponiidæ.

Principal families—Hypochilidæ (*Hypochilus*). Dysderidæ (*Dysdera*, *Segestria*). Caponiidæ (*Caponia*, *Nops*). Filistatidæ (*Filistata*). Uloboridæ (*Uloborus*, *Dinopis*). Argasidæ (*Nephila*, *Gasteracantha*). Pholcidæ (*Pholcus*, *Artema*). Agelenidæ (*Tegenaria*).

Lycosidæ (*Lycosa*). Clubionidæ (*Clubiona*, *Olios*, *Sparassus*). Gnaphosidæ (*Gnaphosa*, *Hemiclæa*). Thomisidæ (*Thomisus*). Attidæ (*Salticus*). Urocteidæ (*Uroctea*). Eresidæ (*Eresus*).

Remarks on the Araneæ.—The Spiders are the most numerous and diversified group of the Arachnida; about 2000 species are known. No noteworthy fossil spiders are known; the best preserved are in amber of Oligocene age. *Protolycosa* and *Arthrolycosa* occur in the Carboniferous. Morphologically, the spiders are

FIG. 63.—Ventral view of a male mygalomorphous Spider. I to VI, the six pairs of prosomatic appendages; a, copulatory apparatus of the second appendage; b, process of the fifth joint of the third appendage; M, mouth; pro, prosternite of the prosoma; mes, mesosternite of the prosoma; observe the contact of the coxæ of the sixth pair of limbs behind it; compare *Liphistius* (Fig. 61) where this does not occur; stg, lung aperture; gn, genital aperture; a, anus with a pair of backwardly migrated spinning appendages on each side of it; compare the position of these appendages in *Liphistius* (Fig. 61). (From Lankester, "Limulus an Arachnid.")

remarkable for the concentration and specialization of their structure, which is accompanied with high physiological efficiency. The larger species of Bird's Nest Spiders (*Avicularia*), the opisthosoma of which is as large as a bantam's egg, undoubtedly attack young birds, and M'Cook gives an account of the capture in its web by an ordinary house spider of a small mouse. The "retrovert" or bent-back first pair of appendages is provided with a poison gland opening on the fang or terminal segment. Spiders form at least two kinds of constructions—snares for the capture of prey and nests for the preservation of the young. The latter are only formed by the female, which is a larger and more powerful animal than the male. Like the scorpions the spiders have a special tendency to cannibalism, and accordingly the male, in approaching the female for the purpose of fertilizing her, is liable to be fallen upon and sucked

FIG. 64.—*Liphistius desultor*. Under side of the uplifted genital or first opisthosomatic somite of the female; g, genital aperture; p, pitted plate, probably a gland for the secretion of adhesive material for the eggs; l, the edges of the lamellæ of the lung-hooks of the first pair. (Original drawing by Pocock.)

dry by the object of his attentions. The sperm is removed by the male from the genital aperture into a special receptacle on the terminal segment of the 2nd prosomatic appendage. Thus held out at some distance from the body, it is cautiously advanced by the male spider to the genital aperture of the female.

For an account of the courtship and dancing of spiders, of their webs and floating lines, the reader is referred to the works of M'Cook (30) and the Peckhams (31), whilst an excellent account of the nests of trap-door spiders is given by Moggridge (32). References to systematic works will also be found at the end of this article (33).

Order 4. Palpigradi—Microthelyphonida (see Fig. 65).—Prosoma covered above by three plates, a larger representing the dorsal elements of the first four somites, and two smaller representing the dorsal elements of the 5th and 6th.

Its ventral surface provided with one prosternal, two mesosternal, and one metasternal plate. Appendages of 1st pair consisting of three segments, completely chelate, without poison gland; of 2nd pair slender, leg-like, tipped with three claws, the

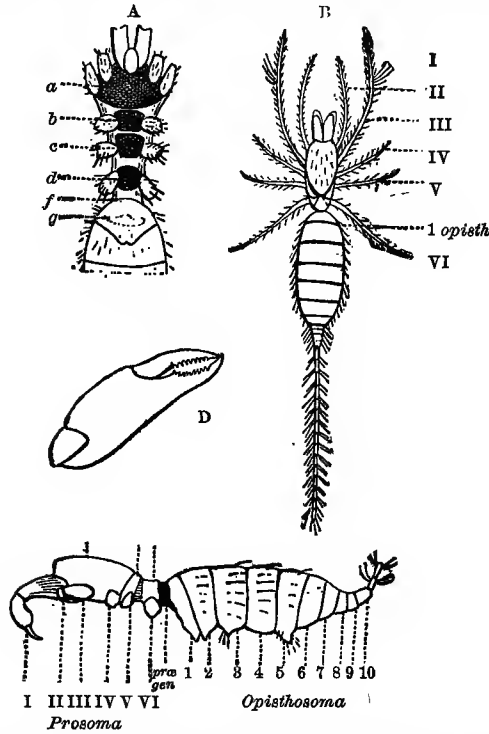

FIG. 65.—*Koenenia mirabilis*, Grassi one of the Psiligradl. A, ventral view of prosoma and of anterior region of opisthosoms with the appendages cut off near the base; *a* and *b*, prosternites; *c*, mesosternite; and *d*, metasternite of the prosoms; *f*, ventral surface of the præ-genital somite; *g*, sternite of the genital somite (first opisthosomatic somite). B, dorsal view. I to VI, prosomatic appendages; 1 *opisth*, genital somite (first opisthosomatic somite). C, lateral view. I to VI, prosomatic appendages; *a*, *b*, *c*, the three tergal plates of the prosoms; *præ-gen*, the præ-genital somite; 1 to 10, the ten somites of the opisthosoma. D, chelicera. (Original drawing by Pocock and Pickard-Cambridge, after Hansen and Sørensen.)

basal segment without sterno-coxal process taking no share in mastication, and widely separated from its fellow of the opposite side; 3rd, 4th, 5th, and 6th appendages similar in form to the 2nd and to each other.

Proboscis free, not supported from below by either the prosternum or the basal segments of the appendages of the 2nd pair.

Opisthosoma consisting of only ten somites, which have no tergal and sternal elements, the præ-genital somite contracted to form a "waist," as in the Pedipalpi; the last three narrowed to form a caudal support for the many-jointed flagelliform telson, as in the Urotricha. Respiratory organs atrophied.

Family—*Koeneniidae* (*Koenenia*).

Remarks.—An extremely remarkable minute form originally described by Grassi (34) from Sicily, and since further described by Hansen (35). Recently the genus has been found in Texas, U.S.A. Only one genus of the order is known.

Order 5. Solifugæ = Mycetophoræ (see Figs. 66 to 69).—Dorsal area of prosoma covered with three distinct plates, two smaller representing the terga of the 5th and 6th somites, and a larger representing those of the anterior four somites, although the reduced terga of the 3rd and 4th are traceable behind the larger plate. The latter bears a pair of median eyes and obsolete lateral eyes on each side. Sternal elements of prosoma almost entirely absent, traces of a prosternum and metasternum alone remaining. Rostrum free, not supported by either the prosternum or the basal segments of the appendages. Appendages of 1st pair large, chelate, bisegmented, articulated to the sides of the head-shield; appendages of 2nd pair simple, pediform, with protrusible (? suctional) organ, and no claws at the tip; their basal segments united in the middle line and furnished with sterno-coxal process. Remaining pairs of appendages with their basal segments immovably fixed to the sternal surface, similar in form, the posterior three pairs furnished with two claws supported on long stalks; the basal segments of the 6th pair bearing five pairs of tactile sensory organs or malleoli. The præ-genital somite is suppressed. Opisthosoma composed of ten somites. Respiratory organs tracheal, opening upon the ventral surface of the 2nd and 3rd, and sometimes also of the 4th somite of the opisthosoma. A supplementary pair of

tracheæ opening behind the basal segment of the 4th appendage of the prosoma.

(? Intromittent organ of male lodged on the dorsal side of the 1st pair of prosomatic appendages.)

Families—Hexisopodidæ (*Hexisopus*). Solpugidæ (*Solpuga*, *Rhagodes*). Galeodidæ (*Galeodes*).

FIG. 66.—*Galeodes*, *sp.*, one of the Solifuga. Ventral view to show legs and somites. I to VI, the six leg-bearing somites of the prosoma; *opisth* 1, first or genital somite of the opisthosoma; *g*, site of the genital aperture; *st*, thoracic tracheal aperture; *1*, anterior tracheal aperture of the opisthosoma in somite 2 of the opisthosoma; *2*, tracheal aperture in somite 8 of the opisthosoma; *a*, anus. (From Lankester, "Limulus an Arachnid.")

FIG. 67.—*Galeodes*, *sp.*, one of the Solifuga. Ventral view with the appendages cut off at the base. I to VI, prosomatic appendages; *s*, prosomatic stigms or aperture of the tracheal system; 1, first opisthosomatic sternite covering the genital aperture *g*; 2, second opisthosomatic sternite covering the second pair of tracheal apertures *sp1*; *sp2*, the third pair of tracheal apertures; 10, the tenth opisthosomatic somite; *an*, the anal aperture. (Originals by Pickard-Cambridge and Pocock.)

FIG. 68.—*Galeodes*, *sp.*, one of the Solifuga. Dorsal view. I to VI, bases of the prosomatic appendages; *o*, eyes; *a*, lateral region of the cephalic plate to which the first pair of appendages are articulated; *b*, cephalic plate with median eye; *c*, dorsal element of somites bearing third and fourth pairs of appendages; *d*, second plate of the prosoma with fifth pair of appendages; *e*, third or hindmost plate of the prosoma beneath which the sixth pair of legs is articulated; 1, 2, 9, 10, first, second, ninth, and tenth somites of the opisthosoma; *an*, anus. (Original.)

Remarks.—These most strange-looking Arachnids occur in warmer temperate, and tropical regions of Asia, Africa, and America. Their anatomy has not been studied, as yet, by means of freshly-

killed material, and is imperfectly known, though the presence of the coxal glands was determined by Macleod in 1884. The proportionately enormous chelæ (chelicerae) of the first pair of appendages are not provided with poison glands; their bite is not venomous.

Galeodes has been made the means of a comparison between the structure of the Arachnida and Hexapod insects by Haeckel and other writers, and it was at one time suggested that there was a

FIG. 69.—*Galeodes*, sp., one of the Solifuga. I to VI, the six prosomatic limbs cut short; o, the eyes; b, c, demarcated areas of the cephalic or first prosomatic plate corresponding respectively to appendages I, II, III and to appendage IV (see Fig. 68); d, second plate of the prosoma-carrying appendage V; e, third plate of the prosoma-carrying appendage VI. The præ-genital somite is absent. 1, first somite of the opisthosoma; 2, second do.; S, prosomatic tracheal aperture between legs IV and V; S' and S'', opisthosomatic tracheal apertures; 10, tenth opisthosomatic somite; an, anus. (Original.)

genetic affinity between the two groups—through *Galeodes*, or extinct forms similar to it. The segmentation of the prosoma and the form of the appendages bear a homoplastic similarity to the head, pro-, meso-, and meta-thorax of a Hexapod with mandibles, maxillary palps and three pairs of walking legs; whilst the opisthosoma agrees in form and number of somites with the abdomen of a Hexapod, and the tracheal stigmata present certain agreements in the two cases. Reference to literature (36).

Order 6. Pseudoscorpiones = Chelonethi, also called Chernetidia (see Figs. 70, 71, 72).—Prosoma covered by a single dorsal shield, at most furnished with one or two diplostichous lateral eyes; sternal elements obliterated or almost obliterated. Appendages of the 1st pair bisegmented completely chelate, furnished with peculiar organs, the *serrula* and the *lamina*. Appendages of 2nd pair very large and completely chelate, their basal segments meeting in the middle line,

FIG. 70.—*Garypus litoralis*, one of the Pseudoscorpiones. Ventral view. I to VI, prosomatic appendages; o, sterno-coxal process of the basal segment of the second appendage; 1, sternite of the genital or first opisthosomatic somite; the præ-genital somite, though represented by a tergum, has no separate sternal plate; 2 and 3, sternites of the second and third somites of the opisthosoma, each showing a tracheal stigma; 10 and 11, sternites of the tenth and eleventh somites of the opisthosoma; an, anus. (Original by Pocock and Pickard-Cambridge.)

FIG. 71.—*Garypus litoralis*, one of the Pseudoscorpiones. Dorsal view. I to VI, the prosomatic appendages; o, eyes; præ-gen, præ-genital somite; 1, tergite of the genital or first opisthosomatic somite; 10, tergite of the tenth somite of the opisthosoma; 11, the evanescent eleventh somite of the opisthosoma; an, anus. (Original.)

pace) narrowed in front; the appendages of the 1st pair small, much narrower, taken together, than the posterior border of the carapace. Serrula on movable digit of appendages of 1st pair fixed throughout its length, and broader at its proximal than at its distal end; the immovable digit with an external process.

Family—Cheliferidæ (*Chelifer* (Figs. 66, 67, 68), *Chiridium*), Garypidæ (*Garypus*).

Sub-order b. Hemictenodactyli.—Dorsal plate of prosoma scarcely narrowed in front; the appendages of the 1st pair large, not much narrower, taken together, than the posterior border of the cara-

FIG. 72.—*Garypus litoralis*, one of the Pseudoscorpiones. Lateral view. I to VI, basal segments of the six prosomatic appendages; o, eyes; præ-gen, tergite of the præ-genital somite; 1, genital or first opisthosomatic somite; 2, 3, 10, the second, third, and tenth somites of the opisthosoma; 11, the minute eleventh somite; an, the anus. (Original.)

pace. The serrula or the movable digit free at its distal end, narrowed at the base; no external lamina on the immovable digit.

Family—Obisidæ (*Obisium*, *Pseudobisium*).

Chthoniidæ (*Chthonius*, *Tridenchthonius*).

Remarks.—The Book-scorpions—so-called because they were, in old times, found not unfrequently in libraries—are found in rotten wood and under stones. The similarity of the form of their appendages to those of the scorpions suggests that they are a degenerate group derived from the latter, but the large size of the præ-genital somite in them would indicate a connexion with forms preceding the scorpions. Reference to literature (37).

Order 7. Podogona = Meridogastra (see Figs. 73 to 76).—Dorsal area of prosoma furnished with two shields, a larger behind representing, probably, the tergal elements of the somites, and a smaller in front, which is freely articulated to the former and folds over the

FIG. 73.—*Cryptostemma Karaschii*, one of the Podogona. Dorsal view of the male enlarged five times linear. III to VI, the third, fourth, fifth, and sixth appendages of the prosoma; a, movable (hinged) sclerite (so-called hood) overhanging the first pair of appendages; b, fused terga of the prosoma followed by the opisthosoma of four somites; an, anus; E, extremity of the fifth appendage of the male modified to subservise copulation. (Original drawing by Pocock and Pickard-Cambridge.)

appendages of the 1st pair. Ventral area without distinct sternal plates. Appendages of 1st pair, tri-segmented, completely chelate. Appendages of 2nd pair, with their basal segments uniting in the middle line below the mouth, weakly chelate at apex. Appendages of 3rd, 4th, 5th, and 6th pairs similar in form; their basal segments in contact in the middle line and immovably welded, except those of the 3rd pair, which have been pushed aside so that the bases of the 2nd and 4th pairs are in contact with each other. A movable membranous joint between the prosoma and the opisthosoma, the generative aperture opening upon the

FIG. 74.—*Cryptostemma Karaschii*, anterior aspect of the prosoma with the "hood" removed. I to IV, first to fourth appendages of the prosoma; a, basal segment of the second pair of appendages meeting its fellow in the middle line (see Fig. 75). (Original drawing by Pocock and Pickard-Cambridge.)

ventral side of the membrane. Præ-genital somite suppressed; the opisthosoma consisting of only four visible somites, in addition to a tubular ring round the anal orifice. Respiratory organs unknown. Intromittent organ of male placed at the distal end of the appendage of the 5th pair.

Family—Cryptostemmidae (*Cryptostemma*) (**Anthracomartus*) Carboniferous.

Remarks on the Podogona.—The name given to this small but

as in the Uropygi, and provided in front with membranous lip-like processes underlying the proboscis. Appendages of the 3rd, 4th, 5th, and 6th pairs similar in form and function, tipped with two claws, their basal segments in contact in the median ventral line. The præ-genital somite wide, not constricted, with large tergal plate, but with its sternal plate small or inconspicuous. Opisthosoma composed, at least in many cases, of eleven somites, the 11th somite very small, often hidden within the 10th. Respiratory organs in the form of tracheal tubes opening by a pair of stigmata in the 2nd and 3rd somites of the opisthosoma. Intromittent organ of male beneath sternum of the 1st somite of the opisthosoma.

Sub-order a. Panctenodactyli.—Dorsal plate of prosoma (cara-

remarkable group has reference to the position of the male intro-

FIG. 75.—*Cryptostemma Karschii*, one of the Podogons. Ventral view. I to VI, the six pairs of appendages of the prosoma, the last three out short; 1, 2, 3, 4, the four somites of the opisthosoma; a, hood overhanging the first pair of appendages; b, position of the genital orifice; c, part of 3rd appendage; d, fourth segment of 2nd appendage. Observe that the basal segment of appendage III does not meet its fellow in the middle line. (Original drawing by Pocock and Pickard-Cambridge.)

mittent organ (Fig. 73, B). They are small degenerate animals with a relatively firm integument. Not more than four species and twice that number of specimens are known. They have been found in West Africa and South America. A fact of special interest in regard to them is that the genus *Anthracomartus*, from the Coal Measures, appears to be a member of the same group. The name *Cryptostemma*, given to the first-known genus of the order, described by Guérin-Ménéville, refers to the supposed concealment of the eyes by the movable cephalic sclerite. Reference to literature (38).

Order 8. Opiliones (see Fig. 77).—Dorsal area of prosoma covered by a single shield bearing a pair of median eyes, or one or two pairs of lateral eyes. Sternal elements much reduced. Appendages of 1st pair large, three segmented, and completely chelate; of 2nd pair either simple and pediform, or prehensile and subchelate; of remaining four pairs, similar in form, ambulatory in function. Mouth lying far back, the basal segment of the 2nd, 3rd, and sometimes of the 4th pairs of appendages furnished with sterno-coxal (maxillary) lobe. Opisthosoma confluent throughout its breadth with the prosoma, with the dorsal plate of which its anterior tergal plates are more or less confluent; nine opisthosomatic somites traceable; the generative aperture thrust far forwards between the basal segments of the 6th or 5th and 6th appendages. Præ-genital somite suppressed. Respiratory organs, tracheal opening by a pair of stigmata situated immediately behind the basal segments of the 6th pair of appendages on what is probably the sternum of the 3rd opisthosomatic somite, and also in some cases upon the 5th segment of the legs.

Intromittent organ of male lying within the genital orifice.

Sub-order a. Laniatores.—The area between the mouth below and the basal segments of the appendages of the 1st pair above occupied by two unpaired skeletal pieces, the *clypeus* and *labrum*. Sternal area of prosoma occupied by a relatively long and very narrow sclerite, composed of prosternal and metasternal elements, and lying between the coxæ of the appendages of the 5th pair, and interposing between the mouth and generative orifice; the latter lodged between the basal segments of the appendages of the 6th pair. Appendages of 2nd pair strong, generally spiny, and armed with a powerful claw. Appendages of 3rd and 4th pairs armed with a single claw; those of 5th and 6th with two claws. Sterno-coxal process of 3rd pair of appendages coalesced with the basal segment; that of the 4th pair not or scarcely developed.

Principal families—Gonyleptidæ (*Gonyleptes*, *Goniosoma*).

Biantidæ (*Biantes*).

Epedanidæ (*Epedanus*, *Acrobunus*).

Assamidæ (*Assamia*, *Pygoplus*).

Oncopodidæ (*Oncopus*, *Pelitus*).

Cosmetidæ (*Cosmetus*).

Sub-order b. Palpatores.—Resembling the Laniatores, but with the sternal area of prosoma very short, the metasternal sclerite represented by a short transverse plate more or less overlapped by the forwardly-projecting sternal element of the opisthosoma that covers the genital orifice and intervenes between the basal segments of the appendages of the 5th and 6th pairs. The genital orifice thus lies far forwards, close behind the mouth and on a level with the space between the basal segments of the appendages of the 5th pair. Appendages of 2nd pair small, weak, in no sense prehensile, unspined, the claw weak or absent; the 3rd-6th pairs of appendages armed with a single claw. Sterno-coxal process of 3rd appendage movably articulated; a similar lobe generally present on basal segment of 4th appendage.

Principal families—Phalangiidæ (*Phalangium*, *Liobunum*).

Nemastomidæ (*Nemastoma*, *Ischyropsalis*).

Trogulidæ (*Trogulus*, *Anelasmacephalus*).

FIG. 76.—*Cryptostemma Karschii*. Extremity of the fifth pair of appendages of the female for comparison with that of the male E in Fig. 73.

Sub-order c. Anepignathi.—Basal segments of appendages of 2nd pair meeting in the middle line across the area that lies between the mouth below and the basal segments of the appendages of the 1st pair above, to the partial or total exclusion of the unpaired skeletal pieces, known as the clypeus and labrum. Genital orifice lying between the basal segments of the appendages of the 6th pair, and separated from the mouth by a relatively long space occupied by the inner extremities of the basal segments of the 3rd, 4th,

FIG. 77.—*Stylocellus sumatranus*, one of the Opiliones; after Thorell. Enlarged. A, dorsal view; I to VI, the six prosomatic appendages; B, ventral view of the prosoma and of the first somite of the opisthosoma, with the appendages I to VI cut off at the base; a, tracheal stigmata; ma, maxillary processes of the coxæ of the third pair of appendages; g, genital aperture. C, ventral surface of the prosoma and opisthosoma; a, tracheal stigmata; l, lateral view of the first and second pair of appendages. E, lateral view of the whole body and two first appendages, showing the fusion of the dorsal elements of the prosoma into a single plate, and of those of the opisthosoma into an imperfectly segmented plate continuous with that of the prosoma.

5th, and 6th pairs of appendages, the sternal sclerites being evanescent. Appendages of 2nd-6th pairs short and strong, furnished with a single claw.

Family—Cyphophthalmidæ (*Cyphophthalmus*, *Stylocellus*, *Petalus*).

Remarks on the Opiliones.—These include the Harvest-men, sometimes called also Daddy-long-legs, with round undivided bodies and very long, easily-detached legs. The intromittent organs of the male are remarkable for their complexity and elaboration. The confluence of the regions of the body and the dislocation of apertures from their typical position are results of degeneration. The Opiliones seem to lead on from the Spiders to the Mites. Reference to literature (39).

Order 9. Rhynchostomi = Acari (see Fig. 78).—Degenerate Arachnids resembling the Opiliones in many structural points, but chiefly distinguishable from them by the following features:—The basal segments of the appendages of the 2nd pair are united in the middle line behind the mouth; those of the 3rd, 4th, 5th, and 6th pairs are widely separated and not provided with sterno-coxal (maxillary) lobes, and take no share in mastication; the respiratory stigmata, when present, belong to the prosoma, and the primitive segmentation of the opisthosoma has entirely or almost entirely disappeared.

Sub-order a. Cryptostigmata.—Integument hard, strengthened by a continuously chitinized dorsal and ventral sclerite. Tracheæ typically opening by stigmata situated in the articular sockets (acetabula) of the 3rd, 4th, 5th, and 6th pairs of appendages.

Family—Oribatidæ (*Oribata*, *Nothrus*, *Hoplophora*).

Sub-order b. Metastigmata.—Integument mostly like that of the Cryptostigmata. Tracheæ opening by a pair of stigmata situated above and behind the base of the 4th or 5th or 6th pair of appendages.

Families—Gamasidæ (*Gamasus*, *Pteroptus*).

Argasidæ (*Argas*, *Ornithodoros*).

Ixodidæ (*Ixodes*, *Rhipicephalus*).

Sub-order c. Prostigmata.—Integument soft, strengthened by special sclerites, those on the ventral surface of the prosoma apparently representing the basal segments of the legs embedded in the skin. Tracheæ, except in the aquatic species in which they are atrophied, opening by a pair of stigmata situated close to or above the base of the appendages of the 1st pair (mandibles).

Families—Trombididæ (*Trombidium*, *Tetranychus*).

Hydrachnidæ (*Hydrachna*, *Atax*).

Halacaridæ (*Halacarus*, *Leptognathus*).

Bdellidæ (*Bdella*, *Eupodes*).

Sub-order d. Astigmata.—Degenerate, mostly parasitic forms approaching the Prostigmata in the development of integumental sclerites and the softness of the skin, but with the respiratory system absent.

Families—Tyroglyphidæ (*Tyroglyphus*, *Rhizoglyphus*).

Sarcoptidæ (*Sarcoptes*, *Analges*).

Sub-order e. Vermiformia.—Degenerate atracheate parasitic

forms with the body produced posteriorly into an annulated caudal prolongation, and the 3rd, 4th, 5th, and 6th pairs of appendages short and only three-jointed.

Family—Demodicidæ (*Demodex*).

Sub-order *f. Tetrapoda*.—Degenerate atracheate gall-mites, in which the body is produced posteriorly and annulated, as in *Demodex*, but in which the appendages of the 3rd and 4th pairs are long and normally segmented, and those of the 5th and 6th pairs entirely absent.

Family—Eriophyidæ (*Eriophyes Phyllocoptes*).

Remarks on the *Rhynchostomi*.—The Acari include a number of forms which are of importance and special interest on account of their parasitic habits. The ticks (*Ixodes*) are not only injurious as blood-suckers, but are now credited with carrying the germs of Texas cattle-fever, just as mosquitoes carry those of malaria.

FIG. 78.—*Holothyrus nitidissimus*, one of the Acari; after Thorell. Enlarged fifteen times linear. A, lateral view with appendages III to VI removed; 1 plate covering the whole dorsal area, representing the fused tergal sclerites of the prosoma and opisthosoma; 2, similarly-formed ventral plate; 3, tracheal stigmata. B, dorsal view of the same animal; II to VI, second to sixth pairs of appendages. The first pair of appendages both in this and in C are retracted. C, ventral view of the same; II to VI as in B; a, genital orifice; b, anus; o, united basal segments of the second pair of appendages; d, basal segment of the sixth prosoamic appendage of the right side. The rest of the appendage, as also of spp. III, IV, and V, has been cut away. (Original drawing by Pocock and Pickard-Cambridge.)

The itch-insect (*Sarcoptes scabiei*) is a well-known human parasite, so minute that it was not discovered until the end of the 18th century, and "the itch" was treated medicinally as a rash. The female burrows in the epidermis much as the female Trap-door Spider burrows in turf in order to make a nest in which to rear her young. The male does not burrow, but wanders freely on the surface of the skin. *Demodex folliculorum* is also a common parasite of the sebaceous glands of the skin of the face in man, and is frequent in the skin of the dog. Many Acari are parasitic on marine and freshwater molluscs, and others are found on the feathers of birds and the hair of mammals. Others have a special faculty of consuming dry, powdery vegetable and animal refuse, and are liable to multiply in manufactured products of this nature, such as mouldy cheese. A species of *Acarus* is recorded as infesting a store of powdered strychnine and feeding on that drug, so poisonous to larger organisms. Reference to literature (40).

(E. R. L.)

Arad, Old, a municipal town of Hungary, on the river Maros, 145 miles S.E. of Budapest; capital of the county of Arad; a well-equipped modern town, with a considerable trade, including a large distillery. After the surrender of Görgey at Világos, the thirteen captured Hungarian generals were here put to death. A statue of liberty has been erected to their memory, and the anniversary of their death is annually celebrated with great solemnities. There is a museum composed of relics of the war of national independence of 1848-49. Population in 1901, 55,987; of the neighbouring village of New Arad, 6044.

Araguay, River. See AMAZON.

Arakan.—This division of Lower Burma on the eastern seaboard of the Bay of Bengal continues to be divided into four districts—Akyab, Northern Arakan Hill Tracts, Sandoway, and Kyaukpyu, which name has been substituted for the older Ramri. Its area is 18,540 square miles, and the population in 1891 was 673,190. The population at the time of its annexation in 1826 did not exceed 100,000. In 1898-99 there were 4014 villages, and the revenue paid was Rs.23,83,406. Akyab remains the only town of importance in the division. Of the 11,865,600 acres in the division, 6,207,270 acres are not capable of cultivation, and in 1898-99 only 800,720 acres were cultivated. The great proportion of the cultivable but not cultivated area was in the Northern Arakan Hill Tracts district, which is under a superintendent, who is usually a police officer with headquarters at Paletwa. The area of the Hill Tracts is 5233 square miles, with a population in 1891 of 14,627, and containing 317 villages. Of the population 13,039 were aborigines—mostly Chins, 1204 were Buddhists and Jains, 366 were Hindus, and 18 were Mahomedans. Only 10,451 acres were cultivated out of the total area of 3,349,120 acres. The rainfall at Paletwa in 1898-99 was 123.91 inches. Sixty-five police maintain order in the district.

Aral (KHVAREZM, ARAL-DENGHIZ), a large lake of Central Asia, situated to the E. of the Caspian Sea, between 43° 41' to 46° 45' N. lat., and 58° 19' to 61° 47' E. long., and by its area the second inland salt sea of the world. It covers 26,166 square miles, and has nearly the same length as width, namely, about 170 miles, if its northern gulf (Kichkine-Denghiz) be left out of account.

Its depth is insignificant, attaining 222 feet only in a depression in the north-west, and 90 feet in the middle, so that notwithstanding its wide area it contains only eleven times as much water as Lake Lemán. Its altitude is 246 feet above the Caspian (Tillo), i.e., about 160 feet above the ocean.

There is no doubt that in recent historical times Lake Aral had a much greater extension than it has now, and that its present area is diminishing at a rapid rate. From a map of 1741 it appears that its north-eastern gulf, Sary-chaganak, protruded about 53 miles farther than it does now, and this is confirmed by what Meyendorff heard in 1820 from the Kirghiz, namely, that, forty years before, the lake reached some hills which are now forty miles from the shore. Moreover, the large Aibughir Gulf on the southern shore, which was full of water in 1858, is now quite dry, and the Laudan, the most western branch of the Amu, which entered this gulf in 1848 and 1859, has quite dried up since. The salinity of its water is much less than that of the ocean, containing only 0.012 of salt (only 0.006 of chloride of sodium), and the lake freezes every year for a great distance from its shores. The opinion that Lake Aral periodically disappeared, which was for a long time countenanced by Western geographers, loses more and more of its probability now that it becomes evident that at a relatively recent period the Caspian Sea extended much farther eastward than it does now, and that Lake Aral communicated with it through the Sary-Kamysh depression. The present writer is even inclined to think that besides this southern communication with the Caspian, Lake Aral may have been, even in historical times, connected with the Mortvyi Kultuk Gulf of the Caspian, discharging part of its water into that sea, through a depression of the Ust-Urt plateau, which is marked by a chain of lakes (Chumyshty, Asmantai, &c.). In this case it might have been easily confounded with a gulf of the Caspian (by Jenkinson). That the level of Lake Aral was much higher in post-Pliocene times is proved by the finding of shells of their characteristic species of *Pecten* and *Mytilus* in the Kara-kum, 33 miles from the lake at an altitude of 70 feet above its present level, and perhaps even up to 200 feet (by Syeverstsoff; see Mushketoff's *Turkestan*). The fishes of Lake Aral belong to fresh-water species, and in some of its rapid tributaries the interesting *Scaphirhynchus*, which represents a survival from the Tertiary epoch, is found. The fishing is very productive, and about 1000 tons of fish are exported yearly to Turkestan, Merv, and even Russia. The shores of the lake are uninhabited, and the nearest settlements are Kazalinsk (7600 inhabitants), 35 miles east, on the Syr, and Chimbai and Kungrad in the delta of the Amu.

Soc.*, 1887.—Prof. MUSHKETTOFF, *Turkestan*, vol. i. 1886, which contains rich bibliographical indications.

(P. A. K.)

Aral-Caspian Region (or DEPRESSION) is the name which is given by geographers to the lowlands in the east of the Caspian Sea, and, by extension, to all the territory comprised between the Lower Volga, the Aral-Irtysh water-parting, the Dzungarian Alatau, and the Hindu Kush. These were also the limits given to it in an excellent work on the geo-botany of this region by the Russian botanist, Borschoff. (See TRANSCASPIAN TERRITORY.) Owing to its special geological structure and vegetation, the general aspect of its steppes, exposed to the powerful disintegrating agency of the wind, and its sandy deserts alternating with prairies and oases (see KARA-KUM), it represents a distinct geographical type. Large areas are covered with the characteristic Aral-Caspian deposits, which spread as a thin layer, attaining a maximum thickness of 90 feet, but are very much destroyed by the rivers, which have often changed their courses in recent times, and by the winds, which freely blow over this flat, open territory. They attain their fullest development in the part of the Aral-Caspian region which lies to the east of the Caspian Sea, and consist nearly always of a yellow-grayish clay, occasionally taking the character of a more or less compact sandstone of the same colour. Their typical fossils are shells of species still living in both the Caspian and the Aral, but in the shallow parts of them only; namely, according to Mushketoff, *Cardium edule*, L., *Dreysena polymorpha*, V. Bened., *Neritina liturata*, Eichw., *Adacna vitrea*, Eichw., *Hydrobia stagnalis*, L., in the Kara-kum; and *Lithoglyphus caspius*, Krynitz., *Hydrobia stagnalis*, *Anodonta ponderosa*, Pfr., and the sponge, *Metschnikowia tuberculata*, Grimm, in the Kyzyl-kum. All these are inhabitants of the littoral zone, and only the *Lithoglyphus caspius* is found at greater depths, not exceeding, however, 100 fathoms in the Caspian Sea. The exact limits of the great Aral-Caspian Post-Pliocene Sea are not yet settled, except in the north-west, where the Ergheni hills of the Kalmyk steppe are a distinct barrier. As to its northern limits, the same Aral-Caspian deposits are known to exist 80 miles, but not more than from 130 to 200 miles, north of Lake Aral. They quite certainly do not cross the Aral-Irtysh water-parting. Their eastern limit lies some 100 miles from Lake Aral, but Severtsoff maintained that they extend also into the drainage area of Lake Balkhash (*q.v.*). In the south the same deposits, containing the same species of *Cardium*, *Dreysena*, *Neritina*, and *Hydrobia*, are known to spread without interruption, 160 miles from Lake Aral, as far as the Bala-ishem wells, in the Sary-kamysh depression (whose surface is below the level of the Caspian), and up the Uzboi for 100 miles from the Caspian. As to their exact extension up the Amu and the Syr, it is not yet known. It is thus concluded that the Aral-Caspian basin had, in Post-Pliocene times, a very wide extension, but that it contained very large islands—Ust-Urt, &c.—which divided it into several parts, its eastern portion communicating with the western, but by one or two narrow straits. These channels, which were formerly taken for old beds of the Amu-daria, have only dried up at a recent epoch, and most probably they existed in historical times.

See MUSHKETOFF'S *Turkestan*, St Petersburg, 1886, where all indications of literature are given. (P. A. K.)

Aran Islands, South; three islands—Inishmore, Inishmaan, and Inisheer—lying across Galway Bay on the W. coast of Ireland. The Congested Districts Board has of recent years made efforts to improve the condition of the inhabitants, especially by introducing better methods of fishing. A curing station has been established at Killeany. Population about 3000.

Ararat, (1) Assyrian *Urardhu*, the country in which

the Ark rested after the Deluge (Gen. viii. 4), and to which the murderers of Sennacherib fled (2 Kings xix. 37; Isaiah xxxvii. 38). The name Urardhu, originally that of a principality which included Mount Ararat and the plain of the Araxes, is given in Assyrian inscriptions from the 9th century B.C. downwards to a kingdom that at one time included the greater part of the later Armenia. The native name of the kingdom was *Biainas*, and its capital was *Dhuspas*, now Van. The first king, Sarduris I. (circ. 833 B.C.), subdued the country of the Upper Euphrates and Tigris. His inscriptions are written in cuneiform, in Assyrian, whilst those of his successors are in cuneiform, in their own language, which is neither Aryan nor Semitic. The kings of Biainas extended their kingdom eastward and westward, and defeated the Assyrians and Hittites. But Sarduris II. was overthrown by Tiglath Pileser II. (743 B.C.), and driven north of the Araxes, where he built Armavir, *Armauria*. Interesting specimens of Biainian art have been found on the site of the palace of Rusas II., near Van. Shortly after 645 B.C. the kingdom fell, possibly conquered by Cyaxares, and a way was thus opened for the immigration of the Aryan Armenians. The name Ararat is unknown to the Armenians of the present day. The limits of the Biblical Ararat are not known, but they must have included the lofty Armenian plateau which overlooks the plain of the Araxes on the north, and that of Mesopotamia on the south. It is only natural that the highest and most striking mountain in the district should have been regarded as that upon which the Ark rested, and that the old name of the country should have been transferred to it. According to the Babylonian account of the Deluge, the resting-place of the Ark was "on the mountain of Nizir," which some writers have identified with Mount Rowanduz, and others with Mount Elburz, near Tehrán. The Kúrds, Syrians, and Nestorians regard Jebel Judi, on the left bank of the Tigris, near Jezire, as the mountain.

SAYCE, "Cuneiform Inscriptions of Lake Van," in *Journal of Royal Asiatic Society*, vols. xiv., xx., and xxvi.—MASPERO, *Histoire ancienne des peuples de l'Orient classique*, tom iii. *Les Empires*, Paris, 1899.—Articles, "Ararat," in *Smith's Dictionary of the Bible*, *Hastings' Dictionary of the Bible*, and *Encyclopædia Biblica*.

(2) ARARAT, Armenian *Massis*, Turkish *Egri Dag*, "Painful Mountain," Persian, *Koh-i-Nuh*, "Mountain of Noah," is the name given to the culminating point of the Armenian plateau which rises to a height of 17,100 feet above the sea. The *massif* of Ararat rises on the north and east out of the alluvial plain of the Araxes, here from 2500 feet to 3000 feet above the sea, and on the south-west sinks into the plateau of Bayezid, about 4500 feet. It is thus isolated on all sides but the north-west, where a *col* about 6900 feet high connects it with a long ridge of volcanic mountains. Out of the *massif* rise two peaks, "their bases confluent at a height of 8800 feet, their summits about 7 miles apart." The higher, Great Ararat, is "a huge broad-shouldered mass, more of a dome than a cone"; the lower, Little Ararat, 12,840 feet, on which the territories of the Tsar, the Sultan, and the Shah meet, is "an elegant cone or pyramid, rising with steep, smooth, regular sides into a comparatively sharp peak" (Bryce). Both peaks are entirely composed of igneous rock, but all eruptive activity has long ceased. On the north and west the slopes of Great Ararat are covered with glittering fields of unbroken *névé*. The only true glacier is on the north-east side, at the bottom of a large chasm which runs into the heart of the mountain. The great height of the snow-line, 14,000 feet, compared with the average of the Alps, 8500-9000 feet, is due to the small rainfall and the upward rush of dry air from the plain of the Araxes. The middle zone of Ararat, 5000-

11,500 feet, is covered with good pasture; the upper and lower zones are for the most part sterile. Many traditions connected with the Deluge gather round Ararat. The garden of Eden is placed in the valley of the Araxes; Marand is the burial-place of Noah's wife; at Arghuri, a village near the great chasm, was the spot where Noah planted the first vineyard, and here were shown Noah's vine, and the monastery of St James, until village and monastery were overwhelmed by a fall of rock, ice, and snow, shaken down by the earthquake of 1840. Since 1856 Ararat has been climbed by Bryce (1876), Markoff (1888), Pastuchow and Lynch (1893).

BRYCE. *Transcaucasia and Ararat*, 4th ed. 1896.—LYNCH. *Armenia*. London, 1901. (c. w. w.)

Ararat, a municipality and railway station in Australia, Victoria, in the county of Ripon, 131½ postal miles N.W. of Melbourne, with which it is connected (*via* Ballarat) by rail. It is the commercial centre of the north-western grain and wool producing district, and is also noted for its quartz and alluvial gold mines. Excellent wine is made. The district also yields the best timber in great quantity. Granite, bluestone, limestone, and slate abound in the neighbourhood. It has a large lunatic asylum, and is an assize town. Altitude, 1072 feet. Rainfall (14 years) 24·37 inches. Population (1881), 2740; (1891), 3151; (1901), 3580.

Aras, *Araxes*, a river which rises in the Bin-geul Dagh, south of Erzerum, and, after flowing eastward through the territories of Turkey and Russia, forms the boundary between Persia and Russia. It formerly joined the Kur, but since 1897, when it changed its lower course, it has run direct to the Kizil Agach Bay of the Caspian.

Arauan. See SAHARA.

Arbela, now Erbil, a small town east of the Tigris, in the Mosul vilayet. The battle in which Alexander defeated Darius was fought at Gaugamela, on the Bumodus, now Khazr Su, a tributary of the Greater Zab, and not at Arbela. In the 14th century the Christians were massacred and almost exterminated. Population, 4000.

Arbitrage.—Arbitrage is the term applied to the system of equalizing prices in different commercial centres by buying in the cheaper market and selling in the dearer. These transactions, or their converse, are mainly confined to stocks and shares, foreign exchanges, and bullion; and are for the most part carried on between London and the Continental capitals, and largely with New York. When prices in London are affected by financial or political causes, all other markets are sooner or later influenced, as London is the banking and financial centre for the commerce of the world. It may, however, also occur that some local event of importance initiates a rise or fall in a particular market which must ultimately affect other countries. For instance, a revolution or a threat of one in France would immediately depress all French securities, and by exciting the fears of capitalists would stimulate transfers of funds and raise all the exchanges against France.

In ordinary times those engaged in arbitrage operate with a very small margin of profit. The great improvement in postal, telegraphic, and telephonic communication enables operators to close transactions with amazing rapidity, while competition reduces the margin of profit to a minimum. Operations in American stocks and shares are carried on between London and New York on a vast scale, while transactions in African mining shares are undertaken to a considerable extent between London and Paris. The frequent fluctuations in the prices of

the latter securities offer a large and fruitful field to bold operators possessed of large resources, while those who have small means often succumb in a commercial crisis. As regards foreign exchange and bullion, arbitrage operators stand on a fairly safe foundation, the fluctuations being slight and involving little or no risk, although they yield a very small margin of profit. In fact arbitrage between London and the continent of Europe has dwindled, owing to competition, to almost vanishing point, but operations with distant countries such as India are large and mainly profitable. Arbitrage with India consists chiefly in buying bills of exchange in London, such as India Council rupee bills amounting to about 16 millions sterling annually, and commercial bills drawn against goods exported to India. The counter-operation consists in purchasing in India, for short or long delivery, sterling bills drawn against exports to Great Britain of Indian produce, such as cotton, tea, indigo, jute, and wheat. These operations greatly facilitate trade and the moving of produce from the interior of India to the seaports. Without this assistance Great Britain's enormous trade could not be carried on, and she would have to revert to the primitive system of barter. The same advantages are afforded to her vast trade with China and Japan, with the material difference that the supply of Government council bills is confined to the Indian trade. The balance of trade with all countries is generally settled by specie shipments; hence, with the Far East, silver and gold play an important part in arbitrage.

It is impossible to imagine the difficulties and confusion which would arise in the absence of the arbitrageur. It is the system of arbitrage, based on principles which are the necessary outcome of successful commerce, which renders vast operations possible, and greatly facilitates the enormous British export and import trade, while maintaining those international connexions which tend to secure general peace and prosperity. (s. m.)

Arbitration.—Since the publication of the ninth edition of this work the law as to arbitration has, both in England and Scotland, undergone considerable modification. The principal changes in the English law have been made by the Arbitration Act, 1889. This statute—which, it should be noted, is an express code as to proceedings in all arbitrations—subdivides its subject matter into two headings:—I. References by consent out of court; II. References under order of court.

I. *References by Consent out of Court*.—Here the first matter to be dealt with is the submission. A submission is defined as a written agreement (which must be signed by both parties or their authorized agents) to submit present or future differences to arbitration, whether a particular arbitrator is named in it or not. Under the law prior to the Act of 1889, (a) an agreement to refer disputes generally, without naming the arbitrators, was always irrevocable, and an action lay for the breach of it, although the court could not compel either of the parties to proceed under it; (b) an agreement to refer to a particular arbitrator was revocable, and if one of the parties revoked that particular arbitrator's authority he could not be compelled to submit to it; (c) when, however, the parties had got their tribunal fixed, and were proceeding to carry out the agreement to refer, the Act 9 and 10 Will. III. c. 15 provided that the submission might be made a rule of court, a provision which gave the court power to assist the parties in the trial of the case, and to enforce the award of the arbitrators; (d) the statute 3 and 4 Will. IV. c. 42 put an end to the power to revoke the authority of a particular arbitrator after the reference to him had been made a rule of court; and—a liability which existed also under the Act of 9 and 10 Will. III. c. 15—any person revoking

the appointment of an arbitrator after the submission had been made a rule of court might be attached. The Arbitration Act, 1889, provides that a submission, unless a contrary intention is expressed in it, is irrevocable except by leave of the court or a judge, and is to have the same effect in all respects as if it had been made an order of court. The object of this enactment was to save the expense of making a submission a rule of court by treating it as having been so made, and it leaves the law in this position that while the authority of an arbitrator, once appointed, is irrevocable, there is no power—any more than there was under the old law—to compel an unwilling party to proceed to a reference, except in cases specially provided for by sections 5 and 6 of the Act of 1889. The former of these sections deals with the power of the court, the latter with the power of the parties to a reference, to appoint an arbitrator in certain circumstances. Section 5 provides that where a reference is to be to a single arbitrator, and all the parties do not concur in appointing one, or an appointed arbitrator refuses to act or becomes incapable of acting, or where the parties or two arbitrators fail, when necessary, to appoint an umpire or third arbitrator, or such umpire or arbitrator when appointed refuses to act, or becomes incapable of acting, and the default is not rectified after seven clear days' notice, the court may supply the vacancy. Under section 6, where a reference is to two arbitrators, one to be appointed by each party, and either the appointed arbitrator refuses to act, or becomes incapable of acting, and the party appointing him fails, after seven clear days' notice, to supply the vacancy, or such party fails, after similar notice, to make an original appointment, a binding appointment (subject to the power of the court to set it aside) may be made by the other party to the reference. The court may compel parties to carry out an arbitration not only in the above cases by directly appointing an arbitrator, &c., or by allowing one appointed by a party to proceed alone with the reference, but also indirectly by staying any proceedings before the legal tribunals to determine matters which come within the scope of the arbitration. The court will generally stay proceedings where the agreement to refer stipulates that the submission of a dispute to arbitration shall be a condition precedent to the right to bring an action in regard to it. On the other hand, the court will refuse to interfere if the subject matter of the litigation falls outside the scope of the reference, or there is some serious objection to the fitness of the arbitrator, or some other good reason of the kind exists.

An arbitrator (and the following observations apply *mutatis mutandis* to an umpire after he has entered on his duties) has power to administer oaths to, or take the affirmations of the parties and their witnesses; and any person who wilfully gives false evidence before him may be prosecuted and punished for perjury. At any stage in the reference he may, and shall if he be required by the court, state in the form of a special case for the opinion of the court any question of law arising in the arbitration. The arbitrator may also state his award in whole or in part as a special case, and may correct in an award any clerical mistake or error arising from an accidental slip or omission. The costs of the reference and the award are in his discretion, and he has a lien on the award and the submission for his fees, for which, apparently—unless upon an express promise to pay them—he cannot sue.

If there is no express provision on the point in the submission, an award under the Arbitration Act, 1889, must be made within three months after the arbitrator has entered on the reference, or been called upon to act by notice in writing from any party to the submission.

The time may, however, be extended by the arbitrator or by the Court. An umpire is required to make his award within one month after the original or extended time appointed for making the award of the arbitrators has expired, or any later day to which he may enlarge it. The court may by order remit an award to the arbitrators or umpire for reconsideration, in which case the reconsidered award must be made within three months after the date of the order. An award may be set aside where the arbitrator has misconducted himself (an arbitrator may also be removed by the court on the ground of misconduct), or where it is *ultra vires*, or the arbitrator has been wilfully deceived by one of the parties, or some such state of things exists. Otherwise it is final. An award may, by leave of the court, be enforced in the same manner as a judgment or decree to the same effect. Under the Stamp Act, 1891, duties ranging from 3d. up to £1, 15s. are payable on awards in England or Ireland.

Provisions for the arbitration of special classes of disputes are contained in many Acts of Parliament (see, e.g., the Local Government Acts, 1888 and 1894, and the Workmen's Compensation Act, 1897).

It may also be noted here that the Conciliation Act, 1896, provides machinery for the prevention and settlement of trade disputes, and that in 1892 a chamber of arbitration for business disputes was established by the joint action of the Corporation of the City of London and the London Chamber of Commerce.

II. *References under Order of Court.*—The court or a judge may refer any question arising in any cause or matter to an official or special referee, whose report may be enforced like a judgment or order to the same effect. This power may be exercised whether the parties desire it or not. The official referees are salaried officers of court. The remuneration of special referees is determined by the court or judge. An entire action may be referred, if all parties consent, or if it involves any prolonged examination of documents, or scientific or local examination, or consists wholly or partly of matters of account.

Scotland.—The law of arbitration has been modified by the Arbitration (Scotland) Act, 1894. An agreement to refer to a person not named or to be named by another person, or to the holder for the time being of any office, is now valid. The court (*i.e.*, any lord ordinary of the Court of Session or sheriff) may appoint an arbiter, on the failure of one of the parties on whom the obligation rests to concur in or make such an appointment. Where arbiters differ in opinion, they, or (if they fail to agree on the point) the court, on the application of either party, may nominate an oversman whose decision is to be final.

The provisions of the English Arbitration Act, 1889, have in substance been adopted by the Indian Legislature (see Act No. 9 of 1899), and by many of the Colonies (see, e.g., Act No. 13 of 1895, Western Australia; No. 24 of 1898, Natal; No. 20 of 1899, Bahamas).

United States.—Arbitration is ordinarily conducted out of court, but in most States an agreement to settle a controversy in this way may be filed in court, and enforced by its authority. There are also statutes of the United States providing facilities for adjusting disputes between certain classes of employers and workmen in this way. The United States law allows arbitration proceedings between corporations engaged in commerce, between the States and their employees, to take place before official arbitrators and at the public expense (30 United States statutes at large, 424).

AUTHORITIES.—RUSSELL, *Arbitration*, London, 1900; *Annual Practice*, London, 1901.—REDMAN, *Arbitration*, London, 1897.—CREWE, *Arbitration Act of 1889*, London, 1898. As to Scots Law, *Green's Encyclopædia of Scots Law*, vol. i. s.v. "Arbitration," Edinburgh, 1896.

ARBITRATION AND CONCILIATION IN LABOUR DISPUTES.

THE terms "arbitration and conciliation," as employed in this article, are used to describe a group of methods of settling disputes between employers and work-people or among two or more sets of work-people, of which the common feature is the intervention of some outside party not directly affected by the dispute. If the parties agree beforehand to abide by the award of the third party, the mode of settlement is described as "arbitration." If there be no such agreement, but the offices of the mediator are used to promote an amicable arrangement between the parties themselves, the process is described as "conciliation." The third party may be one or more disinterested individuals, or a joint-board representative of the parties or of other bodies or persons.

The process here termed "arbitration" is rarely an arbitration in the strict legal sense of the term (at least in the United Kingdom), because of the defective legal personality of the associations or groups of individuals who are usually parties to labour disputes, and the consequent absence in the great majority of cases of a valid legal "submission" of the difference to arbitration. Trade unions, whether consisting of employers or workmen, in the United Kingdom are not corporate bodies capable of entering through their agents into legally binding contracts. Consequently a written agreement on the part of the representatives of employers and workmen to submit a dispute to the decision of a third party is of no legal force except as regards the actual signatories.¹ Broadly speaking, therefore, the provisions of the Arbitration Act, 1889, which consolidated the law relating to arbitration in general, would as a rule have no application to the settlement of collective disputes between employers and workmen, even if the Act had not been expressly excluded by section 3 of the Conciliation Act of 1896 in the case of disputes to which that Act applies. Besides the absence of a legal "submission," labour arbitrations differ from ordinary arbitrations in the fact that the questions referred often (though by no means always) relate to the terms on which future contracts shall be made, whereas the vast majority of ordinary arbitrations relate to questions arising out of existing contracts. The defective "personality" of the parties to labour disputes also prevents the enforcement of an award by legal penalties. Since, however, difficulties of enforcement affect not only settlements arrived at by arbitration, but all agreements between bodies of employers and work-people with regard to the terms of employment, they are most appropriately considered at a later stage of this article.

The term "conciliation" is ordinarily used to cover a large number of methods of settlement, shading off in the one direction into "arbitration" and in the other into ordinary direct negotiation between the parties. In some cases conciliation only differs from arbitration in the absence of a previous agreement to accept the award. The German "*Gewerbegerichten*," when dealing with labour disputes, communicate a decision to both parties, who must notify their acceptance or otherwise (see below). The State Board in Massachusetts sometimes takes similar action.

The conciliation boards established under the New Zealand Arbitration Act of 1894 (see below) make recom-

mendations, though either side may decline to accept them and may appeal to the Court of Arbitration, which in that colony has compulsory powers. Most frequently, however, in Great Britain the mediating party abstains from pronouncing a definite judgment of his own, but confines himself to friendly suggestions with a view of removing obstacles to an agreement between the parties. On the other hand, it is not easy to define how far the "outside party" must be independent of the parties to the dispute, in order that the method of settlement may be properly described as "conciliation." There is a sense in which a friendly conversation between an employer or his manager and a deputation of aggrieved workmen is rightly described as "conciliation," but such an interview would certainly not be covered by the term as ordinarily used at the present day. Again, when the parties are represented by agents (*e.g.*, the officials of an employers' association and of a trade union) the actual negotiators or some of them may not personally be affected by the particular dispute, and may often exercise some of the functions of the mediator or conciliator in a manner not clearly to be distinguished from the action of an outside party. It seems best, however, to exclude such negotiations from our purview so long as those between whom they are carried on merely act as the authorized agents for the parties affected. In the same way a meeting arranged *ad hoc* between delegates of an employers' association and a trade union, for the purpose of arranging differences as to the terms on which the members of the association shall employ members of the union, is not usually classed as "conciliation," unless the meeting is held in the presence of an independent chairman or conciliator, or in pursuance of a permanent agreement between the associations laying down the procedure for the settlement of disputes. If, however, the dispute is considered and arranged not by a casual meeting between two committees and deputations appointed *ad hoc*, but by a permanently organized "joint committee" or board with a constitution, rules of procedure, and officers of its own, the process of settlement is by ordinary usage described as "conciliation," even though the board be entirely representative of the persons engaged in the industry. Such joint boards, as will be seen, play a most important part in conciliation at the present day, and they almost always have attached to them some machinery for the ultimate decision by arbitration of questions on which they fail to agree. Another form of conciliation is that in which the mediating board represents a wider group of industries than those affected by the dispute (*e.g.*, the London and other "district" boards referred to below). Moreover, in some of the most important cases of settlement of disputes by conciliation, the mediating party has not been a permanent board but a disinterested individual, *e.g.*, the mayor, county court judge, government official, or member of parliament. As will be seen below, the Conciliation Act now provides for the appointment of "conciliators" by the Board of Trade.

Voluntary trade boards, however (*i.e.*, permanent joint boards representing employers and work-people in particular trades), are at once the most firmly established and the most important agencies in Great Britain for the prevention and settlement of labour disputes. Among the earliest of such bodies was the board of arbitration in the Macclesfield silk trade, formed in 1849, in imitation of the French "*Conseils des Prud'hommes*," but which only lasted four years. The first board, however, which attained any

¹ The House of Lords decided, in the Taff Vale Railway case (1901), that trade unions may be sued *in tort*, but the decision does not refer to their status as regards contracts.

degree of permanent success was that established for the hosiery and glove trade in Nottingham in 1860, through the efforts of Mr Mundella. In 1864 a board was established in the Wolverhampton building trades, with Mr (afterwards Sir) Rupert Kettle as chairman, and in 1868 boards were formed for the pottery trade, the Leicester hosiery trade, and the Nottingham lace trade. Of the above boards only the last-named is still actively in existence, though a joint committee still exists for settling minor questions in the pottery trade. In 1869, however, there was formed one of the most important of the still existing boards, viz., the board of arbitration and conciliation in the manufactured iron and steel trades of the north of England, with which the names of Rupert Kettle, David Dale, and others are associated. In 1872 joint committees were formed in the Durham and Northumberland coal trades to deal with local questions. The Leicester boot and shoe trade board, the first of an elaborate system of local boards in this trade, was founded in 1875. From about 1870 onwards there was a great movement for the establishment of "sliding scales" in the coal and iron and steel trades, which by regulating wages automatically rendered unnecessary the settlement of general wages by conciliation or arbitration. These sliding scales, however, usually had attached to them joint committees for dealing with disputed questions. A sliding scale arranged by Mr (since Sir) David Dale was attached to the manufactured iron trade board in 1871. A sliding scale for the Cleveland blast furnacemen came into force in 1879. Sliding scales were also adopted in the coal trade in many districts, e.g., South Wales (1875), Durham (1877), and Northumberland (1879). The movement was, however, followed by a reaction, and several of the sliding scales in the coal trade were terminated between 1887 and 1889.

The formation on a large scale of conciliation boards in the coal trade to fix the rate of wages dates from the great miners' dispute of 1893, one of the terms of settlement agreed to at the conference held at the Foreign Office under Lord Rosebery being the formation of a conciliation board covering the districts affected. Northumberland followed in 1894, Durham in 1895, Scotland in 1900.

The first general district board to be formed was that established in London in 1890, through the London Chamber of Commerce, as a sequel to the Mansion House committee which mediated in the great London dock strike of 1889. The example has been followed by several large towns, but the action taken by the boards in some of these provincial districts has been very limited.

The most typical form of machinery for the settlement of disputes by voluntary conciliation is a joint board consisting of equal numbers of representatives of employers and employed. The members of the board are usually elected by the associations of employers and workmen, though in some cases (e.g., in the manufactured iron trade board) the workmen's representatives are elected not by their trade union but by meetings of workmen

employed at the various works. The chairman may be an independent person, or, more usually, a representative of the employers, the vice-chairman being a representative of the workmen. In the arbitration and conciliation boards in the boot and shoe trade, provision is made by which the chair may be occupied by representatives of the employers and workmen in alternate years. An independent chairman usually has a casting vote, which practically makes him an umpire in case of equal voting, but where there is no outside chairman there is usually provision for reference of cases on which the board cannot agree to an umpire, who may either be a permanent officer of the board elected for a period of time (as in the

case of several of the boards in the boot and shoe trade), or selected *ad hoc* by the board or appointed by some outside person or body. Thus the choice of the permanent chairman or umpire of the miners' conciliation board, formed in pursuance of the settlement of the coal dispute of 1893 by Lord Rosebery, was left to the Speaker of the House of Commons. Since the passing of the Conciliation Act, several conciliation boards have provided in their rules for the appointment of umpires by the Board of Trade.

Conciliation boards constituted as described above usually have rules providing that there shall always be equality of voting as between employer and workmen, in spite of the casual absence of individuals on one side or the other. In order to expedite business it is sometimes provided that all questions shall be first considered by a sub-committee, with power to settle them by agreement before coming before the full board. Boards of conciliation and arbitration conforming more or less to the above type exist in the coal, iron and steel, boot and shoe, and other industries in the United Kingdom. A somewhat different form of organization has prevailed in the cotton-spinning trade (since the dispute of 1892-93) and in the engineering trade (since the engineering dispute of 1897-98). In these important industries there are no permanent boards for the settlement of general questions, but elaborate agreements are in force between the employers' and workmen's organizations, which among other things prescribe the mode in which questions at issue shall be dealt with and if possible settled. In the first place, if the question cannot be settled between the employer and his workmen, it is dealt with by the local associations or committees or their officials, and failing a settlement in this manner, is referred to a joint meeting of the executive committees of the two associations. In neither agreement is there any provision for the ultimate decision of unsettled questions by arbitration. The agreement in the cotton trade is known as the "Brooklands Agreement," and a large number of questions have been amicably settled under its provisions. In the building trade, in which (with the exception of the plumbers' board) there are at present no national arrangements for conciliation and arbitration, it is very customary for the local "working rules," agreed to mutually by employers and employed in particular districts, to contain "conciliation rules" providing for the reference of disputed questions to a joint committee with or without an ultimate reference to arbitration. Yet another form of voluntary board is the "district board," consisting in most cases of representatives elected in equal numbers by the local chamber of commerce and trades council respectively. In the case, however, of the London Conciliation Board the workmen's representatives are elected, twelve by specially summoned meetings of trade union delegates and two by co-optation. The functions of district boards are to deal with disputes in any trade which may occur within their districts, and of course they can only take action with the consent of both parties to the dispute, in this respect differing from the majority of "trade" boards, which, as a rule, are empowered by the agreement under which they are constituted to deal with questions on the application of either party. Another interesting type of board is that representing two or more groups of workmen and sometimes their employers, with the object of settling "demarcation" disputes between the groups of workmen (i.e., questions as to the limits of the work which each group may claim to perform). Examples of such boards are those representing shipwrights and joiners on the Clyde, Tyne, and elsewhere. While the arrangements for voluntary conciliation and arbitration differ in this way in various industries, there is an equally wide variation

552 ARBITRATION AND CONCILIATION IN LABOUR

in the character and range of questions which the boards are empowered to determine. For example, some boards in the coal trade (*e.g.*, the conciliation boards in Northumberland and the so-called "Federated Districts") deal solely with the general rate of wages. Others, *e.g.*, the "joint committee" in Northumberland and Durham, confine their attention solely to local questions not affecting the counties as a whole. The Durham conciliation board deals with any general or county questions. This distinction between "general" and "local" questions corresponds nearly, though not entirely, to the distinction often drawn between questions of the terms of future employment and of the interpretation of existing agreements. Some conciliation boards are unlimited as regards the scope of the questions which they may consider. This was formerly the case with the boards in the boot and shoe trade, but under the "terms of settlement" of the dispute in 1895 drawn up at the Board of Trade, certain classes of questions (*e.g.*, the employment of particular individuals, the adoption of piece-work or time-work, &c.) were wholly or partially withdrawn from their consideration, and any decision of a board contravening the "terms of settlement" is null and void. A special feature in the procedure for conciliation and arbitration in the boot and shoe trade, is the deposit by each party of £1000 with trustees, as a financial guarantee for the performance of agreements and awards. A certain class of conciliation boards, mostly in the Midland metal trades, were attached to "alliances" of employers and employed, having for their object the regulation of production and of prices (*e.g.*, the Bedstead Trade Wages Board). Some of these alliances, however, have been dissolved.

At all events up to the year 1896, the development of arbitration and conciliation as methods of settling labour disputes in the United Kingdom was entirely independent of any legislation. Previously to the Conciliation Act of 1896 (described below) several attempts had been made by parliament to promote arbitration and conciliation, but with little or no practical result, and the Act of 1896 repealed all previous legislation on the subject, at the same time excluding the operation of the Arbitration Act of 1889 from the settlement of "any difference or dispute to which this Act applies." The laws repealed by the Conciliation Act need only a few words of mention. During the 18th century the fixing of wages by magistrates under the Elizabethan legislation gradually decayed, and the Acts 20 Geo. II. c. 19 and 31 Geo. II. c. 11, gave summary jurisdiction to justices of the peace to determine disputes between masters and servants in certain circumstances, although no rate of wages had been fixed that year by the justices of the peace of the shire. These and other laws, relating specially to disputes in the cotton-weaving trade, were consolidated and amended by the Arbitration Act of 1824. This Act seems chiefly to have been aimed at disputes relating to piece-work in the textile trades, though applicable to other disputes arising out of a wages contract. It expressly excluded, however, the fixing of a rate of wages or price of labour or workmanship at which the workmen should in future be paid unless with the mutual consent of both master and workmen. The Act gave compulsory powers of settling the disputes to which it relates on application of either party to a court of arbitrators representing employers and workmen nominated by a magistrate. The award could be enforced by distress or imprisonment. The Act was subsequently amended in detail, and by the "Councils of Conciliation Act" of 1867 power was given to the Home Secretary to license "equitable councils of conciliation and arbitration" equally representative of masters and work-

men, who should thereupon have the powers conferred by the Act of 1824. The Act contains provisions for the appointment of conciliation committees, and other details which are of little interest seeing that the Act was never put into operation. Another amendment of the Act of 1824 was made by the Arbitration (Masters and Workmen) Act of 1872, which contemplated the conclusion of agreements between employers and employed, designating some board of arbitration by which disputes included within the scope of the former Acts should be determined. A master or workman should be deemed to be bound by an agreement under the Act, if he accepted a printed copy of the agreement and did not repudiate it within forty-eight hours. Like the previous legislation, however, the Act of 1872 was inoperative. The evidence given before the Royal Commission on Labour (1891-94) disclosed the existence of a considerable body of opinion in favour of some further action by the state for the prevention or settlement of labour disputes, and some impetus was given to the movement by the settlement through official mediation of several important disputes, *e.g.*, the great coal-miners' dispute of 1893 by a conference presided over by Lord Rosebery, the cab-drivers' dispute of 1894 by the mediation of the Home Secretary (Mr Asquith), and the boot and shoe trade dispute of 1895 by a Board of Trade conference under the chairmanship of Sir Courtenay Boyle. In these, and a few other less important cases, the intervention of the Board of Trade or other department took place without any special statutory sanction. The Conciliation Act passed in 1896 was framed with a view to giving express authorization to such action in the future.

This Act is of a purely voluntary character. Its most important provisions are those of section 2, empowering the Board of Trade in cases "where a difference exists or is apprehended between any employer, or any class of employers, and workmen, or between different classes of workmen," to take certain steps to promote a settlement of the difference. They may of their own initiative hold an inquiry or endeavour to arrange a meeting between the parties under a chairman mutually agreed on or appointed from the outside, and on the application of either party they may appoint a conciliator or a board of conciliation who shall communicate with the parties and endeavour to bring about a settlement and report their proceedings to the Board of Trade. On the application of both parties the Board of Trade may appoint an arbitrator. In all cases the Board of Trade has discretion as to the action to be taken, and there is no provision either for compelling the parties to accept their mediation or to abide by any agreement effected through their intervention. There are other provisions in the Act providing for the registration of voluntary conciliation boards, and for the promotion by the Board of Trade of the formation of such boards in districts and trades in which they are deficient. During the first five years after the passage of the Act (*i.e.*, up to the middle of 1901) the number of cases arising under section 2 (providing for action by the Board of Trade for the settlement of actual or apprehended disputes) was 113, and the number of settlements effected 70. Of the 43 disputes not settled under the Act, 10 were settled between the parties during the negotiations, and in 33 cases the applications were refused by the Board of Trade, or their efforts to effect a settlement were unsuccessful. Of the 70 settlements, 32 were effected by conciliation and 38 by arbitration. At present, however, the number of cases of arbitration under the Act appears to be increasing compared with those of conciliation, and several voluntary conciliation boards formed or reorganized since the passage of the Act provide in their rules for an

appeal to the Board of Trade to appoint an umpire in case of a deadlock. Eighteen boards are known to have already adopted this course. The figures given above show that the Conciliation Act of 1896 has by no means, like previous legislation, been a dead letter, though the number of actual disputes settled is naturally small compared with the total number annually recorded. In spite of the complete discretion given to the Board of Trade as regards the offer of its services and to the parties as regards acceptance of its intervention, experience in the great engineering dispute of 1897 and the South Wales coal dispute of 1898, appears to show that public opinion may put pressure on the Board to attempt mediation in a dispute which has attracted popular attention, whatever may be the attitude of the parties directly concerned; and there has been a tendency in some cases to make the action or inaction of the Department a subject of parliamentary debate. Under these conditions intervention must sometimes lead to disappointment, and the danger must also be borne in mind that the expectation of official intervention may occasionally lead the losing side to prolong a hopeless dispute. If, however, direct official mediation in labour disputes is attended with difficulties, these do not apply to the appointment by the Board of Trade of umpires and arbitrators, on an application by both parties or by a voluntary conciliation board.

Arbitration and conciliation in labour disputes as practised in the United Kingdom are entirely voluntary, both as regards the initiation and conduct of the negotiations and the carrying out of the agreement resulting therefrom. In all these respects arbitration, though terminating in what is called

Proposals for compulsion.

a binding award, is on precisely the same legal footing as conciliation, which results in a mutual agreement. Various proposals have been made (and in some cases carried into effect in certain countries) for introducing an element of compulsion into this class of proceeding. There are three stages at which compulsion may conceivably be introduced. (1) The parties may be compelled by law to submit their dispute to some tribunal or board of conciliation; (2) the board of conciliation or arbitration may have power to compel the attendance of witnesses and the production of documents; (3) the parties may be compelled to observe the award of the board of arbitration. The most far-reaching scheme of compulsory arbitration in force in any country is that embodied in the New Zealand Industrial Conciliation and Arbitration Act of 1894. Bills have been introduced into the British House of Commons for clothing voluntary boards of conciliation and arbitration, under certain conditions, with powers to require attendance of witnesses and production of documents, without, however, compelling the parties to submit their disputes to these boards or to abide by their decisions. In the United Kingdom, however, more attention has recently been given to the question of strengthening the sanction for the carrying out of awards and agreements than of compelling the parties to enter into such arrangements. An interesting step towards the solution of the difficulty of enforcement in certain cases is perhaps afforded by the provisions of the terms of settlement of the dispute in the boot and shoe trade drawn up at the Board of Trade in 1895. Under this agreement £1000 was deposited by each party with trustees, who were directed by the trust-deed to pay over to either party, out of the money deposited by the other, any sum which might be awarded as damages by the umpire named in the deed, for the breach of the agreement or of any award made by an arbitration board in consonance with it. Up to the present only one claim for damages has been sustained under this agreement, the amount of the damages given against the union being £300. Nevertheless it cannot be doubted that the

pecuniary liability of the parties has given stability to the work of the local arbitration boards, and the satisfaction of both sides with the arrangement is shown by the fact that the trust-deed, which lapsed in March 1900, was renewed for a further period of two years. Theoretically a trust deed of this kind can only offer a guarantee up to the point at which the original deposit on one side or the other is exhausted, as it is impossible to compel either party to renew the deposit. A proposal was made by the Duke of Devonshire and certain of his colleagues on the Royal Commission on Labour for empowering associations of employers and employed to acquire, if they desired it, sufficient legal personality and corporate character to enable them to sue each other or their own members for breach of agreement. This would give the association aggrieved by a breach of award the power of suing the defaulting organization to recover damages out of their corporate funds, while each association could exact penalties from its members for such a breach. For this reason the suggestion has met with a good deal of support by those interested in arbitration and conciliation.

Apert, however, from any suspicions entertained of it by workmen's associations, the question is not free from difficulties. The object of the change would be to convert what are at present only morally binding understandings into legally enforceable contracts. But apart from the possibility that some of such contracts would be held by the courts to be void as being "in restraint of trade," the tendency might be to give a strict legal interpretation to working agreements which might deprive them of some of their effectiveness for the settlement of the conditions of future contracts between employers and workmen, while possibly deterring associations from entering into such agreements for fear of litigation. Individuals, moreover, could avoid liability by leaving their associations. Many persons are therefore of opinion that the present imperfect sanction for agreements and awards must be accepted as the lesser of two evils. In countries like New Zealand, where the parties are compelled to submit their differences to arbitration, some of the above objections do not apply.

The following statistics are based on the reports of the Labour Department of the Board of Trade on Strikes and Lock-outs. The number of boards of conciliation and arbitration known to have settled disputes in 1899 was 53, of which 50 come under the head of "trade," 2 of "district," and 1 of "general" boards. So far as known about 139 boards are in existence, but several of these did no active work in 1899. Of the 50 trade boards, 11 are connected with the boot and shoe trade, 9 with engineering and shipbuilding, 7 with coal-mining, 13 with iron and steel and other metal trades, 7 with the building trades, and the others with various miscellaneous industries. The importance of the questions dealt with by these boards differs so very greatly—ranging from the classification of a sample to an alteration of wages affecting hundreds of thousands of men—that the statistics of the number of cases settled tend to be somewhat misleading. Nevertheless the following figures may be of some interest. Altogether, 1232 cases were considered by the boards in 1899, of which 506 were withdrawn or settled independently of the boards, and 51 were still unsettled at the end of the year. The remaining 675 cases were settled, 503 by the board or committees and 172 by arbitrators or umpires. The great majority of the cases settled were purely local questions. Thus 350 cases—or more than half the total—were dealt with by the "joint committees" in the Northumberland and Durham coal trades, which confine their action to local questions, such

Statistics of existing agencies.

as fixing the "hewing prices" for new seams. Of the remaining 325 cases, 125 are accounted for by the boot and shoe trade. Here again a large majority of the cases were questions of classifying sample boots, shoes, or materials, *i.e.*, of determining under what heading of the existing piece-work lists a new pattern of boot or a new quality of material ought properly to be classified. During the year, however, several more general questions, *e.g.*, rates of a minimum wage and overtime payment, affecting considerable bodies of men, were determined by the boot and shoe trade boards or their umpires. Thirty-nine cases were settled by a board for the tailoring trade in Aberdeen—all of minor importance. The iron and steel trades account for 30 cases, and engineering and shipbuilding for 81. Among the latter are included a considerable number of "demarcation disputes," *i.e.*, disputes between two bodies of workmen as to the limits of the work to be performed by each. Four joint boards representing shipwrights and joiners on the Tyne, Tees, and Clyde respectively, settled 57 such cases in 1899, of which only 4 were relegated to umpires. The great majority of the above cases did not actually involve stoppage of work, the most useful work of these permanent boards being the prevention rather than the settlement of strikes and lock-outs. During 1899 only 10 strikes were settled by permanent boards—in 1898 the number being 19, and in 1897, 12. In none of these years were any of these strikes of great importance. A certain number of disputes are settled every year by the mediation or arbitration of disinterested individuals, *e.g.*, the local mayor or county court judge. The number of strikes so settled in 1899 was 26, and in the previous year 16.

The operations under the Conciliation Act have been separately described above. Altogether, if the work of all agencies for conciliation and arbitration be included, the number of strikes and lock-outs settled by these means in 1899 was 38. During the five years 1894-99 the annual number of strikes so settled varied between 38 and 45. The number of work-people affected by these disputes in 1899 was 11,705, or about 6 per cent. of the persons involved in all the 719 disputes recorded in that year. It is clear from the above figures that the most important and most hopeful part of the work of agencies for conciliation and arbitration is the adjustment of differences that might otherwise lead to stoppage, rather than the settlement of actual strikes.

The extent to which the methods of arbitration and conciliation can be expected to afford a substitute for strikes and lock-outs is one on which opinions differ very widely. The difficulties arising from the impossibility of enforcing agreements or awards by legal process have already been discussed. Apart from these, however, it is evident that both methods imply that the parties, especially the work-people, are organized at least to the extent of being capable of negotiating through agents. In some industries (*e.g.*, agriculture or domestic service) this preliminary condition is not satisfied; in others the men's leaders possess little more than consultative powers, and employers may hesitate to deal either directly or through a third party with individuals or committees who have so little authority over those whom they claim to represent. And even where the trade organizations are strong, some employers object in any way to recognize the representative character of the men's officials. Recent cases of this kind that attracted attention were Lord Penrhyn's refusal to recognize the Quarrymen's Union or the quarry committee as representing his quarrymen, and the refusal of several important railway companies to deal with the Amalgamated Society of Railway Servants. The question of the "recognition"

of trade unions by employers is a frequent cause of disputes and is further referred to in the article on STRIKES AND LOCK-OUTS. It may be observed, however, that it frequently occurs that in cases in which both employers and employed are organized into associations which are accustomed to deal with each other, one or both parties entertain a strong objection to the intervention of any outside mediator, or to the submission of differences to an arbitrator. Thus the engineering employers in 1897 were opposed to any outside intervention, though ready to negotiate with the delegates chosen by the men. On the other hand, the cotton operatives have more than once opposed the proposal of the employers to refer the rate of wages to arbitration, and throughout the great miners' dispute of 1893 the opposition to arbitration came from the men. Naturally, the party whose organization is the stronger is usually the less inclined to admit outside intervention. But there have been several recent cases in which employers, who refused to deal directly with trade union officials, have been willing to negotiate with a mediator who was well known to be in communication with these officials (*e.g.*, in some of the recent railway disputes).

Apart, however, from the disinclination of one or both parties to allow of any outside intervention, we have to consider how far the nature of the questions in dispute may in any particular case put limits to the applicability of conciliation or arbitration as a method of settlement. Since conciliation is only a general term for the action of a third party in overcoming the obstacles to the conclusion of an agreement by the parties themselves, there is no class of questions which admit of settlement by direct negotiation which may not equally be settled by this method, provided of course that there is an adequate supply of sufficiently skilful mediators. As regards arbitration the case is somewhat different, seeing that in this case the parties agree to be bound by the award of a third party. For the success of arbitration, therefore, it is important that the general principles which should govern the settlement of the particular question at issue should be admitted by both sides. Thus in the manufactured iron trade in the north of England, it has throughout been understood that wages should depend on the prices realized, and the only question which an arbitrator has usually had to decide has been how far the state of prices at the time warranted a particular change of wage. On the other hand, there are many questions on which disputes arise (*e.g.*, the employment of non-union labour, the restriction of piece-work, &c.) on which there is frequently no common agreement as to principles, and an arbitrator may be at a loss to know what considerations he is to take into account in determining his award. Generally speaking, employers are averse from submitting to a third party questions involving discipline and the management of their business, while in some trades workmen have shown themselves opposed to allowing an arbitrator to reduce wages beyond a certain point which they wish to regard as a guaranteed "minimum."

Another objection on the part of some employers and workmen to unrestricted arbitration is its alleged tendency to multiply disputes by providing an easy way of solving them without recourse to strikes or lock-outs, and so diminishing the sense of responsibility in the party advancing the claims. It is also sometimes contended that arbitrators, not being governed in their decisions by a definite code of principles, may tend to "split the difference," so as to satisfy both sides even when the demands on one side or the other are wholly unwarranted. This, it is said, encourages the formulation of demands purposely put high in order to admit of being cut down by an arbitrator. One of the chief practical difficulties in the way of

**Future
scope and
limits.**

the successful working of permanent boards of conciliation, consisting of equal numbers of employers and employed, with an umpire in case of deadlock, is the difficulty of inducing business men whose time is fully occupied to devote the necessary time to the work of the boards, especially when either side has it in its power to compel recourse to the umpire, and so render the work of the conciliation board fruitless. In spite of all these difficulties the practice of arranging differences by conciliation and arbitration is undoubtedly spreading, and it is to be remembered that even in cases in which theoretically a basis for arbitration can scarcely be said to exist, recourse to that method may often serve a useful purpose in putting an end to a deadlock of which both parties are tired, though neither cares to own itself beaten.

Reference must now be made to some of the *Colonial and foreign* principal laws relating to arbitration and conciliation outside the United Kingdom.

New Zealand.—The New Zealand Industrial Conciliation and Arbitration Act, 1894 (amended in detail by several subsequent Acts), provides for the incorporation of associations of employers or workmen under the title of industrial unions, and for the creation in each district of a joint conciliation board, elected by these industrial unions, with an impartial chairman elected by the board, to which a dispute may be referred by any party, a strike or lock-out being thenceforth illegal. If the recommendation of the conciliation board is not accepted by either party, the matter goes to a court of arbitration consisting of two persons representing employers and workmen respectively, and a judge of the supreme court. The award of this court is enforceable by legal process, financial penalties up to £500 being recoverable from defaulting associations or individuals. If the property of an association is insufficient to pay the penalty, its members are individually liable up to £10 each. During the year 1899-1900 thirty-four cases were considered by the conciliation boards, and twenty were sent to the arbitration court. In addition, nine cases of breach of award or agreement were dealt with.

The above is only an outline of the principal provisions of this interesting Act, under which questions of wages, hours, and the relations of employers and workmen generally in New Zealand are now practically the subject of state regulation. Whatever may be the result of the Act when its indirect effects have had time to develop, it is clear that it goes far beyond the mere settlement of strikes, and is more properly to be judged as a measure for the state regulation of industry.

*New South Wales.*¹—In New South Wales a "Conciliation and Arbitration Act" was passed in 1899, resembling the United Kingdom Act in the general character of its provisions, except that an arbitrator or investigator appointed by Government is invested with compulsory powers of summoning witnesses, entering premises, and examining on oath.

Canada.—In 1900 a Conciliation Act was passed by the Dominion Parliament resembling the United Kingdom Act in most of its features.

France.—The French Conciliation and Arbitration Law of December 1892 provides that either party to a labour dispute may apply to the *juge de paix* of the canton, who informs the other party of the application. If they concur within three days, a joint committee of conciliation is formed of not more than five representatives of each party, which meets in the presence of the *juge de paix*, who, however, has no vote. If no agreement results the parties are invited to appoint arbitrators. If such arbitrators

are appointed and cannot agree on an umpire, the president of the civil tribunal appoints an umpire. In the case of an actual strike, in the absence of an application from either party it is the duty of the *juge de paix* to invite the parties to proceed to conciliation or arbitration. The results of the action of the *juge de paix* and of the conciliation committee are placarded by the mayors of the communes affected. The law leaves the parties entirely free to accept or reject the services of the *juge de paix*. During the seven years 1893-99 the Act was put in force in 778 cases—viz., 425 on application of workmen, 23 of employers, 18 of both sides, and 312 without application. Altogether, 204 disputes were settled—88 per cent. by conciliation and 12 per cent. by arbitration.

Germany.—In several Continental countries, courts or boards are established by law to settle cases arising out of existing labour contracts—e.g., the French "*Conseils des Prud'hommes*," the Italian "*Probi Viri*," and the German "*Gewerbegerichten*,"—and some of the questions which come before these bodies are such as might be dealt with in England by voluntary boards or joint committees. The majority, however, are disputes between individuals as to wages due, &c., which would be determined in the United Kingdom by a court of summary jurisdiction. It is noteworthy, however, that the German industrial courts (*Gewerbegerichten*) are empowered under certain conditions to offer their services to mediate between the parties to an ordinary labour dispute. In the case of a strike or lock-out the court must intervene on application of both parties, and may do so of its own initiative or on the invitation of one side. Failing a settlement at a conference between the parties in the presence of the president and assessors of the court, the court arrives at a decision on the merits of the dispute which is communicated to the parties, who are allowed a certain time within which to notify their acceptance or rejection. The court has no power to compel the attendance of the parties or the observance of its decision. During 1896 there were 44 applications for the intervention of the Industrial Courts. Eighteen agreements were brought about and 11 decisions were pronounced by the courts, of which 2 were accepted by both parties and 9 were rejected. In 8 cases the courts made unsuccessful attempts to promote settlements without pronouncing decisions. The above figures are taken from a statement prepared for the Reichstag commission for considering petitions (1897-98).

Switzerland.—The canton of Geneva enacted a law in 1900 providing for the settlement by negotiation, conciliation, or arbitration of the general terms of employment in a trade, subject, however, to special arrangements between employers and workmen in particular cases. The negotiations are to take place between delegates chosen by the associations of employers and employed, or failing them, by meetings summoned by the Council of State on sufficient applications. Failing settlement, the Council of State, on application from either party, is to appoint one or more conciliators from its members, and if this fail the central committee of the "*Prud'hommes*," together with the delegates of employers and workmen, is to form a board of arbitration, whose decision is binding. Any collective suspension of work is illegal during the period covered by the award or agreement.

United States.—In the United States several States have legislated on the subject of conciliation and arbitration, among the first of such Acts being the "Wallace" Act of 1883, in Pennsylvania, which, however, was almost inoperative. Altogether, 24 States have made constitutional or statutory provision for mediation in trade disputes, of which 17 contemplate the formation of permanent State boards. The only State laws which require notice are

¹ Since this article was written a compulsory Arbitration Law has been passed in New South Wales (December 1901).

those of Massachusetts and New York providing for the formation of State boards of arbitration. The Massachusetts board, founded in 1886, consists of one employer, one employed, and one independent person chosen by both. The New York board (1886) consists of two representatives of different political parties, and one member of a *bona-fide* trade organization within the State. In both States it is the duty of the board, with or without application from the parties, to proceed to the spot where a labour dispute has occurred, and to endeavour to promote a settlement. The parties may decline its services, but the board is empowered to issue a report, and on application from either side to hold an inquiry and publish its decision, which (in Massachusetts) is binding for six months, unless sixty days' notice to the contrary is given by one side to the other. Several States (including Massachusetts and New York) provide not only for State boards, but also for local boards.

In Massachusetts, during 1899, the State board had its attention directed to 25 disputes (several, as in previous years, being in the boot and shoe trade). Of these it settled 1 by arbitration, and in 6 others promoted a settlement by conciliation. The remaining cases were settled independently of the Board, or were unsettled when the Report was issued.

Federal legislation can only touch the question of arbi-

tration and conciliation so far as regards disputes affecting commerce between different States. Thus an Act of June 1898 provides that in a dispute involving serious interruption of business on railways engaged in inter-State commerce, the Chairman of the inter-State Commerce Commission and the Commissioner of Labour shall, on application of either party, endeavour to effect a settlement or to induce the parties to submit the dispute to arbitration. While an arbitration under the Act is pending a strike or lock-out is unlawful.

AUTHORITIES.—For the recent development of arbitration and conciliation in the United Kingdom, see the *Annual Reports of the Labour Department of the Board of Trade on Strikes and Lock-outs* from 1888 onwards. Since 1890 these reports have contained special appendices on the work of arbitration boards. See also the *Labour Gazette* (the monthly journal of the Labour Department) from 1893 onward. The *Reports of the Royal Commission on Labour* (1891-94) contain much valuable information on the subject. For the working of the Conciliation Act see the Reports of the Board of Trade on their proceedings under the Conciliation Act, 1896. For the earlier history in the United Kingdom—CROMPTON, *Industrial Conciliation* (1876); PRICE, *Industrial Peace* (1887). For foreign and colonial developments—the Report of the French *Office du Travail, De la Conciliation et de l'Arbitrage dans les Conflits Collectifs entre Patrons et Ouvriers en France et à l'Étranger* (1893); the Annual Reports of the same Department on *Strikes, Lock-outs, and Arbitration*; the *Reports of the Massachusetts and New York State Arbitration Boards*, and of the *New Zealand Department of Labour*; and the *Labour Gazette*.

ARBITRATION, INTERNATIONAL.

INTERNATIONAL arbitration is a proceeding in which two nations refer their differences to one or more selected persons, who, after affording to each party an opportunity of being heard, pronounce judgment on the matters at issue. It is understood, unless otherwise expressed, that the judgment shall be in accordance with the law by which civilized nations have agreed to be bound whenever such law is applicable. An international arbitrator may be the chief of a friendly power, or he may be a private individual. When he is an emperor, a king, or a president of a republic, it is not expected that he will act personally; he may by tacit consent appoint a delegate or delegates to act on his behalf, and avail himself of their labours and views, the ultimate decision being his only in name. In this respect international arbitration differs from civil arbitration, since a private arbitrator cannot delegate his office without express authority. The analogy between the two fails to hold good in another respect also. In civil arbitration the decision or award may be made a rule of court, after which it becomes enforceable by writ of execution against person or property. An international award cannot be enforced directly; in other words, it has no legal sanction behind it. Its obligation rests on the good faith of the parties to the reference, and on the fact that public opinion can, with the help of a world-wide press, always be brought to bear on any state that may seek to evade its moral duty. The obligation of an ordinary treaty rests on precisely the same foundations. True it is that an international award may be disregarded for excess of jurisdiction, ambiguity of language, or corrupt conduct on the part of the arbitrator. But each of these flaws would be equally fatal to a private award. We have said that it is the duty of an international arbitrator to decide in accordance with international law. The eminent jurist, M. Bluntschli, considers that if he does not the award may be set aside. To admit this doctrine would, however, lead to endless disputes, since international law has never been codified. A fresh arbitration might have to be entered on in order to decide, first, what the law was,

and, secondly, whether it applied to the matter in hand. As a matter of fact, there is but a single instance on record of an award being repudiated, viz., that of the king of Holland in 1831 with regard to the north-eastern boundary of the State of Maine. That case was, however, a very peculiar one. The arbitrator was unable to draw the frontier line by reason of the imperfection of the maps then extant, and his direction for a further topographical inquiry was beyond the terms of the reference. The award was, therefore, void for excess just as a private award would have been.

An account of this subject divides itself naturally into four parts: a brief sketch of past history; an examination of a few selected instances in which international arbitration has been successfully resorted to; an account of the various treaties and projects for securing its future employment; and a short discussion of the limits outside which it appears to be inapplicable.

In the sense in which the term is now used, international arbitration is essentially a modern product, since the very existence of international relations is modern. The nearest approach to it before the Christian era was intermunicipal arbitration, as practised in ancient Greece. **History.** For example, the Amphictyonic Councils occasionally acted as arbitrators between one town and another; in this way a dispute was settled between Athens and Delos with regard to a right of precedence in the temple of Apollo in 344 B.C. The ancient Greek towns also sometimes referred their differences to a third town, or even to private individuals. Thus Sparta arbitrated between Athens and Megara with regard to the possession of Salamis; Periander between Athens and Mitylene with regard to the promontory of Sigeum; and Themistocles between Corinth and Corcyra with regard to the island or (as it formerly was) the peninsula of Leucadia. At the period of the Peloponnesian war, the practice of arbitration had become so well recognized that Thucydides (i. 85) puts into the mouth of Archidamus, king of Sparta, the words, "It is impossible to attack as a wrong-doer any one who is willing to answer before an arbitral tribunal." But in all these cases the arbitration was between two Hellenic communities. It would have been no more possible for a Greek to arbitrate with a "barbarian" than to sacrifice at the same altar with him.

The exclusiveness which checked the development of arbitration in Greece told against it with tenfold force in Rome.

Republican Rome dealt with non-Romans as modern European governments have dealt with inferior native races. When in 445 B.C. the Republic was chosen to arbitrate between the towns of Ardea and Aricia, she settled the question by taking the disputed land for herself. The same thing occurred in 180 B.C., when a territorial difference between Neapolis and Nola was referred to the Roman Senate. Under the Cæsars, frequent recourse was had to civil or private arbitration, the procedure of which was perfected by the best intellects of the day, but any other kind was from the nature of things impossible. The vastness of the territory of Imperial Rome was such that she had practically nothing external to herself. She proudly claimed to be "the arbiter of the universe," so that the notion of her arbitrating with an outside power involved a contradiction in terms.

The Middle Ages may not inaptly be characterized as a period of perpetual conflict—between absolutism and democracy, between great feudal lord and rebellious vassal, between Guelf and Ghibelline, between Catholic and Protestant. Amid this clash of arms the Popes were not infrequently appealed to, and there are several instances of their having acted either in that character or as mediators. Witness the intervention of Innocent III. between King John and his barons; of Boniface VIII. between Edward I. and Philippe le Bel; of Leo X. between Maximilian and the doge of Venice. A similar rôle was filled by the mediæval sovereigns, notably by the kings of France. In 1603 a scheme for establishing a General Council was projected by Sully, the minister of Henry IV., to which the fifteen states, into which Europe was to be parcelled out, were to submit all their differences. Needless to say, the scheme came to nothing. In truth, its object was not so much to establish an arbitration tribunal as to disestablish and disendow the House of Austria—a result which was reached after the Thirty Years' War, when northern Protestant Germany was severed from the Catholic monarchy of the south. A century after the publication of Sully's "Grand Design," a more disinterested and more elaborate scheme was prepared by the Abbé St Pierre for settling all international disputes by means of a General League of Christendom. Rousseau says of it that it failed "because it was madness in its author to be wise when the majority of people were fools." However this may be, the seed sown by the good abbé, although it fell on barren ground, was not destined to perish. It produced a crop of other schemes later. Jeremy Bentham, in 1789, advocated the formation of a General Diet—or Congress—to which each of the powers should send two deputies, and he suggested making its decisions coercive by putting any refractory state under the ban of Europe. Immanuel Kant, in 1795, proposed to base all international right on a Federation of Free States, the civil constitution of each of which was to be made republican. Both Bentham and Kant were, indeed, as "voices crying in the wilderness," for Europe had no "ears to hear" after the war of the French Revolution had broken out and had deluged her in blood. Yet no sooner had that struggle ended than organized efforts on behalf of arbitration began to manifest themselves in various ways. The first of such efforts was made in 1816 by the Society of Friends in New York. In 1835 the American Peace Association presented a petition to the Senate of Massachusetts for establishing a "standing Court of Nations." Similar petitions were presented subsequently in Maine and Vermont. The subject was brought before the United States Senate in December 1837, and was referred to the Committee of Foreign Affairs, which reported it to be premature. In 1839 the same association presented a fresh petition for a similar purpose. This met with the same fate. In 1853 the United States Senate voted in favour of inserting arbitration clauses in treaties, "the arbitrators to be eminent jurists, having little or no connexion with politics." In 1849 Mr Richard Cobden advocated a similar proposition in the British House of Commons, and moved for an address to the crown praying that the Queen would instruct her Foreign Secretary to see that it was carried out. He maintained that a treaty for general arbitration would be as binding as any other, and that a country which did not fulfil its obligation to refer would enter on war "with the brand of infamy stamped upon its banners." The motion for an address, was opposed by Lord Palmerston, then first minister, who carried "the previous question" by a majority of 176 to 79. In 1873 Mr Henry Richard re-introduced the subject in a somewhat different form by urging an invitation to foreign powers to concur in a general and permanent system. In spite of much cold water thrown by Mr Gladstone, who had now become premier, Mr Richard obtained a majority of ten in his favour. The Representative Assembly at Westminster had thus, like the Senate at Washington, undergone a change of sentiment in the course of a single generation. Motions substantially similar to Cobden's were carried in the Italian Chamber in August 1873, in the Dutch Chamber in November 1874, in the Belgian Chamber in January 1875.

Almost contemporaneously with Mr Richard's success in Parlia-

ment, fresh impulse was given to the movement by bodies of public or learned men associated together, not for humanitarian purposes, but for the elucidation of international legal principles. The foremost of these was the Institute of International Law (*L'Institut de droit international*), which is composed of men of different nationalities, distinguished in that department of learning. Its first conference was held at Ghent on 18th September 1873, when a committee was appointed with special instructions to study the question. On this committee the United States were represented by Mr Dudley Field, Belgium by M. de Laveleye, Italy by Signor Pierantoni, Germany by Herr Goldschmidt, Great Britain by Sir William Vernon Harcourt (then Professor of International Law at Cambridge). In the same year there was founded in London an "Association for the Reform and Codification of the Law of Nations," which put international arbitration in the forefront of its programme. Its first meeting was held at Geneva in 1874. The name of this body was altered in 1895 to "The International Law Association." In 1888 a third association was formed under the style of "The Permanent Parliamentary Committee in favour of Arbitration and Peace," or, as it is sometimes called for shortness, "The International Parliamentary Union." This union has a permanent office at Berne. Its first meeting was held in Paris in June 1889, under the presidency of the late M. Jules Simon, and was attended by 129 members from England and the United States. In July 1890 the union met again in London under the presidency of the late Lord Herschell, and a committee was then formed to organize similar bodies on the Continent and in America. The meetings of the union continue to take place yearly.

The disputes which have been determined by international arbitration may be arranged in two main groups—A. Those which have arisen between state and state in their sovereign capacities; B. Those in which one state has made a demand upon another state, ostensibly in its sovereign capacity, but really on behalf of some individual or set of individuals whose interests it was bound to protect. To the former group belong territorial disputes, *e.g.*, questions of boundaries on land and of fisheries at sea; to the latter pecuniary claims in respect of acts alleged to have been wrongfully done to one or more subjects of one state by, or with the authority of, another state. Such acts comprise, amongst other things, (a) breaches of neutrality, by aiding and abetting a belligerent power or by permitting hostile operations to take place on neutral soil; (b) unlawful arrests and seizures. The remaining cases are of a miscellaneous character, and do not admit of separate classification.

(A.) "Territorial disputes," says Alexander Hamilton, the eminent American statesman, in the *Federalist*, "have at all times been found one of the most fertile sources of hostility among nations." "Perhaps," *San Juan*. he adds, "the greatest portion of the wars that have desolated the earth have sprung from this origin." This sentiment, true enough at the close of the 18th century, is fortunately no longer correct. The settlement of territorial disputes by arbitration has of late been the rule rather than the exception. We begin with one which was a serious disappointment to Great Britain, having been marred by a mistake in the form of the reference, but in which, notwithstanding, she loyally acquiesced. The treaty of Washington of 1846 provided that the north-western frontier of the United States near the parallel of 49° N. should run in a westerly direction along that parallel to the middle of the channel which separates the continent from Vancouver Island, and thence in a southerly direction through the middle of the same channel and of Fuca Strait to the Pacific Ocean. The dispute was as to the precise way in which this southern line was to be drawn. It was referred to the German emperor to decide whether the line should pass through Rosario Strait or through the Canal de Haro. The emperor appointed a geographer, a jurist, and a diplomat to study the subject and to report to him. This they did, and on the 21st October 1872 he made an award by which the channel of Haro was divided equally between the contending parties, the United States being declared entitled to exclusive

possession of all the other channels to the north of the Strait of Fuca, together with the island of San Juan and several small islets.

The facts of the territorial dispute between Great Britain and the Republic of Venezuela with regard to British Guiana—dating back to 1841 and not settled until 1899—are as follows:—

The British claimed title through the Dutch, the Venezuelans claimed title through Spain. The Dutch in the course of their war of independence had established settlements along the coast of Guiana, of which the most important was Kijkoveral, situated at the point where the Cuyuni, the Massaruni, and the Essequibo rivers unite. In 1648, by the treaty of Munster, they were confirmed in the possession of the territory which they then held. Subsequently they extended their posts along the coast as far as the mouth of the Amakuru, and inland along the courses of the three rivers above named. The British claimed that their rights extended to the whole Cuyuni basin, but the boundary actually insisted upon was a line, laid out by Sir Robert Schomburgk in 1840, and known as the Schomburgk line, which included the district of Barima and so much of the basin of the Cuyuni as lies to the west of the main stream. This claim was based upon Dutch occupation, actual or constructive, of territory previously unoccupied. The Venezuelans claimed the whole country as far as the Essequibo, that is to say, more than half of the colony of British Guiana, as shown on the latest maps. They alleged that the bull of Alexander VI. of 1493 had granted to Spain all territory that she might discover west of a line drawn 100 leagues west of the Azores, and that at the date of the bull the papacy was universally recognized as a competent international authority, particularly in matters affecting territory reclaimed from the heathen. They further alleged that the Spaniards had discovered Guiana, and had thus obtained, even without the bull, an inchoate title, which they had perfected by exploration and acts of sovereignty.

In 1860 it was arranged between the two Governments that neither should enter into or encroach upon the territory in dispute; but subsequently the Venezuelans disregarded this arrangement, and in 1883-84 made grants and concessions in the territory claimed by the British. In November 1886 the British Government issued a notice to the effect that these concessions were invalid; and in consequence of this notice, and of other differences concerning the proposed erection of a lighthouse upon Barima Point, the Venezuelan Government in 1887 broke off diplomatic relations. In 1890 they suggested arbitration, which Great Britain refused on the ground that, as regarded the territory comprised within the Schomburgk line, the British title was clear and there was nothing to arbitrate about. In July 1895 Mr Secretary Olney, on behalf of the United States, addressed a lengthy despatch to the British Government, urging that the refusal to arbitrate should be reconsidered, and intimating that any attempt to put hostile pressure upon Venezuela would be considered by his Government as an infringement of the Monroe doctrine. To this Lord Salisbury replied that Great Britain could not consent to go to arbitration in respect of territory actually settled and occupied by British subjects. On 17th December President Cleveland, in his message to Congress, announced that Great Britain having refused arbitration, he intended to appoint a commission which should report upon the respective rights of the parties, and he added: "When such report is made and accepted, it will, in my opinion, be the duty of the United States to resist by every means in its power, as a wilful aggression upon its rights and interests, the appropriation by Great Britain of any lands, or the exercise of any governmental jurisdiction over any territory, which, after investigation, we shall have determined of right to belong to Venezuela." The effect of this message was to call forth in the United States a great display of warlike enthusiasm, and to occasion a fall in the value of American securities amounting to \$400,000,000. In England it was received with considerable astonishment but without active resentment, the public mind being almost immediately diverted to the troubles arising out of Dr Jameson's raid into the Transvaal. In January 1896 the United States appointed their commission, and invited the British Government to furnish a statement of their case. The British Government declined to recognize the jurisdiction of this commission. Fresh negotiations were then entered into for arbitration, on the understanding that the rights of Great Britain in the settled territory should be protected. In February 1897 a treaty was signed at Washington between Great Britain and Venezuela, in which four arbitrators were named, viz., Lord Herschell and Sir Richard Henn Collins on behalf of Great Britain, and Chief-Justice Fuller and Mr Justice Brewer, both of the Supreme Court of the United States, on behalf of

Venezuela. A fifth arbitrator was to be appointed by these four, or, in the event of their failure to agree, by the king of Sweden and Norway. The four arbitrators agreed to appoint as their colleague M. de Martens, privy councillor and member of the Ministry of Foreign Affairs in Russia. Lord Herschell having died in March 1899, the Lord Chief-Justice of England, Lord Russell of Killowen, was appointed in his place. The court so constituted assembled in Paris in June 1899. On 3rd October the arbitrators published their award. By it Venezuela obtained the district of Barima as far as Point Playa, and a strip of country between the Wenamu and Cuyuni rivers; elsewhere the new boundary coincided with the Schomburgk line. Barima, which is a district strategically important to Venezuela, but otherwise of little value, had been offered to her by the British Government at least three times in the prolonged course of the negotiation. The free navigation of the rivers Amakuru and Barima was secured to Great Britain, which had every reason to be satisfied with the result.

Of disputes with regard to fisheries, the two most important in recent times are the Newfoundland and the Bering Sea cases. The Newfoundland dispute is a very old one, and is not yet closed. Newfoundland fishery. By the treaty of Utrecht of 1713 a right was reserved to French subjects to catch fish and to dry them on that part of Newfoundland which stretches from Cape Bonavista to the northern point of the island, and from thence coming down by the western side reaches as far as Cape Riche. By the treaty of Versailles of 1783 France renounced the fishery from Bonavista to Cape St John on the east coast, receiving in return extended rights upon the west coast as far as Cape Ray. Neither treaty purported to grant exclusive right, but there was annexed to the treaty of Versailles a declaration to the effect that "His Britannic Majesty will take the most positive measures for preventing his subjects from interrupting in any manner by their competition the fishery of the French during the temporary exercise of it which is granted to them upon the coasts of the island of Newfoundland, and he will for this purpose cause the fixed settlements which shall be formed there to be removed." Upon this declaration the French founded a claim to exclusive fishing rights within the limits named. Various conventions were entered into with a view to defining these rights in 1854, 1884, and 1885, but they remained inoperative, the consent of the Newfoundland Legislature—to which they were made subject—having been hitherto refused. Meanwhile the French Government granted a bounty to the French fishermen which enabled them to undersell the colonists. In 1887 the Newfoundland Legislature passed an Act forbidding the sale of bait, which struck a severe blow at the French industry. This was not, however, the whole cause of difference between Great Britain and France. At the date of the treaty of Utrecht, and for more than a century afterwards, the French fished in this region almost entirely for cod, but subsequently they also fished there for lobsters, and about the year 1886 they erected factories for "tinning" or "canning" lobsters at Port au Choix on the north-west coast of the island. This, it was contended, was not within the treaty, which only contemplated cod fishing, and gave no landing rights except in respect of that species of fish. Moreover, the colonial fishermen had, prior to 1886, erected lobster factories of their own on that part of the coast which is known as "the French shore," so that their trade was directly interfered with by the factories at Port au Choix. Mutual protests and remonstrances ensued, each party appealing to their respective governments to expel the intruders. At length, in March 1891, a treaty was signed between Great Britain and France by which the two nations agreed to refer the lobster dispute to a tribunal composed of three jurists named by the two countries in common, and four delegates, two from each country, who were to act as intermediaries between their respective

governments and the other arbitrators. The arbitration tribunal had held no sitting down to the time of writing (1900), but a *modus vivendi* was arranged in 1890 by which no lobster fisheries which were not in operation in July of that year were to be permitted, except with the joint consent of the commanders of the British and French naval stations. This arrangement has been renewed from year to year, and has been the means of keeping the peace.

Another important fishery dispute arose between Great Britain and the United States with regard to the fur seals in Bering Strait. The facts are as follows:—

In the year 1867 the United States Government had purchased from Russia all her territorial rights in Alaska and the adjacent islands. The boundary between the two powers as laid down by the treaty for purchase was a line drawn from the middle of Bering Strait south-west to a point midway between the Aleutian and Komandorski Islands, dividing Bering Sea into two parts, of which the larger was on the American side of this line. This portion included the Pribyloff Islands, which are the principal breeding grounds of the seals frequenting those seas. By certain Acts of Congress, passed between 1868 and 1873, the killing of seals was prohibited upon the islands of the Pribyloff group and in "the waters adjacent thereto," except upon certain specified conditions. No definition of the meaning of the words "adjacent waters" was given in the Act. In 1870 the exclusive right of killing seals upon these islands was leased by the United States to the Alaska Commercial Company, upon conditions limiting the numbers to be taken annually, and otherwise providing for their protection. As early as 1872 the operations of foreign sealers attracted the attention of the United States Government, but any precautions then taken seem to have been directed against the capture of seals on their way through the passages between the Aleutian Islands, and no claim to jurisdiction beyond the three-mile limit appears to have been put forward. On 12th March 1881, however, Mr French, acting secretary of the United States Treasury, in answer to a letter asking for an interpretation of the words "waters adjacent thereto" in the Acts of 1868 and 1873, stated that all the waters east of the boundary line were considered to be within the waters of Alaska territory. In March 1886 this letter was communicated to the San Francisco Customs by Mr Manning, secretary of the Treasury, for publication. In the same summer three British sealers, the *Carolena*, *Onward*, and *Thornton*, were captured by an American revenue cutter sixty miles from land. They were condemned by the district judge on the express ground that they had been sealing within the limits of Alaska territory. Diplomatic representations followed and an order for release was issued, but in 1887 further captures were made and were judicially supported upon the same grounds. The respective positions taken up by the two governments in the controversy which ensued may be thus indicated. The United States claimed as a matter of right an exclusive jurisdiction over the sealing industry in Bering Sea; they also contended that the protection of the fur seal was, upon grounds both of morality and interest, an international duty, and should be secured by international arrangement. The British Government repudiated the claim of right, but were willing to negotiate upon the question of international regulation. Between 1887 and 1890 negotiations were carried on between Russia, Great Britain, and the United States with a view to a joint convention. Unfortunately the parties were unable to agree as to the principles upon which regulation should be based. The negotiations were wrecked upon the question of pelagic sealing. The only seal nurseries were upon the Pribyloff Islands, which belonged to the United States, and the Komandorski group, which belonged to Russia. Consequently to prohibit pelagic sealing would have been to exclude Canada from the industry. The United States, nevertheless, insisted that such prohibition was indispensable on the grounds—(1) that pelagic sealing involved the destruction of breeding stock, because it was practically impossible to distinguish between the male and female seal when in the water; (2) that it was unnecessarily wasteful, inasmuch as a large proportion of the seals so killed were lost. On the other hand, it was contended by Great Britain that in all known cases the extermination of seals had been the result of operations upon land, and had never been caused by sealing exclusively pelagic. The negotiations came to nothing, and the United States fell back upon their claim of right. In June 1890 it was reported that certain American revenue cutters had been ordered to proceed to Bering Sea. Sir Julian Pauncefote, the British ambassador at Washington, having failed to obtain an assurance that British vessels would not be interfered with, laid a formal protest before the United States Government.

Thereupon followed a diplomatic controversy, in the course of which the United States developed the contentions which were afterwards laid before the tribunal of arbitration. The claim that Bering Sea was *mare clausum* was abandoned, but it was asserted that Russia had formerly exercised therein rights of exclusive jurisdiction which had passed to the United States, and they relied *inter alia* upon the ukase of 1821 by which foreign vessels had been forbidden to approach within 100 Italian miles of the coasts of Russian America. It was pointed out by Great Britain that this ukase had been the subject of protest both by Great Britain and the United States, and that by treaties similar in their terms, made between Russia and each of the protesting powers, Russia had agreed that their subjects should not be troubled or molested in navigating or fishing in any part of the Pacific Ocean. The American answer was that the Pacific Ocean did not include Bering Sea. They also claimed an interest in the fur seals, involving the right to protect them outside the three-mile limit. In August 1890 Lord Salisbury proposed that the question at issue should be submitted to arbitration. This was ultimately assented to by Mr Secretary Blaine on the understanding that certain specific points, which he indicated, should be laid before the arbitrators. On 29th February 1892 a definitive treaty was signed at Washington. Each power was to name two arbitrators, and the president of the French Republic, the king of Italy, the king of Norway and Sweden, were each to name one. The points submitted were as follows:—(1) What exclusive jurisdiction in the sea now known as Bering Sea, and what exclusive rights in the seal fisheries therein, did Russia assert and exercise prior, and up to the time of, the cession of Alaska to the United States? (2) How far were her claims of jurisdiction as to the seal fisheries recognized and conceded by Great Britain? (3) Was the body of water now known as Bering Sea included in the phrase "Pacific Ocean," as used in the treaty of 1825 between Great Britain and Russia, and what rights, if any, in Bering Sea were held exclusively exercised by Russia after the said treaty? (4) Did not all the rights of Russia as to jurisdiction and as to the seal fisheries in Bering Sea east of the water boundary, in the treaty between the United States and Russia of the 30th March 1867, pass unimpaired to the United States under that treaty? (5) Had the United States any and what right of protection over, or property in, the fur seals frequenting the islands of Bering Sea when such seals are found outside the three-mile limit? In the event of a determination in favour of Great Britain, the arbitrators were to determine what concurrent regulations were necessary for the preservation of the seals, and a joint commission was to be appointed by the two powers to assist them in the investigation of the facts of seal life. The question of damages was reserved for further discussion, but either party was to be at liberty to submit any question of fact to the arbitrators, and to ask for a finding thereon. The tribunal was to sit at Paris. The treaty was approved by the Senate on 29th March 1892, and ratified by the President on 22nd April.

The United States appointed as arbitrator Mr John H. Harlan, a Justice of the Supreme Court, and Mr John T. Morgan, a member of the Senate. The British arbitrators were Lord Hannan and Sir John Thompson. The neutral arbitrators were the Baron de Courcel, the Marquis Visconti Venosta, and Mr Gregers Gram, appointed respectively by the president of the French Republic, the king of Italy, and the king of Norway and Sweden. The sittings of the tribunal began in February and ended in August 1893. The main interest of the proceedings lies in the second of the two claims put forward on behalf of the United States. This claim cannot easily be stated in language of precision; it is indicated rather than formulated in the last of the five points specially submitted by the treaty. But its general character may be gathered from the arguments addressed to the tribunal. It was suggested that the seals had some of the characteristics of the domestic animals, and could therefore be the subject of something in the nature of a right of property. They were so far amenable to human control that it was possible to take their increase without destroying the stock. Sealing upon land was legitimate sealing; the United States being the owners of the land, the industry was a trust vested in them for the benefit of mankind. On the other hand, pelagic sealing, being a method of promiscuous slaughter, was illegitimate; it was *contra bonos mores* and analogous to piracy. Consequently the United States claimed a right to restrain such practices, both as proprietors of the seals and as proprietors and trustees of the legitimate industry. It is obvious that such a right was a novelty hitherto unrecognized by any system of law. Mr Carter, therefore, as counsel for the United States, submitted a theory of international jurisprudence which was equally novel. He argued that the determination of the tribunal must be grounded upon "the principles of right," that "by the rule or principle of right was meant a moral rule dictated by the general standard of justice upon which civilized nations are agreed," that "this international

standard of justice is but another name for "international law," that the particular recognized rules were but cases of the application of a more general rule, and that where the particular rules were silent the general rule applied. The practical effect of this contention appears to be that an international tribunal can make new law and apply it retrospectively. In spite of this ingenious argument, which was strenuously opposed by Sir Charles Russell, the leading counsel for Great Britain, the judgment of the arbitrators was in favour of Great Britain on all points. It only remained for the arbitrators to consider the question of regulation which had also been submitted to them. Upon this point the arguments of the American counsel were allowed their due weight. A close time was appointed for sealing, the use of firearms was forbidden in Bering Sea, and pelagic sealing was prohibited within sixty miles of the Pribyloff Islands. The award was signed and published on 15th August 1893. The question of damages which had been reserved was ultimately settled in 1897 by a joint commission appointed by the two powers in February 1896, the total amount awarded to the British sealers being \$473,151.26.

(B.) We pass now to State action on behalf of individuals. The following is an illustration of a dispute of this class, which was settled by arbitration nearly forty years after the occasion which gave rise to it. On the night of 26th

September 1814, during the war between Great Britain and the United States, the *General Arm-strong*, an American privateer, fired upon the boats of a British squadron which had just entered the port of Fayal, an island of the Azores group. The British squadron retaliated next day by cannonading the privateer within the limits of the port, and managed to destroy her. Fayal and its port were then, as now, Portuguese territory, and the United States claimed to be indemnified by the Portuguese Government for the loss of the privateer, on the ground that the local authorities had committed a breach of neutrality in not interfering on her behalf when the British squadron opened fire. By treaty of 26th February 1851, it was agreed to submit this claim to arbitration, and Louis Napoleon, then president of the French Republic, was chosen arbitrator. It was proved that the governor of Fayal was aware on 27th February of what was going on, but it was also proved that his protection had not been invoked by the American skipper until after the firing had commenced, and that he then at once sent a remonstrance to the British captain requiring him to cease hostilities. It was further shown that the guns of the fort were insufficient to allow of an armed intervention by the Portuguese. In these circumstances the arbitrator, while recognizing the principle that a neutral power is bound to make compensation to a belligerent whose property has been lost or destroyed within the neutral jurisdiction by the hostile action of the opposite belligerent, by his award of 30th November 1852 absolved the Portuguese Government from blame (partly on the ground that the appeal to the local authorities was too late, and partly on the ground that the governor had no force sufficient to enable him to interfere with effect).

This arbitration had an interesting sequel. When the United States Government failed to obtain redress from the Portuguese, the owners of the privateer demanded it at the hands of their own Government, alleging that by espousing their cause in the arbitration proceedings the United States had admitted the claim against themselves. They succeeded in procuring both the House of Representatives and the Senate of the United States to pass a vote in their favour, but the claim was rejected by the Supreme Court on the grounds that it was bad, both in law and in morals. It is obvious that to have allowed it would have been to make a very awkward precedent. Governments would have to be very shy in future of arbitrating in such cases in the interests of private persons, if whenever the award proved adverse they were bound to compensate their clients out of the national exchequer.

A far more famous arbitration on breaches of neutrality took place twenty years afterwards between the United States and Great Britain. It is instructive both from the historical and the legal point of view, and is, therefore, worth stating at some length.

In 1861, as is well known, the southern states of North America

seceded from the rest on the slavery question and set up a separate government under President Jefferson Davis. Hostilities began with the capture of Fort Sumter by the Confederates on 13th April 1861. On 19th April President Abraham Lincoln declared a blockade of the southern ports. On 14th May the British Government issued a proclamation of neutrality, by which the Confederates were recognized as belligerents. This example was followed shortly afterwards by France and other nations. The blockade of the southern ports was not at first effective, and blockade-running soon became an active industry. The Confederates established agencies in England for the purchase of arms, which they despatched in ordinary merchant vessels to the Bahamas, whence they were transhipped into fast steamers specially constructed for the purpose. But this was not all. In February 1862 they contracted for a gunboat, which they called the *Oreto*, to be built for them at Liverpool. Mr C. F. Adams, the United States Minister, having brought this circumstance to the notice of the British Government, an inquiry was ordered and the report was that the *Oreto* was a fast steamer, pierced for four guns and generally suitable for warlike purposes, but that she was destined for a firm in Palermo. This was enough to rouse suspicion, but no positive evidence was obtainable. On 22nd March the *Oreto* left Liverpool and was next heard of, not at Palermo, but at Nassau in the Bahamas. There she was seized by the Colonial Government, acting upon representations made by the British naval authorities. She was, however, released by the local courts on the ground that there was no conclusive evidence against her. She left Nassau in the company of a British-built ship, from which she received her armament at Green Kay, and entered the port of Mobile, whence she afterwards emerged under the name of the *Florida* as a fully equipped man-of-war commissioned by the Confederate Government. In October 1865 she was captured in Brazilian waters by a vessel of the United States.

The case of the *Alabama* was still more remarkable. In June 1862 this ship, originally known as "No. 290," was being built by Messrs Laird at Birkenhead. She was then nearly completed and was obviously intended for a man-of-war. On 23rd June Mr Adams forwarded to Earl Russell a letter from the United States Consul at Liverpool, giving certain particulars as to her character. This letter was laid before the law officers, who advised that, if these particulars were correct, the vessel ought to be detained. On 21st July sworn evidence, which was supplemented on 23rd July, was obtained and laid before the Commissioners of Customs (who were the proper authorities to enforce the provisions of the Foreign Enlistment Act of 1819), but they declined to move. On 23rd July the same evidence was laid before the law officers, who advised that there was sufficient ground for detention. By some accident, which has never been satisfactorily explained, but was probably connected with the severe illness of Sir John Harding, the Queen's Advocate, the papers were not returned till 29th July. Instructions were then issued to seize the vessel, but she had already sailed on the evening of the 28th. Although she remained for two days off the coast of Anglesey, there was no serious attempt at pursuit. She afterwards made her way to the Azores, where she received her armament, which was brought from Liverpool in two British ships. Captain Semmes there took command of her under a commission from the Confederate Government. After a most destructive career she was sunk off Cherbourg by the *Kearsarge* on 19th June 1864.

Another vessel, the *Sea King*, which had been employed as a merchant ship, left London in October 1864 and was met at Madeira by the *Laurel* from Liverpool with men, arms, and officers. Her name was then changed to *Shenandoah* and the Confederate flag was hoisted on board her. After a cruise of ninety days, during which she destroyed certain North American vessels, she put into Melbourne on 25th January 1865. In spite of the protest of the United States Consul she was allowed to remain till 18th February to effect repairs and to take on board considerable supplies of coal and provisions. She also contrived to enlist forty-five men. Some investigation was made by the colonial authorities, but they were satisfied with her captain's assurance that he had enlisted no one since her arrival. After a cruise in the Arctic Seas she returned to Liverpool in November 1865 and was afterwards handed over to the United States.

On these facts the United States Government alleged against Great Britain two grievances, or sets of grievances. The first was the recognition of the southern states as belligerents and a general manifestation of unfriendliness in other ways. The second was in respect of breaches of neutrality in allowing Confederate vessels to be built and equipped on British territory. Correspondence ensued extending over several years. At length in February 1871 a commission was appointed to sit at Washington in order, if possible, to arrive at some common understanding as to the mode in which the questions at issue might be settled. With respect to the *Alabama* claims the British commissioners suggested that they should be submitted to arbitration. The

American commissioners refused "unless the principles which should govern the arbitrators in the consideration of the facts could be first agreed upon." After some discussion the British commissioners consented that the three following rules should apply. A neutral government is bound—(1) to use due diligence to prevent the fitting out, arming, or equipping within its jurisdiction of any vessel, which it has reasonable ground to believe is intended to cruise or to carry on war against a power with which it is at peace, and also to use like diligence to prevent the departure from its jurisdiction of any vessel intended to cruise or carry on war as above, such vessel having been specially adapted, in whole or in part, within such jurisdiction, to warlike use; (2) not to permit or suffer either belligerent to make use of its ports or waters as the base of naval operations against the other, or for the purpose of the renewal or augmentation of military supplies or arms or the recruitment of men; (3) to exercise due diligence in its own ports and waters, and as to all persons within its jurisdiction to prevent any violation of the foregoing obligation and duties. The arrangements made by the commission were embodied in the treaty of Washington, which was signed on 8th May 1871, and approved by the Senate on 24th May. Article 1, after expressing the regret felt by Her Majesty's Government for the escape, in whatever circumstances, of the *Alabama* and other vessels from British ports, and for the depredations committed by these vessels, provided that "the claims growing out of the acts of the said vessels, and generically known as the *Alabama* claims" should be referred to a tribunal composed of five arbitrators, one to be named by each of the contracting parties and the remaining three by the king of Italy, the president of the Swiss Confederation, and the emperor of Brazil respectively. By Article 2 all questions submitted were to be decided by a majority of the arbitrators, and each of the contracting parties was to name one person to attend as agent. Article 6 provided that the arbitrators should be governed by the three rules quoted above, and by such principles of international law not inconsistent therewith as the arbitrators should determine to be applicable to the case. By the same article the parties agreed to observe these rules as between themselves in future, and to bring them to the knowledge of other maritime powers. Article 7 provided that the decision should be made within three months from the close of the argument, and gave power to the arbitrators to award a sum in gross in the event of Great Britain being adjudged to be in the wrong.

The treaty was, on the whole, welcomed in England. The United States appointed Mr C. F. Adams as arbitrator, and Mr J. C. Bancroft Davis as agent. The British Government appointed Sir Alexander Cockburn as arbitrator, and Lord Tenterden as agent. The arbitrators appointed by the three neutral powers were Count Sclopis (Italy), M. Staempfli (Switzerland), Baron d'Itajuba (Brazil). The first meeting of the tribunal took place on 15th December 1871 in the Hôtel de Ville, Geneva. As soon as the cases had been formally presented, the tribunal adjourned till the following June. There followed immediately a controversy which threatened the collapse of the arbitration. It was found that in the American case damages were claimed not only for the property destroyed by the Confederate cruisers, but in respect of certain other matters known as "indirect losses," viz., the transference of the American marine to the British flag, the enhanced payments of insurance, the expenses of pursuit, and the prolongation of the war. But this was not all. The American case revived the charges of "insincere neutrality" and "veiled hostility" which had figured in the diplomatic correspondence, and had been repudiated by Great Britain. It dwelt at length upon such topics as the premature recognition of belligerency, the unfriendly utterances of British politicians, and the material assistance afforded to the Confederates by British traders. The inclusion of the indirect losses, and the other matters just referred to, caused great excitement in England. That they were within the treaty was disputed, and it was urged that, if they were, the treaty should be amended or denounced. In October 1872 Lord Granville notified to General Schenck, the United States Minister, that the British Government did not consider that the indirect losses were within the submission, and in April the British counter-case was filed without prejudice to this contention. On the 15th of June the tribunal reassembled and the American argument was filed. The British agent then applied for an adjournment of eight months, ostensibly in order that the two governments might conclude a supplemental convention, it having been meanwhile privately arranged between the arbitrators that an extra-judicial declaration should be obtained from the arbitrators on the subject of the direct claims. On 19th June Count Sclopis intimated on behalf of all his colleagues that, without intending to express any opinion upon the interpretation of the treaty, they had arrived at the conclusion that "the indirect claims did not constitute upon the principles of international law applicable

to such cases a good foundation for an award or computation of damages between nations." In consequence of this intimation Mr Bancroft Davis informed the tribunal on 25th June that he was instructed not to press those claims; and accordingly on 27th June Lord Tenterden withdrew his application for an adjournment, and the arbitration was allowed to proceed. The discussion turned mainly on the question of the measure of "due diligence." The United States contended that it must be a diligence commensurate with the emergency or with the magnitude of the results of negligence. The British Government maintained that while the measure of care which a government is bound to use in such cases must be dependent more or less upon circumstances, it would be unreasonable to require that it should exceed that which the governments of civilized states were accustomed to employ in matters concerning their own security or that of their citizens. The tribunal adopted the view suggested by the United States. The vessels complained of were the *Florida* and her tenders the *Clarence*, *Tacony*, and *Archer*; the *Alabama* and her tender the *Tuscaloosa*; the *Shenandoah*; the *Georgia*, the *Sumter*, the *Nashville*, the *Tallahassee*, the *Chickamarga*, the *Sallie*, the *Jefferson Davis*, the *Music*, the *Boston*, and the *V. H. Joy*. The tribunal found that Great Britain was responsible for all the depredations of the *Florida* and *Alabama*, and for those committed by the *Shenandoah* after she left Melbourne. In the case of the *Alabama* the court was unanimous; in the case of the *Florida* Sir A. Cockburn alone, and in the case of the *Shenandoah* both he and Baron d'Itajuba, dissented from the majority. The tenders were held to follow in each case the fate of their principals. In the cases of the other vessels the judgment was in favour of Great Britain. The tribunal decided to award a sum in gross, and (Sir A. Cockburn again dissenting) fixed the damages at \$15,500,000. On 14th September the award was formally published and signed by all the arbitrators except Sir A. Cockburn, who filed a lengthy statement of his reasons. This document contained an elaborate reply to certain attacks which had been made upon the good faith of the British Government—attacks which had better have been left unnoticed. They formed no part of the issue; and if they were to be refuted that task was for the British counsel, not for the British arbitrator.

The stipulation that the three rules should be jointly submitted by the two powers to foreign nations has never been carried out. For this the British Government has been blamed by some. But there appears to have been a general impression upon both sides, as well as among Continental publicists, that the language of the rules was not sufficiently precise to admit of their being generally accepted as a canon of neutral obligations.

Of instances of arbitration on unlawful arrests and seizures we may specially note the following. On 7th June 1863 three officers of a British ship, the *Forté*, stationed on the coast of Rio Janeiro, had a fracas with a Brazilian sentinel, and were in consequence arrested by the police and lodged in prison. This being notified to the British Consul, he explained to the authorities who the prisoners were, whereupon they were at once liberated. The British Government took up the matter and demanded redress from the Brazilian Government. The dispute threatened to be serious. It was referred, by consent, to the arbitration of the king of Belgium, who pronounced against the officers, on the ground that as they were not in uniform when arrested, no insult to the British Navy could possibly have been intended.

In September 1854 the steamer *Benjamin Franklin* and the barque *Catherine Augusta*, both the property of Carlos Butterfield and Co., cleared at New York for the port of St Thomas in the Danish West Indies. The *Catherine Augusta* was laden with cannon and other war material. At that time revolution was supposed to be imminent in Venezuela, and there were grounds for suspecting that these two vessels were destined to aid the insurgents. On the voyage the *Catherine Augusta* was much damaged by a storm, so that it became necessary for her to land her cargo for repairs. The Danish governor, who had received a communication from Venezuela, insisted on her giving, as a condition of her landing, security to the extent of \$20,000 that no breach of the neutrality of the port was intended. To this the owners were compelled to agree.

The original expedition, whatever its design, appears to have been abandoned, since the two vessels remained in the port awaiting the event of some negotiations for their sale to Mexico. In the meanwhile the *Benjamin Franklin* had been chartered by the Royal British Mail Steamship Company for a voyage to Barbadoes and back. She neglected to provide herself before starting with the permit required by the local regulations, and was accordingly fired at from one of the Danish forts. One shot struck her, but did little injury, and her voyage was only delayed a day. In 1860 Mr Secretary Cass brought to the notice of the Danish Government a claim by Carlos Butterfield and Company in respect of the detention of the two ships and of the firing into the *Benjamin Franklin*. After protracted negotiations, the matter was ultimately referred to Sir Edmund Monson, then British Minister at Athens. He made his award on 22nd January 1890, and decided that both claims were unfounded.

In 1888 a Dutch craft, the property of an Amboynese firm, drifted from her moorings in the Malay archipelago and was carried to the island of Buru, no one

The "*Costa Rica Packet*."

being on board at the time. Shortly afterwards the owners were informed that she had been taken possession of by a whaling-vessel called the *Costa Rica Packet* (John Carpenter, a British subject, being master), then on his way from New South Wales, and that Carpenter had transferred the cargo to his own ship and had sold it at Batchian. A complaint was at once lodged against the master before the officials at Macassar, and they, considering that a *prima facie* case against the master had been made out, issued a warrant for his arrest. Accordingly, on the arrival of the *Packet* at Ternate, Carpenter was seized and brought to Macassar to be tried—his ship proceeding to Batavia without him. When the facts came to be further inquired into at Macassar, it became evident that the wrongful appropriation, if any such there had been, had taken place on the high seas, more than three miles from land. The court therefore held, in conformity with the well-known rule, that it had no jurisdiction to interfere, Carpenter being answerable for his acts to the British Government alone. It therefore ordered his discharge. It was now Carpenter's turn to complain. When he was set free the Batavian mail had just left Macassar; he was consequently forced to remain there over three weeks, and when at last he reached Batavia, it was too late to take advantage of the whaling season in the southern seas. The *Packet* being useless except as a whaling-vessel had to be sold at Singapore at a loss. Heavy damages were claimed against the Netherlands Government by all the parties interested, and a correspondence ensued between that Government and the British which extended over four years. At length, in May 1895, both Governments signed an arbitration treaty by which they agreed to invite a third power to nominate a jurist of undoubted reputation who should settle the points in difference. The power chosen was Russia, and the Emperor Nicholas II. nominated, as arbitrator, Professor F. de Martens. He, by his award in 1897, declared the Netherlands Government liable to pay £8550, distributed as follows:—£3800 to the owners of the *Packet*; £3150 to Carpenter; £1600 to the remaining officers and the crew; each of these amounts to carry interest at 5 per cent. as from the date of Carpenter's arrest.

The latest arbitration on illegal seizure is that known as the Delagoa Bay Railway case, of which the facts are as follows:—

In December 1883 the Portuguese Government granted to Colonel M'Murdo, an American citizen, a concession for the construction and working during ninety-nine years of a railway

from Lorenzo Marques, the port of Delagoa Bay, to the frontier of the Transvaal. It was a term of the concession that the Portuguese Government should not construct *Delagoa Railway.* or allow within the district of Lorenzo Marques any other railway from the coast to the Transvaal parallel to the M'Murdo line within a distance of sixty miles. It was further provided that the concessionaire should have the absolute right of fixing the charges both for passengers and goods. In furtherance of his scheme Colonel M'Murdo formed a Portuguese company, but this company being unable to raise sufficient capital delegated its powers and transferred the bulk of its property to an English company, formed in March 1887 and called "The Delagoa Bay and East African Railway (Limited)." The last-named company issued shares and bonds which were largely taken up by Colonel M'Murdo and by English investors. Before the grant of the concession of 1883 an agreement had been made between the South African Republic and Portugal whereby the former bound itself, whenever the Delagoa Bay Railway should reach the Transvaal frontier, to continue the line as far as Pretoria. At this period the frontier of the Transvaal had not been finally delimited, but the Portuguese officials placed it in their maps at about 80 kilometres from the coast. The Portuguese Government agreed that, if this distance was increased, the company which had undertaken to make the railway to the frontier should be allowed a reasonable extension of time. On 17th May 1884 the Portuguese Government promised to the Transvaal Government a concession for a steam tramway parallel to the projected railway in case the English company failed to complete the railway by the prescribed date, and also promised that the steam tramway should be used both for passengers and goods if the Portuguese Government failed to agree with the English company as to the through rates to be charged on the railway. This promise was embodied in a commercial treaty negotiated by President Kruger (who made a special visit to Lisbon for the purpose), and was kept secret from Colonel M'Murdo and the shareholders and creditors of the English company. The frontier line of the Transvaal was ultimately drawn through Komati Poort, a point about five miles farther from the coast than that shown on the Portuguese maps. The Portuguese Government thereupon required that the railway from Lorenzo Marques should be continued up to the new frontier, eight extra months (of which five were in the rainy season) being allowed for the extension. This was an unreasonable term, and was not, and could not be, complied with. At the end of the eight months the Portuguese Government declared Colonel M'Murdo's concession forfeited, and seized the nearly completed railway.

The Governments of Great Britain and the United States remonstrated in the interest of the widow of Colonel M'Murdo and the other creditors of the English company, the British Government going so far as to despatch a gunboat to Delagoa Bay and threaten to back its remonstrance by force. Here in truth was a *casus belli* with Portugal, for that country appeared to have broken its pledges under pressure from, and in deference to the political aims of, the South African Republic. Happily pacific counsels prevailed. An agreement was come to between Great Britain, the United States, and Portugal, whereby it was referred to arbitrators to be named by the Federal Council of Switzerland to determine the compensation to be paid by Portugal to the parties interested in the forfeited undertaking, the illegality of the proceedings of the Portuguese Government being admitted by the form of the reference. The subsequent dates are remarkable. The arbitrators were named in 1890, and in that year Portugal paid £28,000 on account. The court began to sit at Berne in 1892; the pleadings closed in 1896. It was then decided to appoint a commission of experts to make local inquiries and to report. When the report came in, the sittings were resumed, and were not concluded until the summer of 1898. The award (which was unanimous) was published on 29th March 1900. It directed Portugal to pay to the Governments of Great Britain and the United States, within six months from the publication of the award, the sum of £612,500 (in addition to the £28,000 paid in 1890), together with interest at 5 per cent. per annum from 25th June 1889 down to the time of payment, making a total of nearly £1,000,000 sterling. This sum was to be employed in compensating the bond-holders and other creditors of the Delagoa Bay Railway Company according to their several priorities, such priorities to be settled by arrangement between the claimants themselves. The costs of the arbitration were to be borne equally by the three governments, that is to say, one-third by each.

Closely akin to international arbitration is the proceeding by Mixed Commission, on which all the parties in difference are represented. Such commissions have been most frequently resorted to for settling the indemnities to

be paid to non-combatants in respect of losses occasioned by war. Amongst the earliest of these commissions was that appointed under the treaty of 19th November 1794, negotiated with Lord Grenville by Mr John Jay, the distinguished American lawyer and statesman, and known as "The Jay Treaty," the object of

which was to settle the indemnities to be paid by Great Britain and the United States respectively to owners of merchant ships captured during the American revolutionary war. Similar commissions were appointed in pursuance of the treaty of Vienna of 20th November 1815. In 1843, wholesale claims for indemnity were settled by a mixed

TABLE I.
Territorial Disputes.

Date of Agreement to refer.	Parties.	Arbitrating Authority.	Subject Matter.	Result.
24th Dec. 1814 (Treaty of Ghent)	Great Britain and United States	Mixed commission	Islands in Passamaquoddy Bay near the mouth of the St Croix river	24th Nov. 1817.—Dispute settled
Do.	Do.	Do.	Northern boundary of U.S.	18th June 1822.—Delimitation effected
29th Sept. 1827	Do.	King of the Netherlands	North-east boundary of U.S.	9th Aug. 1842.—Award not accepted by U.S., but dispute settled by Webster-Ashburton Treaty
13th Jan. 1868	Great Britain and Portugal	General Ulysses S. Grant, President of U.S.	Sovereignty over island of Bulama, off west coast of Africa	21st April 1870.—In favour of Portugal
1871	Great Britain and United States	Mixed commission	Nova Scotia fisheries	23rd Nov. 1871.—\$5,500,000 awarded to Great Britain, the American commissioners dissenting. Congress, however, voted the full amount
Sept. 1872	Great Britain and Portugal	President of French Republic	Territories and islands in Delagoa Bay	24th July 1875.—In favour of Portugal
31st Dec. 1873	Italy and Switzerland	Mixed commission	Boundary between Italy and Canton of Ticino	23rd Sept. 1874.—In favour of Italy
1874	Persia and Afghanistan	Generals Goldsmid and R. Pollock (British officers)	Boundaries on north-west frontier of India	Delimitation effected
3rd Feb. 1876	Argentine Republic and Paraguay	President of United States	Frontier dispute	12th Nov. 1878.—In favour of Paraguay
1878	Argentine Republic and Chile	Ministers of U.S. in the two countries	Strait of Magellan and land boundaries	Sept. 1881.—Delimitation effected
13th July 1878 (Treaty of Berlin)	Turkey and Greece	Representatives of Great Britain, France, Germany, Austria, Russia	Territorial sovereignty	1st July 1880.—Thessaly and part of Epirus to be ceded to Greece. Decision embodied in treaty of 14th June 1881
14th Sept. 1881	Colombia and Venezuela	King Alfonso XII. of Spain, and on his death the Queen Regent Christina	Boundary dispute	May 1891.—In favour of Colombia
10th Sept. 1885	Great Britain and Russia	Mixed commission	Afghan boundary	21st May 1886.—Delimitation effected
24th Dec. 1886	Nicaragua and Costa Rica	President Cleveland	Right of navigation in San Juan river, &c.	21st March 1888.—Mainly in favour of Costa Rica
1st Aug. 1887	Peru and Ecuador	King of Spain, and on his death the Queen Regent Emperor of Russia	Territory east of Rio Bamba	Delimitation effected
29th Nov. 1888	France and Holland	Viceroy of India	Boundaries of French and Dutch Guiana	25th May 1891.—In favour of Holland
Jan. 1891	Persia and Afghanistan		Frontier of the Hashtadan district	Delimitation effected
1893	Great Britain, Russia, and Afghanistan	Anglo-Russian commission	Use of waters of river Kushk	Dispute settled
1897	France and Germany	Mixed commission	Hinterland of Togo, Gold Coast of Africa	11th July 1897.—Dispute settled
April 1897	France and Brazil	Federal Council of Switzerland	Boundary between Brazil and French Guiana	1st Dec. 1900.—Awarded to Brazil 147,000 square miles of the disputed territory to the Araguay river on the S. and France about 3000 square miles to the N. of the Tumuc Humac mountains. Practically in favour of Brazil
12th Nov. 1898	Argentine Republic, Chile, and Bolivia	Mixed commission	Boundary of the province of Atacama	25th March 1899.—Delimitation effected

commission after certain preliminary points had been decided by arbitration in the following circumstances. France had found it necessary to take punitive measures against certain Moorish tribes on the West Coast of Africa in order to protect her colonies at Senegal from the arbitrary exactions by which they were oppressed. With this view she blockaded the coast of Portendic, but failed to notify the fact to the owners of the British vessels who traded with the nations in gum and other exports. The result

was that the commercial arrangements of the British owners were upset and they claimed compensation at the hands of their Government. Correspondence on the subject with the French Government went on for four years. It was finally agreed to refer to the king of Prussia the determination of two questions, one of fact, the other of law. (1) Did the blockade occasion losses to the British traders in the exercise of their lawful calling? (2) If yea, was France bound to make these losses good? The king

of Prussia decided both questions in the affirmative. A mixed commission was then appointed to assess the damages to be paid to the traders. They were fixed at 41,770 francs 89 centimes. The precision of these figures

TABLE II.
Claims in respect of Seizures and Arrests.

Date of Agreement to refer.	Parties.	Arbitrating Authority.	Subject Matter.	Result.
14th Feb. 1851	France and Spain	King of the Netherlands	Claims and cross-claims in respect of seizures of vessels in 1823-24	Claims adjusted
1864	Great Britain and Peru	Senate of Hamburg	Imprisonment by Peru of Capt. T. Melville White, a British subject	Claim disallowed
16th June 1870	United States and Spain	Mixed commission	Seizure of American s.s. <i>Colonel Lloyd Aspinwall</i>	15th Nov. 1870.—\$19,170,250 awarded to U.S.
1872	Japan and Peru	Emperor of Russia	Seizure of Peruvian barque <i>Maria Luz</i>	17th May 1875.—In favour of Japan
17th Aug. 1874	United States and Colombia	Mixed commission	Seizure of American s.s. <i>Montijo</i> by insurgents of Panama	27th June 1885.—\$33,401 awarded to U.S.
15th Oct. 1879	France and Nicaragua	French court of cassation	Seizure of French ship <i>Le Phare</i>	29th July 1880.—40,320 francs awarded to France
26th March 1881	The Netherlands and Hayti	President of French Republic	Seizure of Dutch ship <i>The Havana Packet</i>	16th March 1883.—140,000 francs awarded to the Netherlands
28th Feb. 1885	United States and Spain	Italian minister at Madrid	Seizure of American s.s. <i>The Masonic</i> at Manila	27th June 1885.—\$5,167,407 awarded to U.S.
28th Feb. 1893	United States and Ecuador	British minister at Quito	Arrest of an American citizen at Quito	In favour of U.S.
1896	Great Britain and Belgium	President of French court of cassation	Arrest of Mr Ben. Tillett, a British subject	Jan. 1899.—In favour of Belgium

TABLE III.
Miscellaneous Claims for Damages.

Date of Agreement to refer.	Parties.	Arbitrating Authority.	Subject Matter.	Result.
20th Oct. 1818	Great Britain and United States	Emperor of Russia	Obligation to restore slaves in possession of the British	21st April 1822.—In favour of U.S.
11th April 1839	United States and Mexico	King of Prussia	Losses of U.S. citizens during war between France and Mexico	Claims only partially settled, and war between U.S. and Mexico in 1846
18th July 1850	Great Britain and Greece	Mixed commission	Losses of British subjects during riots in Athens	Claims settled, the most remarkable being that of Don Pacifico, a native of Gibraltar, and therefore a British subject, who demanded £21,295 and was awarded £150 only
10th Nov. 1858	United States and Chile	King of the Belgians	Seizure of specie on board the U.S. brig <i>Macedonian</i> by Lord Cochrane, then admiral of Chilean fleet	16th May 1863.—Chile to refund three-fifths of the value of the specie with interest
15th July 1864	Great Britain and Argentine Republic	President of Chile	Losses arising out of decree of Argentine Government prohibiting vessels from Monte Video to enter Argentine ports	1st Aug. 1870.—In favour of Argentine Republic
14th March 1870	United States and Brazil	British Minister at Washington	Loss of whale-ship <i>Canada</i>	11th July 1870.—\$10,070,494 awarded to U.S.
1873	Great Britain and Brazil	Envoys of U.S. and Brazil at Rio de Janeiro	Claims by earl of Dundonald in respect of services rendered by his father, Admiral Cochrane, to Brazil during her war of independence	6th Oct. 1873.—£38,175 awarded to Earl Dundonald
23rd July 1873	Great Britain and France	Mixed commission	Duties levied in France on mineral oils	5th Jan. 1874.—314,393 francs awarded to British claimants
1874	China and Japan	British minister at Peking	Murder of Japanese citizens by Chinese in islands of Formosa	500,000 taels awarded to Japan
24th May 1884	United States and Brazil	Hon. Wm. Strong, ex-judge of the supreme court of U.S.	Claims in respect of law proceedings in Hayti against two American citizens	14th June 1885.—In favour of U.S., but award not enforced
24th Feb. 1891	France and Venezuela	President of Swiss Confederation	Claim by French contractor in respect of a judgment obtained by him in Venezuelan courts, of which execution was refused by the executive	30th Dec. 1896.—4,346,656 francs awarded to French plaintiff

shows that the indemnity was for actual losses sustained and proved, and not, as in the *Alabama* case, a round sum awarded, as between state and state, to satisfy claims to be ascertained thereafter. Another mixed commission with very extensive powers was appointed under the treaty of Washington of 15th January 1880 between the

United States and France. This treaty dealt both with claims and counterclaims, namely—(1) claims by American citizens against the French Government for damages sustained by them during the last war between France and Mexico, or during that of 1870-71 between France and Germany, or during the insurrection of the Commune; (2) counterclaims by French citizens against the United States Government for damages sustained at the hands of American citizens during the War of Secession of 1861-65. The commission was composed of three persons, one named by the French Government, one by the president of the United States, and the third by the emperor of Brazil. The losses sustained by French subjects during the war between Chile and Peru were ascertained in the same manner in pursuance of a treaty of 2nd November 1862. Examples of similar commissions might be easily multiplied, but the practice is too well established to make it worth while to particularize them here.

A large number of international differences, without reckoning those already specially noted or the war-indemnity claims just referred to, have been adjusted, or put in trim for adjustment, either by arbitration or by mixed commissions, since the pacification of 1815. The majority of these cases are summarized in the preceding tables, which have been compiled in part from the volumes of Professor Moore and in part from Dr Evans Darby's revised list, respectively mentioned at the end of this article.

Up to this point we have only dealt with arbitrations on what may be termed specific differences. There are, however, in existence several conventions which provide for the settlement by international arbitration not merely of specific differences, but of all differences, present and future, which may arise between the contracting parties as regard certain subjects, *e.g.*, commerce or navigation. Clauses to this effect (*clauses compromissaires*) have been agreed to since 1862 between Great Britain on the one hand, and Italy, Greece, Portugal, Mexico, Uruguay respectively on the other hand; between Belgium on the one hand, and Italy, Greece, Sweden, Norway, and Denmark respectively on the other hand; between France and Korea; between Italy and Montenegro; between Austria-Hungary and Siam; between Spain and Sweden and Norway; between Denmark and Venezuela; between the Netherlands and Rumania; between Japan and Siam. The conventions of the Postal Union of 1874 and 1891, and of 1890 for the international transport of goods by rail, are instances of the same class. There are also in existence conventions for settlement by international arbitration of all differences without exception. Such are the treaties of Guadalupe-Hidalgo of 1848 between the United States and Mexico; of Belgium with Hawaii and Siam in 1862 and 1868 respectively; with Venezuela in 1884, and Ecuador in 1887; of 1888 between Switzerland and San Salvador and Ecuador; and of 1894 between Spain on the one hand, and Honduras and Colombia on the other.

So much has been actually accomplished. Other schemes for general arbitration have been mooted and carried to a certain point, although they have not yet been realized. When, in December 1882, President Garfield announced in his annual message his willingness to assist any measure which might tend to secure peace, the Swiss Government responded by offering to agree to a general arbitration treaty with the United States. A draft treaty was accordingly prepared, and submitted to the Swiss Federal Council, which adopted it on 24th July 1883; but owing to the death of Mr Secretary Frelinghuysen, who had been the principal American negotiator, the project fell through. A similar proposal was brought forward at the Inter-American Congress held at Washington 1889-90, which was attended by delegates from the United States and seventeen Republics of Central and South America. It took the form of a solemn recommendation by the delegates to their respective governments "to

adopt arbitration as a principle of American international law for the settlement of the differences, disputes, or controversies that might arise between two or more of them." A treaty to this effect was signed by delegates from the United States and also from Guatemala, Honduras, Nicaragua, San Salvador, Venezuela, Ecuador, Brazil, and Bolivia, but was not ratified by the governments named in it within the prescribed time. An attempt to revive it was made by the smaller states in 1891 but without success.

In 1896 an effort was made by the representatives of Great Britain and the United States to provide for the submission to arbitration of "all questions in difference between those countries which might fail to adjust themselves by diplomatic negotiations." A treaty to this effect was prepared and signed on 11th January 1897 by the British ambassador (Sir Julian Pauncefote) and Mr Secretary Olney. It presented three forms of procedure, one for pecuniary claims or groups of pecuniary claims which did not in the aggregate exceed £100,000; a second for pecuniary claims beyond that amount, and a third for territorial claims, including rights of navigation and of access to fisheries. For the settlement of the first set of claims, each of the contracting parties was to nominate one arbitrator who was to be a jurist of repute, and the two arbitrators so nominated were to select a third, who was to be the president of the tribunal. The award of the majority was to be final. The second set of claims was to be referred to a tribunal similarly constituted, but in this case the award was only to be final if the tribunal was unanimous. If not unanimous, either of the contracting parties might demand a review of the award within six months from its date. In such case, the matter in controversy was to be submitted to a tribunal consisting of five jurists, no one of whom was to be a member of the original tribunal whose award was to be reviewed. The five jurists were to be nominated as follows:—two by each of the contracting parties, and one to act as umpire by the four thus nominated. The award of the majority of the members was to be final. The third set of claims (territorial) was to be submitted to a tribunal composed of six members, three of whom, subject to a particular exception, were to be judges of the Supreme Court of the United States or justices of Circuit Courts to be nominated by the president of the United States, the other three being judges of the British Supreme Court of Judicature or members of the Judicial Committee of the Privy Council nominated by the British Crown. The award in this case was to be final if made by a majority of five to one. In the event of its being less than five to one, it was not to be binding if protested against by either party within three months of publication. If so protested against, or if there was no award by reason of the numbers being equally balanced, there was to be no recourse to hostile measures of any description until the mediation of one or more friendly powers had been invited by one of the contracting parties. In spite of the elaborate care and caution with which this treaty was drawn, it remains a dead letter for want of ratification by the respective governments on whose behalf it was signed. It may be that its very elaborateness has proved a bar to its success, just as a parade of too many safety appliances on the eve of a mountaineering expedition is apt to unbrace our nerves and enhance our sense of danger.

The plan of establishing a standing arbitration tribunal advocated by Jeremy Bentham has been already referred to. In 1838 the New York Peace Society proposed to establish a Board of International Arbitration, and the idea was further worked out in 1842 by James Mill. Subsequently Mr Dudley Field in America, Dr Goldschmidt in Germany, Sir Edmund Hornby and Mr Leone Levi in England, successively produced draft rules of procedure by which, unless otherwise agreed, the permanent court was to be bound. Dr Goldschmidt's rules were revised and adopted by the Institute of International Law in 1875, and again considered by the Inter-Parliamentary Conference held at Brussels in 1895. All these efforts, however, excellent as they were in their generation, have been thrown into the shade by the work of the Peace Conference initiated in 1898 by the emperor of Russia, and held at the Hague in the following year. On 24th August 1898 Count Muravieff handed to all the foreign representatives accredited to the court of St Petersburg a circular informing them that the Tsar proposed to their respective governments the holding of a Conference "which should occupy itself with the grave question of the excessive armaments which

Hague Conference.

weighed upon all nations with a view of putting an end to their progressive development." This circular was shortly followed by another setting forth a preliminary draft programme for the Conference, which embraced not only the reduction of armaments and the more humane conduct of warfare, but also "the employment of good offices of mediation and arbitration in cases lending themselves thereto." The Conference met on 18th May 1899 at the Hague, and was attended by delegates from nineteen states under the presidency of Baron de Staal, the Russian ambassador at London. Other well-known delegates were Sir Julian Pauncefote (afterwards Lord Pauncefote), British ambassador at Washington; Mr Seth Low, president of Columbia University, New York; M. Leon Bourgeois, ex-premier of France, Count Munster, German ambassador at Paris. The Conference was divided into two sections, the province of the first being to deal with the limitation of armaments; of the second, with the laws of warfare; of the third, with mediation and arbitration. At one of the early sittings of the third section (over which M. Bourgeois presided), Baron de Staal produced a draft convention for rendering arbitration compulsory in certain cases and optional in others. Under the compulsory class were ranged disputes relating to pecuniary damages sustained by a state owing to the illegal or negligent action of another state—disputes relating to the interpretation of postal, telegraph, and railway conventions, of conventions relating to the navigation of international rivers, and divers other matters. To this convention (officially described as the "Russian project") was appended a draft code of procedure closely resembling that under which the Venezuelan arbitration was at that moment being conducted in Paris. Sir Julian Pauncefote took a bolder line. He urged, in a few pithy sentences, the importance of organizing a permanent international tribunal, the services of which might be called into requisition at will, and produced to the committee a short sketch of the mode in which such a tribunal might be set up. His proposition met with general acceptance, and the committee then proceeded to settle the necessary details for carrying it out, adopting in the main the code of procedure which had been suggested by Russia.

The result was embodied in twenty-seven articles, of which only the most important can be noted here. (Art. 23) Each of the signatory powers is to designate within three months from the ratification of the Convention four persons at the most, of recognized competence in international law, enjoying the highest moral consideration, and willing to accept the duties of arbitrators. Two or more powers may agree to nominate one or more members in common, or the same person may be nominated by different powers. Members of the court are to be appointed for six years, and may be re-nominated. (Art. 25) The signatory powers desiring to apply to the tribunal for the settlement of a difference between them are to notify the same to the arbitrators. The arbitrators who are to determine this difference are, unless otherwise specially agreed, to be chosen from the general list of members in the following manner:—each party is to name two arbitrators, and these are to choose a chief arbitrator or umpire (*sur-arbitre*). If the votes are equally divided the selection of the chief arbitrator is to be entrusted to a third power to be named by the parties. (Art. 25) The tribunal is to sit at the Hague when practicable, unless the parties otherwise agree. (Art. 27) "The signatory powers consider it a duty in the event of an acute conflict threatening to break out between two or more of them to remind these latter that the permanent court is open to them. This action is only to be considered as an exercise of good offices."

The procedure of the court is proposed to be regulated by twenty-seven articles, in which the following points are the most important. The agent of each party is first to communicate to the court and to the opposite party all deeds and documents on which it proposes to rely, one copy at least being in the language which the court authorizes to be used before it. After the documentary evidence has been lodged, the oral argument is to begin. This is to be taken down in writing, but it is only to be made public with the consent of the parties. The members of the tribunal may

question the agents and counsel on any point which they desire to have cleared up. The tribunal is to be the sole judge of the extent of its own jurisdiction and of the rules of international law, if any, which are applicable to the case. The deliberations of the court are to take place with closed doors. The decision is to be that of the majority, and is to set forth the reasons on which it is based. It is to be in writing and signed by all the members, the minority members when appending their signature being at liberty to signify their dissent. There is to be no appeal; but if a new fact is discovered, which was unknown at the time both to the tribunal and to the party alleging it, and the fact be such that had it been then known it might have exercised a decided influence on the decision, that decision may be revised. Before, however, revision can be had, the tribunal must recognize the existence of the new fact or facts and admit them to have the characteristics just mentioned.

The Hague arbitration Convention was signed on 29th July 1899, on behalf of France, Russia, the United States, and thirteen other powers. It was also signed a few days later on behalf of Great Britain. On 4th September 1900, all the powers represented, with the exception of China, duly deposited formal ratifications of the Convention at the foreign office of the Dutch Government. Several of the powers nominated members of the Permanent Arbitration Court, pursuant to Art. 23 mentioned above, those nominated on behalf of Great Britain being Lord Pauncefote, Sir Edward Malet, Sir Edward Fry, and Professor Westlake.

Although, in some of the treaties and most of the projects enumerated above, the range of matters proper to be dealt with by international arbitration is assumed to be unlimited, there is a general *Limits and prospects.* consensus of opinion amongst specialists that some limitation there must be. Bluntschli, Rouard de Card, Goldschmidt, Kamarowski, Ferdinand Dreyfus, Michel Revon, all exclude questions of national independence, and some of them also exclude questions of "national honour" and of "territorial integrity." The language in which these reservations are couched is not, however, particularly happy, since it is open to more interpretations than one. What, for instance, is meant by the phrase "national independence" in this connexion? If it be taken in its strict acceptance of autonomous state sovereignty, the exception is somewhat of a truism. No self-respecting power would, of course, consent to submit to arbitration a question of life or death. This would be as if a man were to commit suicide in order to avoid fighting a duel. On the other hand, if the exception be taken to exclude all questions which, when decided adversely to a state, impose a restraint on its freedom of action, then the exception is too wide, since it would exclude such a question as the true interpretation of an ambiguous treaty, a subject with which experience shows international arbitration is well fitted to deal. Again, we may ask, what is meant by the phrase "national honour"? It was thought at one time that the honour of a nation could only be vindicated by war, though all that had happened was the slighting of its flag or its accredited representative during some sudden ebullition of local feeling. France once nearly broke off peaceful relations with Spain because her ambassador at London was assigned a place below the Spanish ambassador, and on another occasion she despatched troops into Italy because her ambassador at Rome had been insulted by the friends and partisans of the Pope. The truth is that the extent to which national honour is involved depends on factors which have nothing to do with the immediate subject of complaint. So long as general good feeling subsists between two nations, neither will easily take offence at any discourteous act of the other. But when a deep-seated antagonism is concealed beneath an unruffled surface, the most trivial incident will bring it to the light of day. "Outraged national honour" is a highly elastic phrase. It may serve as a pretext for a

serious quarrel whether the alleged "outrage" be great or small. A similar criticism may be passed on the phrase "territorial integrity." Every boundary dispute is a dispute about territory, and nothing is easier than for a state to declare that the tract of land it covets forms, or—like the *angulus ille* of Horace—ought to form, an integral part of its dominions. Yet, as we have seen, this class of dispute is just that which has been most frequently arbitrated on, and in nearly every case successfully.

Weighing, then, each of these exceptions in the balance, and finding them all wanting in precision, we prefer to discard them altogether and to cast about for a fresh classification. M. Despagne has suggested one in his work on *Public International Law* (Paris, 1894) which is both convenient and complete. All state differences, this writer points out, may be classed, as regards their subject matter, under one of two heads—(1) those which have a legal character, (2) those which have a political character. Under "legal differences" may be ranged as many as are capable of being decided, when once the facts are ascertained, by settled, recognized rules, or by rules not settled nor recognized but (as in the *Alabama* case) taken to be such for the purpose in hand. Boundary cases and cases of indemnity for losses sustained by non-combatants in time of war, of which we have already mentioned several instances, belong to this class. To it also belong those cases in which arbitrators have to adapt the provisions of an old treaty to new and altered circumstances, somewhat in the way in which English courts of justice apply the doctrine of *cy-pres*. Of these last the Newfoundland fishery case is an illustration. "Political differences," on the other hand, are such as affect states in their external relations or in relation to their subjects or dependants who may be in revolt against them. Some of these differences may be slight, whilst others may be vital, or (which amounts to the same thing) may seem to the parties to be so. All differences falling under the first of these two general heads appear to be suitable for international arbitration. Differences falling under the second general head are for the most part unsuitable, and may only be adjusted (if at all) through the mediation of a friendly power.

The interesting problem of the future is, Are we to regard this condition of things as permanent or as transitory? The answer depends on several considerations which can only be glanced at here. It may be that, just as the usages of civilized nations have slowly crystallized into international law, so there may come a time when the political principles that govern states in relation to each other will be so clearly defined and so generally accepted as to acquire something of a legal or quasi-legal character. If they do, they will pass the line which at present separates arbitrable from non-arbitrable matter. This is the juridical aspect of the problem. But there is also an economic side to it by reason of the conditions of modern warfare. As M. de Bloch has explained at some length in his monumental treatise on the subject, war has become much more terrible now than formerly, in consequence of the increase of armaments and the greater

perfection of weapons of destruction. Already the nations are groaning under the burdens of militarism, and are for ever diverting energies that might be employed in the furtherance of useful productive work to purposes of an opposite character. The interruption of maritime intercourse, the stagnation of industry and trade, the rise in the price of the necessaries of life, the impossibility of adequately providing for the families of those—call them reservists, *landwehr*, or what you will—who are torn away from their daily toil to serve in the tented field,—these are considerations that may well make us pause before we abandon a peaceful solution and appeal to brute force. Lastly, there is the moral aspect of the problem. In order that international arbitration may do its perfect work, it is not enough to set up a standing tribunal, whether at the Hague or elsewhere, and to equip it with elaborate rules of procedure. Tribunals and rules are, after all, only machinery. If this machinery is to act smoothly we must improve our motive power, the source of which is human passion and sentiment. Although religious animosities between Christian nations have died out, although dynasties may now rise and fall without rousing half Europe to arms, the springs of warlike enterprise are still to be found in commercial jealousies, in imperialistic ambitions, and in the doctrine of the survival of the fittest which lends scientific support to both. These must one and all be cleared off the world's stage before we can enter on that era of universal peace towards the attainment of which the Tsar declared, in his famous circular of 1898, the efforts of all governments should be directed.

AUTHORITIES.—Amongst special treatises are—KAMAROWSKY, *Le tribunal international* (traduit par Serge de Westman), Paris, 1887; ROUARD DE CARD, *Les destinées de l'arbitrage international, depuis la sentence rendue par le tribunal de Genève*, Paris, 1892; MICHEL REVON, *L'arbitrage international*, Paris, 1892; ALESSANDRO CORSI (Marchese), *Arbitrati Internazionali*, Pisa, 1894; FERDINAND DREYFUS, *L'arbitrage international*, Paris, 1894 (where the earlier authorities are collected); A. MERIGNHAC, *Traité de l'arbitrage international*, Paris, 1895; LE CHEVALIER DESCAMPS, *Essai sur l'organisation de l'arbitrage international*, Bruxelles, 1896; FERAUD-GIRAUD, "Des traités d'arbitrage international général et permanent," *Revue de droit international*, Bruxelles, 1897. Of similar works in English there is a singular dearth. The most important is by an American, J. B. MOORE, *History of the International Arbitrations to which the United States has been a Party*, Washington, 1898. The Appendices to this work (which is in six volumes) contain, with much other matter of great value, full historical notes of arbitrations between other powers. Arbitration and Mediation will be found briefly noticed in PHILLIMORE'S *International Law*; in SIR HENRY MAINE'S *Lectures delivered in Cambridge in 1887*; in W. E. HALL'S *International Law* (Clarendon Press, Oxford); and more at length in an interesting paper contributed by MR JOHN WESTLAKE to the *International Journal of Ethics*, Oct. 1896, which its author has reprinted privately. A London journal, *The Herald of Peace and International Arbitration*, issued some years ago a list of instances in which arbitration or mediation had been successfully resorted to during the 19th century. The late Mr Dudley Field, of New York, subsequently enlarged this list, which has been revised down to 1899 by Dr W. Evans Darby, and is published, along with the texts of several projects for unlimited arbitration, at the offices of the Peace Society, 47 New Broad Street, London. *A History of the Hague Conference*, 1899, has been published by the International Arbitration Association, 40 Outer Temple, London. (M. H. C.)

Arboretum.—That part of a botanical garden which is reserved for the growth and display of trees is technically called an Arboretum. The term, in this restricted sense, was seemingly first so employed in 1838 by J. C. Loudon, in his book upon arboreta and fruit trees. Professor Bayley Balfour, F.R.S., the Regius Keeper of the Royal Botanic Garden in Edinburgh, has

described an arboretum as a living collection of species and varieties of trees and shrubs arranged after some definite method—it may be properties, or uses, or some other principle,—but usually after that of natural likeness. The plants are intended to be specimens showing the habit of the tree or shrub, and the collection is essentially an educational one. According to another point of view,

which is favoured by Mr Charles Jordan, the Superintendent of Regent's Park, London, an arboretum should be constructed with regard to picturesque beauty rather than systematically, although it is admitted that for scientific purposes a systematic arrangement is a *sine quâ non*. In this more general respect, an arboretum affords shelter, improves local climate, renovates bad soils, conceals objects unpleasing to the eye, heightens the effect of what is agreeable and graceful, and adds value, artistic and other, to the landscape. What Loudon called the "gardenesque" school of landscape naturally makes particular use of trees. By common consent the arboretum in the Royal Botanical Gardens at Kew is the finest in the world. Its beginnings may be traced back to 1762, when, at the suggestion of Lord Bute, the Duke of Argyll's trees and shrubs were removed from Whitton Place, near Hounslow, to adorn the Princess of Wales's garden at Kew. The Duke's collection was famous for its cedars, pines, and firs. Most of the trees of that date have perished, but the survivors embrace some of the finest of their kind in the gardens. The botanical gardens at Kew were thrown open to the public in 1841 under the directorate of Sir William Hooker. Including the arboretum, their total area did not then exceed 11 acres. Four years later the pleasure grounds and gardens at Kew occupied by the king of Hanover were given to the nation and placed under the care of Sir William for the express purpose of being converted into an arboretum. Hooker rose to the occasion, and, zealously reinforced by his son and successor, Sir Joseph—*patre claro filius clarior*—established a collection which is alike the envy and admiration of the botanists of every country. The Kew nursery dates from 1850 and the new pinetum from 1870. Of the total acreage (250) of the Gardens, no fewer than 180 acres are monopolized by the arboretum. Of the more specialized arboreta in the United Kingdom the next to Kew are those in the Royal Botanic Garden in Edinburgh and the Glasnevin Garden in Dublin. The gardens of the Royal Botanical Society in London are beautifully wooded, but owing to the limited space at its disposal (18 acres), the Society has not been able to make a speciality of trees. This is also true of the oldest botanical garden in Great Britain, at Oxford, which was founded in 1632. The quaint "Physic" garden at Chelsea, which Sir Hans Sloane gave to the Apothecaries' Society, is devoted to medicinal plants and herbs. In the Botanical Gardens at Glasgow, where Sir W. J. Hooker laboured before his transference to Kew, there are many choice trees, and in Bournemouth the gardens of the Evergreen Valley constitute to all intents and purposes an arboretum, even to the labelling of the specimens. In the United States the Arnold Arboretum at Boston ranks next to Kew for size and completeness. It takes its name from its donor, the friend of Emerson. It was originally a well-timbered park, which, by later additions, now covers 222 acres. Practically, it forms part of the park system so characteristic of the city, being situated only four miles from the centre of population. There is a fine arboretum in the botanical gardens at Ottawa, in Canada (65 acres). On the continent of Europe the classic example is still the Jardin des Plantes in Paris, where, however, system lends more of formality than of beauty to the general effect. Of course superb collections of trees were made before arboreta, as such, were devised. Noblemen and other wealthy amateurs collected trees, as other rich men collected paintings or books. They spared neither pains nor money in acquiring specimens, even from distant lands, to which they sent out expert collectors at their own charges. This, too, the Royal Horticultural Society (founded, 1804; charter, 1809) was once wont to do, with fruitful results, as in the case of Mr David Douglas's remarkable expedition to North

America in 1823-24. It will be remembered that when the Laird of Dumbiedikes lay dying (*The Heart of Midlothian*, chap. viii.) he gave his son one bit of advice which Bacon himself could not have bettered. "Jock," said the old reprobate, "when ye hae naething else to do, ye may be aye sticking in a tree; it will be growing, Jock, when ye're sleeping." Sir Walter assures us that a Scots earl took this maxim so seriously to heart that he planted a large tract of country with trees, a practice which in these days is promoted by the English and Royal Scottish Arboricultural Societies.

For the cultivation of trees, both in its technical and economic sense, the reader is referred to the exhaustive article on ARBORICULTURE in the ninth edition of this work and the article on FORESTS in this Supplement. (J. A. M.)

Arbroath, a royal and parliamentary burgh (Montrose group), seaport and manufacturing town of Forfarshire, Scotland, 77 miles N.N.E. of Edinburgh by rail. Spinning and weaving factories number over 30, and there are engineering works, boot factories, and chemical works. In 1877 the old harbour was converted into a wet dock, and the new harbour and entrance deepened. There is a shipbuilding yard, and at the end of 1898, 11 vessels of 1959 tons were registered as belonging to the port. Entrances and clearances were:—1898, entered 243 vessels of 30,588 tons, cleared 246 vessels of 29,435 tons. Recent erections include two churches, parish church (rebuilt), free library, guild hall (rebuilt), and academy. Population (1881), 21,995; (1901), 22,372.

Arcachon, a modern sea-side town of France, department of Gironde, arrondissement of Bordeaux, 37 miles W.S.W. of that city. It comprises two distinct parts, the summer town, extending for three miles along the shore on a firm sandy beach, and the winter town, more inland, with numerous villas scattered amongst pine woods, resorted to by consumptive patients. The neighbouring forest has an area of about 1300 square miles. The principal industries are oyster-culture and fishing. The former is conducted on a very large scale; there are 5900 oyster parks, covering an area of over 8000 acres, yielding, in 1898, 319,772,100 oysters, of the total value of £112,000. The port has trade with Spain and England. Population, 8000.

Arch, Joseph (1826—), founder of the National Agricultural Labourers' Union, was born at Barford, a village in Warwickshire, 10th November 1826. His parents belonged to the labouring class. He inherited a strong sentiment of independence from his mother; and his objections to the social homage expected by those whom the catechism boldly styled his "betters" made him an "agitator." Having educated himself by unremitting exertions, and acquired fluency of speech as a Methodist local preacher, he founded in 1872 the National Agricultural Labourers' Union, of which he was president. A rise then came in the wages of agricultural labourers, but this had the unforeseen effect of destroying the union; for the labourers, deeming their object gained, ceased to "agitate." Mr Arch nevertheless retained sufficient popularity to be returned to parliament for North-west Norfolk in 1885; and although defeated next year owing to his advocacy of Irish Home Rule, he regained his seat in 1892, and held it in 1895, retiring in 1900. He was deservedly respected in the House of Commons; seldom has an agitator been so little of a demagogue. A biography written by himself or under his direction, and edited by Lady Warwick (1898), tells the story of his career.

ARCHÆOLOGY (CLASSICAL).

IT is proposed in the present article to give some account of the progress and the results of archæological investigation in regard to the monuments of ancient Greece and Rome in the years since the publication of the ninth edition of this work. The articles on classical archæology and architecture were published in 1875, that on gems in 1879, that on pottery in 1885, that on terracottas in 1888. Generally speaking, therefore, we have to report the progress of twenty-five years. It is not intended here to re-discuss questions considered in the articles above mentioned, except so far as this may be made necessary by the discovery of new materials. For an account of the excavations carried on at various classical sites in recent years, the reader is referred to special articles in the present publication. Especially we must mention the articles on Athens, Eleusis, Mycenæ, Cyprus, Epidaurus, Megalopolis, Dodona, Rome, Delphi. In the present article the results of these excavations will be considered, not on the topographic or architectural side (see ARCHITECTURE, II.), but only in so far as they have extended our knowledge of ancient art, especially of sculpture. We begin with a general account of the progress made in institutions, in publications, and in excavations connected with classical archæology; afterwards we shall give, under periods, a more detailed account of recently discovered monuments and works of art, with the information to be derived from them.

Archæological Institutes.—Perhaps in no respect has the activity of the last quarter of the 19th century been more marked than in the founding and organization of institutions for the forwarding of archæological research. The old international "Istituto di Corrispondenza Archeologica" has been transmuted into the Roman branch of the German Archæological Institute. That great institution, which is the main centre of archæological activity, has its headquarters at Berlin, with branches at Rome and Athens. The French have also schools at Rome and Athens, as have now the English and Americans. Austria has recently established a powerful institute, with various branches. The Society for the Promotion of Hellenic Studies in England, the Archæological Institute in America, the Accademia dei Lincei in Italy, and the Greek Archæological Society, are all active in publishing journals, in finding the funds for excavations, and the scholars to take charge of them, and in extending archæological knowledge. France, Germany, and Austria provide from the public purse bursaries to trained archæological students, enabling them to stay for a term of years at the schools of Athens and Rome for purposes of study and research. In Germany also a certain number of teachers in the schools are every year provided with the means of making archæological tours in Greece and Italy, under the guidance of the best specialists; while in the great museums of Germany holiday courses are annually arranged for the benefit of students who wish to keep abreast of the progress of archæological discovery. In England and America efforts are made to work by private subscription in the same direction in which so much is done by the governments of the Continent with public funds. Travelling studentships at the universities, and bursaries awarded by the Committee of the British School at Athens, avail to prevent England from being entirely left behind in the movement; and the funds of the American Institute have in recent years enabled American students to do much excellent work in exploration.

Naturally also the great museums of Europe are not only centres of research, and keenly alive to the necessity of pro-

curring fresh objects, but also are awake to the duty of publishing in a systematic way the works of ancient art which they contain. Besides the public museums, we may mention, in this connexion, the Ny-Carlsberg collection at Copenhagen, the Tyszkiewicz collection, and the Barracco collection, the contents of which are published in excellent form.

Journals.—The most important periodicals in connexion with classical archæology are now the following:—Published in English: the *Journal of Hellenic Studies*, the *Annual of the British School at Athens*, *Archæologia*, the *American Journal of Archæology*. Published in French: *Bulletin de Correspondance Hellénique*, *Revue Archéologique*, *Monuments et Mémoires*, *Piot*. Published in German: *Jahrbuch des Arch. Instituts*, *Mittheilungen des Arch. Instituts*, *Römische Abtheilung* and *Athenische Abtheilung*, *Jahreshefte des oesterreich. Arch. Instituts*. Published in Italian: *Monumenti Antichi* and *Atti dell' Accad. dei Lincei*, *Bullettino della Commiss. Archeol. Comunale di Roma*. Published in Greek: *Ephemeris Archaiologikè*, *Deltion Archaiologikon*. To the subject of coins in particular, numismatic journals are dedicated in almost all countries of Europe; among them the English *Numismatic Chronicle* occupies a satisfactory position.

Books.—To give any complete account, or even a bare list, of important works on classical archæology published during the last twenty-five years would exceed the space at our disposal. We can select only a few works of special value, mentioning more particularly those which are published in English.

(1) *General Handbooks.*—Manuals of Classical Archæology have been published by Mr A. S. Murray and Mr Talfourd Ely. There is also a new brief *History of Greek Art* by Prof. F. B. Tarbell. Miss J. E. Harrison has published some *Introductory Studies in Greek Art*. A more complete *Griechische Kunstgeschichte* by Prof. Brunn, begun in 1893, does not come down below the archaic period. Sittl's *Klassische Kunst-Archäologie* is useful as a compendium. A new edition by Wernicke (recently deceased) of C. O. Müller's *Denkmäler der alten Kunst* is in progress. Of the greatest value to the ordinary scholar is Baumeister's *Denkmäler*, a dictionary of archæological evidence suited for easy reference. To those who wish to procure a mass of archæological material at moderate cost, it is safe to commend M. S. Reinach's *Répertoire de la statuaire grecque et romaine* and *Répertoire des vases peints grecs et étrusques*, published at five francs a volume, with his other cheap reprints of expensive works.

(2) *Architecture.*—There is no recent systematic work in English on classical architecture, but Mr Penrose's *Principles of Athenian Architecture* (new edition) is a work of importance. Besides the handbooks already mentioned, which give chapters to architecture, we may refer to the seventh volume of Perrot and Chipiez's *Histoire de l'art dans l'antiquité (La Grèce archaïque)*, Bötticher's *Tektonik der Hellenen*, and Uhde's *Architekturformen des class. Alterthums*, as well-illustrated and standard works.

(3) *Sculpture.*—A. S. Murray's *History of Greek Sculpture* and E. A. Gardner's *Handbook of Greek Sculpture* are important works; as is also H. Stuart Jones's *Ancient Writers on Greek Sculpture*. There are also valuable histories of Greek sculpture in French by Collignon, and in German by Overbeck (4th edit. 1893). Among recent books on sculpture in English may be mentioned Waldstein's *Essays on the Art of Pheidias*, Furtwängler's *Masterpieces of Greek Sculpture*, Michaelis's *Ancient Marbles in Great Britain*, and P. Gardner's *Sculptured Tombs of Hellas*. The German literature of the subject is very extensive.

(4) *Vases.*—A good book on Greek vases is at present a crying need. The most useful general book on the subject is Rayet and Collignon's *Histoire de la céramique grecque*. For archaic vases, Dumont and Chaplain's *Céramiques de la Grèce propre* is valuable, though somewhat out of date (1888). Prof. Furtwängler has just issued the first part of a great work on Greek vases, the plates of which are executed with great care, so as faithfully to represent the style of the vases. We have in English, Harrison and Maccoll's *Greek Vase Paintings*, and A. S. Murray's *Designs from*

Greek Vases in the British Museum, and *White Athenian Vases*; also the illustrated catalogues of vases in the British Museum, the Ashmolean and Fitzwilliam Museums, and the Louvre. Three small works in German by W. Klein, *Euphronios, Vasen mit Meistersignaturen*, and *Vasen mit Lieblingsinschriften*, are indispensable to the student. The best general collection of vase-paintings is still Gerhard's *Auserlesene Vasenbilder*, 1840.

(6) *Terra-Cottas*.—Two small works can be recommended: E. Pottier's *Statuettes de terre cuite*, and Miss C. A. Hutton's *Greek Terra-Cotta Statuettes*, which is published with A. S. Murray's *Greek Bronzes*.

(8) *Gems*.—A recent work is J. H. Middleton's *Engraved Gems of Classical Times*. But quite recently A. Furtwängler has published a large work on Greek gems, *Antike Gemmen*, which is the product of vast learning, and must needs form the basis of future study.

(7) *Coins*.—No branch of archæology has been more completely transformed in the last quarter of a century than numismatics. Previously, coins had been treated, much as gems are, as individual works of art, beautiful in themselves, and giving valuable information as to ancient mythology and geography. But in recent years the close and intimate relations which prevail between the coins of ancient cities and the history of those cities have been more closely regarded, from which point of view the exact dates and weights of the coins become most important. The strictly historic treatment of Roman coins was begun by Mommsen in his *Geschichte des römischen Münzwesens*. A similar treatment of Greek coins is attempted by Mr B. V. Head in his *Historia Numorum*, a work in which an endeavour is made to arrange the coins of all Greek cities under periods, in close connexion with the history of those cities. The *British Museum Catalogue of Greek Coins*, which is dominated by the same purpose, is now approaching completion. The *Historia Numorum* is the most useful work to a collector of Greek coins. To a collector of Roman coins M. Babelon's editions of Cohen's *Monnaies de la république romaine*, and *Monnaies de l'empire romain* are necessary. Mr G. F. Hill's *Handbook of Greek and Roman Coins* is an excellent summary. Prof. Ridgeway has published a work on the *Origin of Currency and Weight-Standards*. P. Gardner's *Types of Greek Coins* deals mainly with the art of coins.

(8) *Corpuses*.—The Academies of Berlin and Vienna have done much in recent years in the way of publishing vast collections and compendia of ancient monuments, each of which is a *Corpus*, that is, contains all known monuments of the class dealt with. It is impossible to overrate the value of these monumental publications, each of which, being complete up to the date of publication, relieves the student from the necessity of hunting through books of an earlier date. The *Corpus of Greek Inscriptions* by Boeckh, and the more recent *Corpus of Roman Inscriptions* and *Corpus of Attic Inscriptions* are well known. To these are now added, a *Corpus of Attic Sepulchral Monuments* (nearly complete), a *Corpus of Sarcophagi*, a *Corpus of Terra-Cottas*, a *Corpus of Greek Coins*, all in course of gradual publication. Other works of the same class are in preparation. The labour of producing these works is enormous, and for the most part it is unpaid, German archæologists freely spending their lives in the effort to advance scientific knowledge.

(9) *Other Works*.—Besides the works mentioned, we may set down a few books of a more general character: C. Diehl's *Excursions in Greece*, P. Gardner's *New Chapters in Greek History*, D. G. Hogarth's *Authority and Archæology*, *Sacred and Profane*, Lady Evans's *Greek Dress*, and the dictionaries of classical antiquities.

The valuable translation of and commentary on Pausanias' *Description of Greece*, by J. G. Frazer, has enabled the English reader for the first time to grasp the results of the great intellectual activity of the archæologists at Athens. The edition of Pliny's *Chapters on the History of Art*, by Misses Jex-Blake and Sellers, is also important. In the matter of bringing ancient monuments into relation with Greek mythology, the books of C. O. Müller have been succeeded by far more elaborate and completer works. Most comprehensive of all these is Overbeck's *Kunstmythologie*. The collection here made of monuments bearing on the cults of Zeus, Hera, Demeter, Poseidon, and Apollo is enormous; unfortunately, the completion of the work has been prevented by Prof. Overbeck's death. For monuments relating to other deities, we have to go to the *Lexicons* of Baumeister and Roscher. Mr L. R. Farnell has published in English a work called *Cults of the Greek States*, which deals in detail with the art representations of some of the Greek deities.

Research and Excavation.—Three sites of the first importance in Greece proper have been carefully excavated in the last quarter of a century, besides those like Troy,

Tiryns, and Mycenæ, which have yielded mainly pre-historic monuments. These are Olympia, the Athenian Acropolis, and Delphi. The excavation at Olympia was carried out at great cost by the German Government; and the results are published in a series of vast and costly volumes, which are epoch-making in the development of archæology. It must not be forgotten that in the thorough investigation of a great site like Olympia, which was for ages one of the chief centres of Greek life and art, the whole result is far greater than the sum of the separate discoveries. It is not merely that we have gained a knowledge of the plans of buildings and of their architectural details, a series of valuable works of sculpture and bronzes, and the text of a number of important documents recording treaties and decrees and public honours. We further discover the relations of these monuments among themselves. Their very situations and the level of their bases show us their respective dates and their comparative importance. We find ourselves in a museum, but in a museum not arranged on any arbitrary principle, but, so to speak, by the hands of history herself, affording us almost infinite opportunities for comparing, inferring, and connecting the remains which have come down to us with ancient belief and custom.

Of Delphi it is too early to speak, as the excavators to whom the task of its exploration has been confided by the French Government have as yet published but few of their results. But enough is known to assure us that the harvest on this site also is very rich. The topography of the site and the position of the main buildings and the principal dedications can be determined with accuracy. In sculpture of the end of the 6th and the early part of the 5th century, the site is certainly very rich, and the inscriptions are already known to be very numerous and of great historic value. (See DELPHI.)

The acropolis of Athens (*q.v.*) has been carefully and completely excavated by the Greek Archæological Society. The great importance of the finds is mainly due to an event which, at the time, must have seemed fatal to all record of the city's beauty—the havoc wrought by the Persians, when they occupied the rock-fortress in 480 B.C. When the Athenians in the next year, after the victory of Plataea, returned to their citadel, they found it a mass of ruins, and nothing remained but to bury out of sight the shattered fragments of their shrines and the works of art which had been dedicated to their goddess. But their loss has been our gain, for the wreck of the ruined Athens of the early 5th century has rested quietly in the ground from that day to this, and has only now been dragged forth and ranged in the Athenian museums. To the archæologist, nothing seems more desirable than to secure a fixed date for a series of monuments. And on this site the year 480 is defined by the circumstances of the case as the time below which all the monuments to be found in certain strata cannot be brought. We are thus able to reconstruct in imagination, at all events in outline, the surface of the Acropolis as it existed in the days of Pisistratus and of Themistocles.

The extensive precinct of the god Æsculapius in the neighbourhood of Epidaurus has also been cleared by the Greek archæologists under M. Kavvadias. Here the main interest, besides that which belongs to recovered fragments of buildings and series of sculptures, arises from the fact that Epidaurus was a sort of Baden of antiquity, a resort of those who were out of health and sought recovery either at the hands of the physician-god or from the natural salubrity of the place and its healthful regimen. We find on the spot not only shrines of the deities, but covered seats shielded from all the winds, an abundant supply of water for baths, porticoes as a refuge from summer heat, and a theatre and a stadium for the refresh-

ment of the mind and the exercise of the body. (See EPIDAURUS.)

Many other sites in Greece proper have yielded valuable results. At Megalopolis, a party of English students have recovered the plans of various buildings, in particular of the theatre and the hall of assembly where the representatives of the cities of Arcadia met in conclave. The ground plan of Corinth is being rapidly recovered by American archæologists, who have also succeeded in revealing the phases which the Argive Heræum passed through in the course of long ages. The temples of Apollo Ptoos in Bœotia, of Athena Alea at Tegea, of the great goddesses at Lycosura, have also been in part brought to light, with happy results for the history of Greek sculpture. Of these results we shall have to speak further in the course of this article.

Among the islands of the Ægean, there has been of late years much research and excavation. The results belong in great part to the prehistoric age of Greece, and are spoken of in the article on MYCENÆAN CIVILIZATION. But Delos in particular has furnished us not only with the foundations of temples and the plans of private houses, but also with some very important examples of sculpture, which may be said to give us the clue to the history of the rise of the art.

Mr Petrie's important excavations in Egypt, and the more recent and equally striking discoveries of Mr A. J. Evans in Crete, have been valuable as fixing the dates of early classes of Ægean and Mycenaean pottery, and revealing to us the nature of the early Ægean civilization. And the site of Naucratis in particular, excavated by Mr Petrie and Mr Ernest Gardner in 1884-86, has given us dates for various kinds of early Ionian pottery, as well as furnished us with valuable data for recovering the history of the Greek alphabet.

Partial excavations have been made on the sites of some of the great Ionian cities of Asia Minor. At Ephesus, the researches of Wood, which have enriched the British Museum with many architectural and sculptural fragments from the great temple of Artemis, have been resumed by the Austrian Government. The temple of Apollo at Miletus has been explored by MM. Rayet and Thomas; further excavations are taking place on this site. The Americans have made extensive excavations at Assos. The site of Pergamon, which has been occupied by the German Archæological Institute, has yielded results which have added an important chapter to Greek art, and shown us the sculptors of Greece working under new conditions and in a new style. Clazomenæ and other cities have furnished us from their burying-grounds sarcophagi and painted vases which throw light on the origin and early history of Ionian art. It is unnecessary to proceed further with this enumeration; what has been written will be sufficient to give the reader some idea of the energy with which excavation has been carried on in Greece of late years, and of the richness and variety of the results which it has attained.

Turning to Italy, we naturally think first of Rome. In that centre of the world, the main interest of all excavation must be topographic and historic, and for results of this character the reader must turn to the article ROMÆ. But in the course of investigation a great number of important works of ancient sculpture and painting have been brought to light, most of which now adorn the museums of the Capitol and the new museum of the Terme. We may instance the wonderful bronze figures of a Hellenistic king and of a pugilist, and the wall-paintings of the house at Prima Porta. Of other excavations in Italy, an excellent summary will be found in Prof. von Duhn's article in vol. xvi. of the *Journal of Hellenic*

Studies. At Locri two Ionic temples have been discovered. The building of an arsenal at Tarentum has been the occasion of the discovery of very rich deposits of terra-cotta votive offerings. At Pompeii a house of great beauty and interest, which bears the name of the Vettii, has been found, and has furnished a number of fresh paintings. Excavations at Falerii deserve a particular mention, because their results are separately arranged in a special museum at Rome, that of the Villa Papa Giulio, giving us materials for tracing the artistic history of the city from period to period. At this museum is also a very attractive restoration of a Greek temple, with its decoration in terra-cotta and its brilliant colouring.

The researches of Signor Orsi in Sicily on the sites of Megara and Syracuse have resulted in the establishment of an archæological history of Sicily, which may be traced in the museums of Syracuse and Palermo from the earliest days down to the period of Greek invasion, and onwards to the Roman age. The site of Selinus, which has long been a valuable mine of sculpture of the early period, has again in recent years furnished us with metopes from its temples of great interest; and the plan of the city has now been in great measure laid bare, as well as of the fortifications erected by Hermocrates, when at the end of the 5th century he turned the ruins of the town into a fortress whence to wage war against the Carthaginians. No country is more full of the memorials of history than Sicily; but we cannot pursue this subject; we must refer the reader to the ample and most interesting history of Sicily by Mr Freeman, a writer who fully understood how much light existing remains may cast on the past history of a city.

A class of ancient buildings which has received special attention in recent years is the great open-air theatres with which every Greek city was provided. *Theatres.* Fresh theatres have been excavated at Piræus, Eretria, Delos, Megalopolis, Epidaurus, and other places; and the model of all such erections, the theatre of Dionysus at Athens, has been most carefully investigated. In this work the leading part has been taken by Dr Dörpfeld of Athens. The result has been the setting forth by Dr Dörpfeld, with the utmost skill, of the view that there was no stage in use in Greek theatres, but that the actors and the chorus performed together in the space at the back of the orchestra, and in front of the stage buildings. (See Dörpfeld and Reisch, *Das griechische Theater*.) This novel view has met with severe criticism in Germany, and especially in England. The arguments against it are set forth by Haigh, in his *Attic Theatre*. It is likely that scholars will long be divided in their opinions as to the existence or non-existence of a stage among the Greeks. In the opinion of the present writer it can be proved from extant remains that a stage was in use in Greek theatres of the 3rd century B.C., and although we cannot demonstrate that the same was the case in the days of the great Attic tragedians, it is by far the most likely supposition. However this be, the researches and the book of Dr Dörpfeld have enabled us to approach all questions in regard to the staging of Greek plays with far greater knowledge.

The materials for a reconstruction of the private houses of the Greeks have also been rapidly accumulating. At Delos, at Assos, at Priene, and on other sites, the plans of ancient houses have been brought to light. *Houses.* At present, few of these plans have been published; but it has become clear that we have hitherto been misled by Vitruvius into the belief that Greek houses were of uniform plan, like the temples; whereas they varied greatly according to the ground, the fortune of the builder, or the fashion of the district. For gaining a sense of the

external conditions of ancient life, Pompeii is still by far the most useful site. The recent book on Pompeii by Mau, translated by Kelsey, is by a writer who has an unequalled knowledge of the site; and the more ambitious work of C. Weichardt (*Pompeii vor der Zerstörung*) brings before the reader's eyes, by means of skilled restorations, the actual state of Pompeii before its sudden destruction.

We propose next to treat briefly of the advances made by recent discovery in our knowledge of Greek and Roman monuments and art, dividing our account into the same periods which Mr Murray has adopted in his article, CLASSICAL ARCHÆOLOGY, in the ninth edition of this Encyclopædia.¹

The periods accepted are the following:—I. 900-700 B.C. II. 700-480 B.C. III. 480-400 B.C. IV. 400-320 B.C. V. After 320 B.C.

Period I. 900-700 B.C.

In Mr A. S. Murray's earlier article the art of the later prehistoric age of Greece, now usually called the Mycenaean age, is included with that of historic Greece, to which indeed it naturally serves as an introduction. But for our present purposes the art of Mycenæ is reserved for separate treatment (see MYCENÆAN CIVILIZATION). We have therefore to deal only with the art which succeeded that called Mycenaean, beginning about the year 900 B.C. The fact is now generally allowed that the Mycenaean civilization was for the most part destroyed by an invasion

Dorian invasion.

from the north. This invasion appears to be that called in Greek tradition the Dorian immigration. Archæological evidence abundantly proves that it was the conquest of a more by a less rich and civilized race. In the graves of the period 900-700 B.C. we find none of the wealthy spoil which has made celebrated the tombs of Mycenæ and Baphion (Vaphio). The character of the pottery and the bronze-work which is found in these later graves reminds us of the art of the necropolis of Hallstadt in Austria, and other sites belonging to what is called the bronze age of North Europe. Its predominant characteristic is the use of geometrical forms, the lozenge, the triangle, the mæander, the circle with tangents, in place of the elaborate spirals and plant-forms which mark Mycenaean ware. For this reason the period from the 9th to the 7th century in Greece passes by the name of "the Geometric Age." It would seem that in the remains of the Geometric Age we may trace the influence of the Dorians, who, coming in as a hardy but uncultivated race, probably of purer Aryan blood than the previous inhabitants of Greece, not only brought to an end the wealth and the luxury which marked the Mycenaean age, but also replaced an art which was in character essentially Oriental by one which belonged rather to the North and the West. The great difficulty inherent in this view, a difficulty which has yet to be met, lies in the fact that some of the most abundant and characteristic remains of the geometric age which we possess come, not from Peloponnesus, but from Athens and Bœotia, which were never conquered by the Dorians.

The geometric ware is for the most part adorned with painted patterns only. We engrave (Fig. 1) a characteristic example, a small two-handled vase from Rhodes in the Ashmolean Museum, the adornment of which consists in zigzags, circles with tangents, and lines of water-birds, perhaps swans. Other geometric vases will be found in *Ency. Brit.* vol. xix. p. 607, Fig. 16. Sometimes, however, especially in the case of large vases

¹ It is not to be supposed that the present writer agrees with all the views set forth by Mr Murray in that article; on many of the subjects of which he treats scholars will always differ among themselves.

from the cemetery at Athens which adjoins the Dipylon gate, scenes from Greek life are depicted, from daily life, not from legend or divine myth. Especially scenes from the lying in state and the burial of the dead are prevalent. We engrave an excerpt from a Dipylon vase (Fig. 2), in which is seen a dead man on his couch surrounded by

FIG. 1.—Geometric vase from Rhodes. Ashmolean Museum.

mourners, male and female. Both sexes are apparently represented naked, and are distinguished very simply; some of them hold branches to sprinkle the corpse or to keep away flies. It will be seen how primitive and conventional is the drawing of this age, presenting a wonderful contrast to the free drawing and realistic modelling of the Mycenaean age. In the same graves with the pottery are sometimes found plaques of gold or bronze,

FIG. 2.—Corpse with mourners. *Mon. d. Inst.* ix. 89.

and towards the end of the geometric age these sometimes bear scenes from mythology, treated with the greatest simplicity. For example, in the museum of Berlin are the contents of a tomb found at Corinth, consisting mainly of gold work of geometric character. But in the same tomb were also found gold plates or plaques of *repoussé* work bearing subjects from Greek legend.

FIG. 3.—Gold plaques: Corinth. *Aroh. Zeit.* 1884, 8.

Two of these (Fig. 3) we engrave. On one plate Theseus is slaying the Minotaur, while Ariadne stands by and encourages the hero. The tale could not have been told in a simpler or more straightforward way. On another plate we have an armed warrior with his charioteer in a chariot drawn by two horses. The

treatment of the human body is here more advanced than

FIG. 4.—Handle of tripod: Olympia, iv. 38.

on the vases of the Dipylon. On the site of Olympia, where Mycenaean remains are not found, but the earliest monuments seem to belong to the Dorian age, a quantity of dedications in bronze have been found, the decoration of which belongs to this style. We engrave (Fig. 4) the handle of a tripod from Olympia, which is adorned with geometric patterns and surmounted by the figure of a horse. In the 7th century, however, it was

not unusual to adorn votive tripods and coffers with mythologic representations. Especially interesting is one plate of bronze, also from Olympia, used for some such purpose (Fig. 5), and showing in *repoussé* work, finished with the graving tool, a winged Artemis grasping two lions, and Herakles shooting a centaur, whose front legs are human, not equine. In the upper lines of the relief are pairs of eagles and griffins. Another similar plate represents again Herakles shooting. More than one breastplate has come from Olympia engraved by the tool with scenes such as one finds on early vases. Votive models of animals are also abundant. In fact, the history of Greek art from 800 to 500 B.C. can be nowhere better traced than in the plates of Furtwängler's great work on the bronzes of Olympia.

FIG. 5.—Bronze plate: Olympia.

Period II. 700-480 B.C.

It was in the 6th century that the genius of the Greeks, almost suddenly, as it seems to us, emancipated itself from the thralldom of tradition and passed beyond the limits with which the nations of the East and West had hitherto been content, in a free and bold effort towards the ideal. Thus the 6th century marks the stage in art in which it may be said to have become definitely Hellenic. The Greeks still borrowed many of their decorative forms, through Phœnician agency, from the old-world empires of Egypt and Babylon, but they used those forms freely to express their own meaning. And gradually, in the course of the century, we see both in the painting of vases and in sculpture a national spirit and a national style forming under the influence of Greek religion and mythology, Greek athletic training, Greek worship of beauty. We must here lay emphasis on the fact, which is sometimes overlooked in an age which is greatly given to the Darwinian search after origins, that it is one thing to trace

back to its original sources the nascent art of Greece, and quite another thing to follow and to understand its gradual embodiment of Hellenic ideas and civilization. The immense success with which the veil has in late years been lifted from the prehistoric age of Greece, and the clearness with which we can discern the various strands woven into the web of Greek art, have tended to fix our attention rather on what Greece possessed in common with all other peoples at the same early stage of civilization than on what Greece added for herself to this common stock. In many respects the art of Greece is incomparable—one of the great inspirations which have redeemed the world from mediocrity and vulgarity. And it is the searching out and appreciation of this unique and ideal beauty in all its phases, in idea and composition and execution, which is the true task of Greek archæological science.

In very recent years it has been possible, for the first time, to trace the influence of Ionian painting, as represented by vases, on the rise of art. The discoveries at Naucratis and Daphnæ in Egypt, due to the keenness and pertinacity of Mr Petrie, opened a new light in this matter. It became evident that when those cities were first inhabited by Ionian Greeks, in the 7th century, they used pottery of several distinct but allied styles, the most notable feature of which was the use of the lotus in decoration, the presence of continuous friezes of animals and of monsters, and the filling up of the background with rosettes, lozenges, and other forms. We engrave a vase found in Rhodes (Fig. 6) to illustrate this Ionian decoration. The sphinx, the deer, and the swan are prominent on it, the last-named serving as a link between the geometric ware and the more brilliant and varied ware of the Ionian cities.

Ionian vases.

The assignment of the many species of early Ionic ware to various Greek localities, Miletus, Samos, Phocæa, and other cities, is a work of great difficulty, which is now closely occupying the attention of archæologists. For the results of their studies the reader is referred to two recent German works, Boehlau's *Aus ionischen und italischen Nekropolen*, and Endt's *Beiträge zur ionischen Vasenmalerei*.

The feature which is most interesting in this pottery from our present point of view is the way in which representations of Greek myth and legend gradually make their way, and relegate the mere decoration of the vases to borders and neck. One of the earliest examples of representation of a really Greek subject is the contest of Menelaus and Euphorbus on a plate found in Rhodes (*Ency. Brit.* xix. p. 611, Fig. 24). On the vases of Melos, of the 7th century, which are, however, not Ionian, but rather Dorian in character, we have a certain number of mythological scenes, battles of Homeric heroes, and the like. One of these we engrave (Fig. 7). It represents Apollo in a chariot drawn by winged horses, playing on the lyre, and accompanied by a pair of Muses, meeting his sister Artemis. It is notable that Apollo is bearded, and that Artemis holds her stag

FIG. 6.—Jug from Rhodes. Mus. Napoléon, 57.

by the horns, much in the manner of the deities on Babylonian cylinders; in the other hand she carries an arrow; above is a line of water-birds.

Some sites in Asia Minor and the islands adjoining, such cities as Samos, Cameirus in Rhodes, and the Ionian colonies on the Black Sea, have furnished us with a mass

FIG. 7.—Vase painting: Melos. Conze, *Mel. Thongefässe*, 4.

of ware of the Ionian class, but it seldom bears interesting subjects; it is essentially decorative. For Ionian ware which has closer relation to Greek mythology and history we must turn elsewhere. The cemeteries of the great Etruscan cities, Cære in particular, have preserved for us a large number of vases, which are now generally recognized as Ionian in design and drawing, though they may in some cases be only Italian imitations of Ionian imported ware. Thus has been filled up what was a blank page in the history of early Greek art. The Ionian painting is unrestrained in character, characterized by a license not foreign to the nature of the race, and wants the self-control and moderation which belong to Doric art, and to Attic art after the first.

Some of the most interesting examples of early Ionic painting are found on the sarcophagi of Clazomenæ. In that city in archaic times an exceptional custom prevailed of burying the dead in great coffins of terra-cotta adorned with painted scenes from chariot-racing, war, and the chase. The British Museum possesses some remarkable specimens, which are published by Mr Murray in his *Terra-Cotta Sarcophagi of the British Museum*. On one of them he sees depicted a battle between Cimmerian invaders and Greeks, the former accompanied to the field by their great war-dogs. In some of the representations of hunting on these sarcophagi the hunters ride in chariots, a way of hunting quite foreign to the Greeks, but familiar to us from Assyrian wall-sculptures. We know that the life of the Ionians before the Persian conquest was refined and not untinged with luxury, and they borrowed many of the stately ways of the satraps of the kings of Assyria and Persia.

In Fig. 8 we engrave a curious product of the Ionian workshops, a fish of solid gold, adorned with reliefs which

FIG. 8.—Fish of Gold. Furtwängler, *Goldfund v. Vetersfelde*.

represent a flying eagle, lions pulling down their prey, and a monstrous sea-god among his fishes. This relic is

the more valuable on account of the spot where it was found—Vetersfelde in Brandenburg. It furnishes a proof that the influence and perhaps the commerce of the Greek colonies on the Black Sea spread far to the north through the countries of the Scythians and other barbarians. The fish dates from the 6th century B.C.

From Ionia the style of vase-painting which has been called by various names, but may best be termed the "orientalizing," spread to Greece proper. Its main home here was in Corinth; and small Corinthian unguent-vases bearing figures of swans, lions, monsters, and human beings, the intervals between which are filled by rosettes, are found wherever Corinthian trade penetrated, notably in the cemeteries of Sicily. For the larger Corinthian vases, which bore more elaborate scenes from mythology, we must again turn to the graves of the cities of Etruria. Here, besides the Ionian ware, of which mention has already been made, we find pottery of three Greek cities clearly defined, that of Corinth, that of Chalcis in Eubœa, and that of Athens. Corinthian and Chalcidian ware is most readily distinguished by means of the alphabets used in the inscriptions (see *Ency. Brit.* xix. p. 609), which have distinctive forms easily to be identified. Whether in the paintings coming from the various cities any distinct differences may be traced is a far more difficult question, into which we cannot now enter. The subjects are mostly from heroic legend, and are treated with great simplicity and directness. There is a manly vigour about them which distinguishes them at a glance from the laxer works of Ionian style. We figure (Fig. 9) a group from a Chalcidian vase which represents the conflict over the

FIG. 9.—Fight over the body of Achilles. *Mon. d. Inst.* i. 51.

dead body of Achilles. The corpse of the hero lies in the midst, the arrow in his heel. The Trojan Glaucus tries to drag away the body by means of a rope tied round the ankle, but in doing so is transfixed by the spear of Ajax, who charges under the protection of the goddess Athena. Paris on the Trojan side shoots an arrow at Ajax. The other combatants of the group we omit for want of space. In Fig. 10 is a scene from a Corinthian vase. Ajax falls on his sword in the presence of his colleagues, Odysseus and Diomedes. The short stature of Odysseus is a well-known Homeric feature. These vases are black-figured; the heroes are painted in silhouette on the red ground of the vases. Their names are appended in archaic Greek letters.

The early history of vase-painting at Athens is complicated. It was only by degrees that the geometric style gave way to, or developed into, what is known as the black-figured style. It would seem that until the age of Pisistratus Athens was not notable in the world of art, and nothing could be ruder than some of the vases of Athens in the 7th century, for example that here figured, on one side of which are represented the winged Harpies (Fig. 11) and on the other Perseus accompanied by Athena flying from the pursuit of the Gorgons. This vase retains in its decoration some features of geometric style; but the lotus and rosette, the lion and sphinx,

which appear on it, belong to the wave of Ionian influence. Although it involves a departure from strict chronological order, it will be well here to follow the course of development in pottery at Athens until the

in 564 B.C. We engrave (Fig. 12) the reverse of a somewhat later black-figured vase of the Panathenaic class, given at Athens as a prize to the winner of a foot-race at the Panathenæa, with the foot-race (*stadion*) represented on it. A large number of Athenian vases of the 6th century have reached us, which bear the signatures of the potters who made, or the artists who painted them; lists of these will be found in the useful work of Klein, *Griechische Vasen mit Meistersignaturen*. The recent excavations on the acropolis have proved the erroneousness of the view, strongly maintained by Brunn, that the mass of the black-figured vases were of a late and imitative fabric. We now know that, with a few exceptions, vases of this class are not later than the early part of the 5th century. The same excavations have also proved that red-figured vase-painting, that is, vase-painting in which the background was blocked out with black, and the figures left in the natural colour of the vase (*Ency. Brit.* xix. p. 613) originated at Athens in the last quarter of the 6th century. We cannot here give a detailed account of the beautiful series of Athenian vases of this fabric. Many of the finest of them are in the British Museum. We engrave, as an example (Fig. 13), a group by the painter Pamphæus, representing Heracles wrestling with the river-monster Achelous, which belongs to the age of the

FIG. 10.—Suicide of Ajax. *Mus. Napoléon*, 66.

end of our period. Neighbouring cities, and especially Corinth, seem to have exercised a strong influence at Athens about the 7th century. We have even a class of vases called by archæologists Corintho-Attic. But in the course of the 6th century there is formed at Athens a

FIG. 11.—Harpies: Attic vase. *Arch. Zeit.* 1882, 9.

distinct and marked black-figured style. The most remarkable example of this ware is the so-called François vase at Munich, by Clitias and Ergotimus, recently smashed by a madman, which contains, in most careful and precise rendering, a number of scenes from Greek

(T A I O - P O N N) R .

FIG. 12.—Foot-race: Panathenaic vase. *Mon. d. Inst.* x. 48 m.

myth. One of these vases is dated, since it bears the name and the figure of Callias in his chariot (*Mon. dell' Inst.* iii. 45), and this Callias won a victory at Olympia

FIG. 13.—Herakles and Achelous. *Wiener Vorlegeblätter*, D. 6.

Persian wars. The clear precision of the figures, the vigour of the grouping, the correctness of the anatomy, and the delicacy of the lines are all marks of distinction. The student of art will perhaps find the nearest parallel to these vase-pictures in Japanese drawings (*q.v.*). The Japanese artists are very inferior to the Greek in their love and understanding of the human body, but equal them in freshness and vigour of design. At the same time began the beautiful series of white vases made at Athens for the purpose of burial with the dead, and found in great quantities in the cemeteries of Athens, of Eretria, of Gela in Sicily, and of some other cities. They are well represented in the British Museum, and that of Oxford.

We now return to the early years of the 6th century, and proceed to trace, by the aid of recent discoveries, the rise of architecture and sculpture. The Greek temple in its character and form gives the clue to the whole character of Greek art. It is the abode of the deity, who is represented by his sacred image; and the flat surfaces of the temple offer a great field to the sculptor for the depicting of sacred legend. The process of discovery has emphasized the line which divides Ionian from Dorian architecture and art. We will speak first of the temples and the sculpture of Ionia. The Ionians were a people

far more susceptible than the Dorians to the influences of Oriental civilization. The dress, the art, and the luxury of Western Asia irresistibly attracted them, and we may suspect that Ionian workmen in the service of Asiatic rulers contributed largely to the adornment and the beauty of the palaces of Nineveh and Persepolis. Two of the great Ionian temples, dating from the 6th century, have been excavated in recent years. At Miletus, the labours of Messrs Rayet and Thomas have succeeded in discovering the plan of the great temple of Apollo, and even of the underground oracular chamber which lay beneath it, but the architectural fragments which they have brought to light belong all to a later construction; and the only figures which can be considered as belonging to the original temple destroyed by Darius are the dedicated seated statues, some of which, brought away by Sir Charles Newton, are now preserved at the British Museum. At Ephesus Mr Wood has been

FIG. 14.—Sculptured pillar: Ephesus. Brit. Museum.

more successful, and has recovered considerable fragments of the temple of Artemis, to which, as Herodotus tells us, Croesus presented many columns. The lower part of one of these columns, bearing figures in relief of early Ionian style, has been put together at the British Museum (Fig. 14); and remains of inscriptions recording the presentation by Croesus are still to be traced. Reliefs from a cornice of somewhat later date are also to be found at the British Museum. Among the Ægean islands, Delos has furnished us with the most important remains of early art. French excavators have there found a very early statue of a woman dedicated by one Nicandra to Artemis (Fig. 16), a figure which may be instructively compared with another from Samos, dedicated to Hera by Cheramnes. The Delian statue is in shape like a flat beam; the Samian, which is headless, is like a round tree. The arms of the Delian figure are rigid to the sides; the Samian lady has one arm clasped to her breast (Fig. 15). A great improvement on these helpless and inexpressive figures is marked by another figure found at Delos, and connected, though without absolute certainty, with a basis recording the execution of the statue by Archermus and Micciades, two sculptors who stood, in the middle of the 6th century, at the head of a sculptural school at Chios. The representation (Fig. 17) is of a running or flying figure, having six wings, like the seraphim in the vision of Isaiah, and clad in long drapery. It may be a statue of Nike or Victory, who is said to have been represented in winged form by Archermus. The figure, with its neatness and precision of work, its expressive face and strong outlines, certainly marks great progress in the art of sculpture. When we examine the early sculpture of Athens, we find reason to think that the Chian school had great influence in that city in the days of Pisistratus.

At Athens, in the age 650-480, we may trace two quite distinct periods of architecture and sculpture. In the earlier of the two periods, a rough limestone was used

alike for the walls and the sculptural decoration of temples; in the later period it was superseded by marble, whether native or imported. Every visitor to the museum of the Athenian acropolis stands astonished at the recently recovered groups which decorated the pediments of Athenian temples before the Page of isistratus—groups of large size, rudely cut in soft

FIG. 15.—Figure dedicated to Hera: Paris.

FIG. 16.—Figure dedicated to Artemis: Athens.

stone, of primitive workmanship, and painted with bright red, blue, and green, in a fashion which makes no attempt to follow nature, but only to produce a vivid result. The two largest in scale of these groups seem to have belonged to the pediments of the early 6th century temple of Athena. One represents the combat between Zeus and Hercules, who kneel back to back in the middle of the

FIG. 17.—Nike of Chian school, restored.

group, and their monstrous opponents Typhon and his wife Echidna; the other represents the struggle between Hercules and Triton in the presence of the serpent-footed Cecrops, first king of Attica. On other smaller pediments, perhaps belonging to shrines of Hercules and Dionysus, we have again conflicts of Hercules with Triton or with other monstrous foes. It is notable how fond the Athenian artists of this early time are of exaggerated

muscles and of monstrous forms, which combine the limbs of men and of animals; the measure and moderation which mark developed Greek art are as completely absent as are skill in execution or power of grouping. We engrave (Fig. 18) a small pediment in which appears in relief the slaying of the Lernaean hydra by Hercules. The hero strikes at the many-headed water-snake, somewhat inappropriately, with his club. Iolaus, his usual com-

FIG. 18.—Athenian pediment: Heraklea and Hydra. *Athen. Mittheil.* x. 287.

panion, holds the reins of the chariot which awaits Hercules after his victory. On the extreme left a huge crab comes to the aid of the hydra.

There can be little doubt that Athens owed its great start in art to the influence of the court of Pisistratus, at which artists of all kinds were welcome. We can trace a gradual transformation in sculpture, in which the influence of the Chian and other progressive schools of sculpture is visible, not only in the substitution of island marble for native stone, but in increased grace and truth to nature, in the toning down of glaring colour, and the appearance of taste in composition. A transition between the older and the newer is furnished by the well-known statue of the calf-bearer, an Athenian preparing to sacrifice a calf to the deities, which is made of marble of Hymettus, and in robust clumsiness of forms is not far removed from the limestone pediments. The sacrificer has been commonly spoken of as Hermes or Theseus, but he seems rather to be an ordinary human votary of the goddess.

In the time of Pisistratus or his sons a peristyle of columns was added to the old temple of Athena; and this necessitated the preparation of fresh pediments. These were of marble. In one of them was represented the battle between gods and giants; in the midst Athena herself striking at a prostrate foe (Fig. 19). In these

FIG. 19.—Pediment: Athena and giant. *Athen. Mittheil.* xxii. 8.

figures no eye can fail to trace remarkable progress. On about the same level of art are the charming statues of votaries of Athena, dedicated to her, which were set up in the latter half of the 6th century in the acropolis,

whose graceful though conventional forms, and delicate colouring, make them one of the great attractions of the Acropolis Museum. We engrave (Fig. 20) a figure which, if it be rightly connected with the basis on which it stands, is the work of the sculptor Antenor, who was also author of a celebrated group representing the tyrant-slayers, Harmodius and Aristogeiton. To the same age belong many other votive reliefs of the acropolis, representing horsemen, scribes, and other votaries of Athena.

FIG. 20.—Figure of Antenor, restored.

From Athens we pass to the seats of Dorian art. And in doing so we find a complete change of character. In place of draped goddesses and female figures, we find nude male forms. In place of Ionian softness and elegance, we find hard rigid outlines, strong muscular development, a greater love of and faithfulness to the actual human form—the influence of the palæstra rather than of the harem. To the known series of archaic male figures, recent years have added many examples. We may especially mention a series of figures from the temple of Apollo Ptoos in Bœotia, probably representing the god himself. Still more noteworthy are two colossal nude figures of Apollo, remarkable both for force and for rudeness, found at Delphi, the inscriptions of which prove them to be the work of an Argive sculptor. From Crete we have acquired the upper part of a draped figure (Fig. 21), whether male or female is not

FIG. 21.—Bust from Crete.

certain, which should be an example of the early Dædalid school, whence the art of Peloponnesus was derived; but we can scarcely venture to treat it as a characteristic product of that school; rather the likeness to the dedication of Nicandra (Fig. 16) is striking.

Next in importance to Athens, as a find-spot for works of early Greek art, ranks Olympia. Olympia, however, did not suffer like Athens from sudden violence, and the explorations there have brought to light a continuous series of remains, beginning with the bronze tripods of the geometric age already mentioned,

Olympia,
Sparta,
Selinus.

and ending at the barbarian invasions of the 4th century A.D. Notable among the 6th-century stone-sculpture of Olympia are the pediment of the treasury of the people of Megara, in which is represented a battle of gods and

FIG. 22.—Head of Hera : Olympia.

giants, and a huge rude head of Hera (Fig. 22), which seems to be part of the image worshipped in the Heræum. Its flatness and want of style are noteworthy. Among the temples of Greece proper the Heræum of Olympia stands almost alone for antiquity and interest, its chief rival, besides the temples of Athens, being the other temple of Hera at Argos. It appears to have been originally constructed of wood, for which stone was by slow degrees, part by part, substituted. In the time of Pausanias one of the pillars was still of oak, and at the present day the varying diameter of the columns and other structural irregularities bear witness to the process of constant renewal which must have taken place. The early small bronzes of Olympia form an important series, figures of deities standing or striding, warriors in their armour, athletes with exaggerated muscles, and women draped in the Ionian fashion, which did not become unpopular in Greece until after the Persian wars. Excavations at Sparta have not produced any sculptures admirable in an artistic way; but they have revealed interesting monuments belonging to the worship of ancestors, which seems in the conservative Dorian states of Greece to have been more strongly developed than elsewhere. On some of these stones, which doubtless belonged

FIG. 23.—Spartan tombstone : Berlin.

to the family cults of Sparta, we see the ancestor seated holding a wine-cup, accompanied by his faithful horse or dog; on some we see the ancestor and ancestress seated side by side (Fig. 23), ready to receive the gifts of their descendants, who appear in the corner of the relief on a much smaller scale. The male figure holds a wine-cup, in allusion to the libations of wine made at the tomb. The female figure holds her veil and the pomegranate, the recognized food of the dead. A huge serpent stands erect behind the pair. The style of these sculptures is as striking as the subjects; we see lean rigid forms with severe outline carved in a very low relief, the surface of which is not rounded but flat. The name of Selinus in Sicily, an early Megarian colony, has long been associated with some of the most curious of early sculptures, the metopes of

ancient temples, representing the exploits of Hercules and of Perseus. Even more archaic metopes have in recent years been brought to light, one representing a seated sphinx, one the journey of Europa over the sea on the back of the amorous bull (Fig. 24), a pair of dolphins swimming beside her. In simplicity and in rudeness of work these reliefs remind us of the limestone pediments of Athens (Fig. 18), but yet they are of another and a severer style; the Ionian laxity is wanting.

When the results of the recent French excavations at Delphi are published, there is no doubt that we shall be able to add a new and important chapter to the history of 6th-century art. Of three treasure-houses, those of Sicyon, Cnidus, and Athens, the sculptural adornments have been in great part recovered. These sculptures form a series almost covering the century 570-470 B.C., and include representations of some myths of which we have hitherto had no example. Although the results of the excavations at Delphi are not yet published, we say here a few words as to the sculpture which has been discovered, leaving to the article DELPHI an account of the topography and the buildings of the sacred site. Of the

FIG. 24.—Metope; Europa on Bull: Palermo.

archaic temple of Apollo, built as Herodotus tells us by the Alcæonidæ of Athens, the only sculptural remains which have come down to us are some fragments of the pedimental figures. Of the treasuries which contained the offerings of the pious at Delphi, the most archaic of which there are remains is that belonging to the people of Sicyon. To it appertain a set of exceedingly primitive metopes. One represents Idas and the Dioscuri driving off cattle; another, the ship Argo; another, Europa on the bull; others merely animals, a ram or a boar. The treasury of the people of Cnidus (or perhaps Siphnos) is in style some half a century later. To it belongs a long frieze representing a variety of curious subjects: a battle, perhaps between Greeks and Trojans, with gods and goddesses looking on; a gigantomachy in which the figures of Poseidon, Athena, Hera, Apollo, Artemis, and Cybele can be made out, with their opponents, who are armed like Greek hoplites; Athena and Hercules in a chariot; the carrying off of the daughters of Leucippus by Castor and Pollux; Æolus holding the winds in sacks. The Cnidian treasury was restored in the French Exposition of 1900. The cornice of the front was supported by two archaic figures of Caryatids; a sphinx and two running Victories stand on the top of the pediment as acroteria, while within the pediment is represented the struggle between Apollo and Hercules for the possession of

the Delphic tripod. The treasury of the Athenians, erected at the time of the Persian wars, was adorned with some metopes of singularly beautiful and clear-cut style, representing the deeds of Hercules and Theseus. Besides the decoration of the treasuries, and the charioteer mentioned below, there were found two very rude figures of Apollo naked, by Argive artists, a colossal sphinx on a lofty pillar dedicated by the people of Naxos, and other statues.

Period III. 480-400 B.C.

On the age of the great early masters of sculpture, of Myron, Phidias, and Polycleitus, much light has been thrown in the last quarter of a century, partly by means of new excavation, but also, in a scarcely less degree, through the careful re-examination of known monuments. Under this period, the first place certainly belongs to the great temple of Zeus at Olympia. The statue by Phidias which once occupied the place of honour in that temple, and was regarded as the noblest monument of Greek religion, has of course disappeared, nor are we able with confidence to restore it. But the plan of the temple, its pavement, some of its architectural ornaments, remain. The marbles which occupied the pediments and the metopes of the temple have been in large part recovered, having been probably thrown

down by earthquakes and gradually buried in the alluvial soil. The utmost ingenuity and science of the archæologists of Germany have been employed in the recovery of the composition of these groups; and although doubt remains as to the places of some figures, and their precise attitudes, yet we may fairly say that we know more about the sculpture of the Olympian temple of Zeus than about the sculpture of any other great Greek temple. The exact date of these sculptures is not certain, but we may with some confidence give them to the middle of the 5th century or a few years earlier. (In speaking of them we shall mostly follow the opinion of Dr Treu, whose masterly work in vol. iii. of the great German publication on Olympia is a model of patience and of science.) In the eastern pediment (Fig. 25), as Pausanias tells us, were represented the preparations for the chariot-race between Œnomaüs and Pelops, the result of which was to determine whether Pelops should find death, or a bride and a kingdom. In the midst, invisible to the contending heroes, stood Zeus the supreme arbiter. On one side of him stood Œnomaüs with his wife Sterope, on the other Pelops and Hippodameia, the daughter of Œnomaüs, whose position at once indicates that she is on the side of the new-comer, whatever her parents may feel. Next on either side are the four-horse chariots of the two competitors, that of

FIG. 25.—East pediment: Olympia. Two restorations.

Œnomaüs in the charge of his perfidious groom Myrtilus, who contrived that it should break down in the running, that of Pelops tended by his grooms. At either end, where the pediment narrows to a point, reclines a river-god, at one end Alpheus, the chief stream of Olympia, at the other end his tributary Cladeus. Only one figure remains, not noticed in the careful description of Pausanias, the figure of a handmaid kneeling, perhaps one of the attendants of Sterope. Our engraving gives two conjectural restorations of the pediment, that of Treu and that of Kekule, which differ principally in the arrangement of the corners of the composition; the position of the central figures and of the chariots can scarcely be called in question. The moment chosen is one, not of action, but of expectancy, perhaps of preparation for sacrifice. The arrangement is undeniably stiff and formal, and in the figures we note none of the trained perfection of style which belongs to the sculptures of the Parthenon, an almost contemporary temple. Faults abound, alike in the rendering of drapery and in the representation of the human forms, and the sculptor has evidently trusted to the painter who was afterwards to colour his work, to remedy some of his clumsiness, or to make clear the ambiguous. Nevertheless there is in the whole a dignity, a sobriety, and a simplicity which reconcile us to the knowledge that this pediment was certainly regarded in antiquity as a noble work, fit to adorn even the palace of Zeus. In the other, the western, pediment (Fig. 26), the subject is the riot of the Centaurs when they attended the wedding of Pirithous in Thessaly,

and, attempting to carry off the bride and her comrades, were slain by Pirithous and Theseus. In the midst of the pediment, invisible like Zeus in the eastern pediment, stands Apollo, while on either side of him Theseus and Pirithous attack the Centaurs with weapons hastily snatched. Our engraving gives two possible restorations. The monsters are in various attitudes of attempted violence, of combat and defeat; with each grapples one of the Lapith heroes in the endeavour to rob them of their prey. In the corners of the pediment recline female figures, perhaps attendant slaves, though the farthest pair may best be identified as local Thessalian nymphs, looking on with the calmness of divine superiority, yet not wholly unconcerned in what is going forward. Though the composition of the two pediments differs notably, the one bearing the impress of a parade-like repose, the other of an overstrained activity, yet the style and execution are the same in both, and the shortcomings must be attributed to the inferior skill of a local school of sculptors compared with those of Athens or of Ægina. It even appears likely that the designs also belong to a local school. Pausanias, it is true, tells us that the pediments were the work of Alcámenes, the pupil of Phidias, and of Pæonius, a sculptor of Thrace, respectively; but it is almost certain that he was misled by the local guides, who would naturally be anxious to connect the sculptures of their great temple with well-known names.

The metopes of the temple are in the same style of art as the pediments, but the defects of awkwardness and want of mastery are less conspicuous, because the narrow

limits of the metope exclude any elaborate grouping. The subjects are provided by the twelve labours of Hercules; the figures introduced in each metope are but two or at most three; and the action is simplified as much as possible. The example figured (Fig. 27) represents Her-

cules holding up the sky on a cushion, with the friendly aid of a Hesperid nymph, while Atlas, whom he has relieved of his usual burden, approaches, bringing the apples which it was the task of Hercules to procure.

Another of the fruits of the excavations of Olympia is

FIG. 26.—West pediment: Olympia. Two restorations.

the floating Victory by Pæonius, unfortunately faceless (Fig. 28), which was set up in all probability in memory of the victory of the Athenians and their Messenian allies at Sphacteria in 425 B.C. The inscription states that it was dedicated by the Messenians and people of Naupactus from the spoils of their enemies, but the name of the enemy is not mentioned in the inscription. The statue of Pæonius, which comes floating down through the air with drapery borne backward, is of a bold and innovating type,

FIG. 27.—Metope: Olympia; restored. *Olympia*, III. 45.

and we may trace its influence in many works of the next age.

Among the discoveries at Delphi none is so striking and valuable to us as the life-size statue in bronze of a charioteer holding in his hand the reins. This has been shown by M. Homolle to be part of a chariot-group set up by Polyzaus, brother of Gelon and Hieron of Syracuse, in honour of a victory won in the chariot-race at the Pythian games at Delphi (Fig. 29). The charioteer is evidently a high-born youth, and is clad in the long chiton which was necessary to protect a driver of a chariot from the rush of air. The date would be about 480-470 B.C. Bronze groups representing victorious chariots with their drivers were among the noblest and most costly dedications of antiquity; the present figure is our only satisfactory representative of

them. In style the figure is very notable, tall and slight beyond all contemporary examples. The contrast between the conventional decorousness of face and drapery and the lifelike accuracy of hands and feet is very striking, and indicates the clashing of various tendencies in art at the time when the great style was formed in Greece.

On the works of Phidias recent discovery has thrown some light, though but little which is direct. Much interest was aroused in 1880 by the finding at Athens of a marble reduction, a yard high, of the great Parthenos statue of Phidias (Fig. 30);

FIG. 28.—Nike of Pæonius; restored. *Olympia*, III. 48.

but cooler consideration has forced us to allow that though the new statuette may be an authority as to some details of the Phidian statue, such as the decoration of the helmet, the attitude of the small figure of Victory, and the position of the snake, it is not to be implicitly trusted. The pillar which is introduced to support the weight of the figure of Victory seems to most artists a device unworthy of the genius of Phidias, though there is other evidence of its actual existence. In any case, this statuette cannot serve to give us any adequate notion of the great statue as a whole. Prof. Furtwängler has of late largely contributed to Phidian literature. He believes

himself to have discovered at Dresden copies of the Lemnian Athena, one of the most noted of the works of Phidias. The reasons for the identification are set forth in his *Masterpieces of Greek Sculpture*. In the same work and the later *Intermezzi* will be found very ingenious

FIG. 29.—Bronze Charioteer: Delphi. *Mémoires, Piot, 1897, 16.*

attempts to reconstruct and to explain the pediments of the Parthenon. But safer guides for the restoration of the wonderful sculptural decoration of the noblest of Greek temples will be found in Dr Sauer's careful researches into the evidence to be won on the spot from the existing backgrounds and bases of the pediments, from which one may judge of the positions and attitudes of some of the figures. And the finding of the head of Hebe in the Parthenon frieze is a most fortunate event, as giving us a well-preserved girl's head of the Phidian school.

To our knowledge of the art of Polycleitus many additions have been made. Among the bases discovered at

Polycleitus.

Olympia, whence the statues had been removed, are three or four which bear the name of Polycleitus, and the definite evidence furnished by

these bases as to the position of the feet of the statues which they once bore has enabled archæologists, especially Prof. Furtwängler, to identify copies of those statues

FIG. 30.—Statuette of Athena Parthenos.

Doryphorous and Diadumenus, we have quite a gallery of athletes, boys and men, who all claim relationship, nearer or more remote, to the school of the great Argive master. It might have been hoped that the recent excavations, made under the leadership of Prof. Waldstein at the Argive Heræum, would have enlightened us as to the style of Polycleitus. Just as the sculptures of the Parthenon are the best monument of Phidias, so it might seem likely that the sculptural decoration of the great temple which contained the Hera of Polycleitus would show us at large how his school worked in marble. Unfortunately the fragments of sculpture from the Heræum are few. The most remarkable is a female head, which may perhaps come from a pediment (Fig. 32). But archæologists are not in agreement whether it is in style Polycleitan, or whether it rather resembles in style Attic works. Other heads and some highly-finished fragments of bodies come apparently from the metopes of the same temple. (See also under ARGOS.)

FIG. 31.—Torso of young Hermes: Boston.

The series of known Lycian tombs, most of which were secured by Sir Charles Fellows for the British Museum, has been enriched through the acquisition by the museum of Vienna of the sculptured friezes which adorned a heroon near Gyeul Bashi. In the midst

Lycia.

FIG. 32.—Female head: Heræum.

of the enclosure was a tomb, and the walls of the enclosure itself were adorned within and without with a great series of reliefs, mostly of mythologic purport. Many subjects which but rarely occur in early Greek art, the siege of Troy, the adventure of the Seven against Thebes, the carrying off of the daughters of Leucippus, Ulysses shooting down the Suitors, are here represented in detail. Prof. Benndorf, who has published these sculptures in an admirable volume, is disposed to see in them the influence of the Thasian painter Polygnotus. Any one can see their

regards the manner of Polycleitus on Roman copies of the

kinship to painting, and their subjects recur in some of the great frescoes painted by Polygnotus, Micon, and others for the Athenians. Like other Lycian sculptures, they contain non-Hellenic elements; in fact Lycia forms a link of the chain which extends from the wall-paintings of Assyria to works like the columns of Trajan and of Antoninus, but is not embodied in the more purely idealistic works of the highest Greek art. The date of the Vienna tomb is not much later than the middle of the 5th century. We engrave a small part of the frieze of this monument (Fig. 33). It will be seen

FIG. 33.—Odysseus and suitors; hunting of boar. Heroon of Gyul Bashli Trysa, Pl. 7.

that in this fragment there are two scenes, one directly above the other. In the upper line Ulysses accompanied by his son Telemachus, is in the act of shooting the suitors, who are reclining at table in the midst of a feast; a cup-bearer, possibly Melanthius, is escaping by a door behind Ulysses. In the lower line is the central group of a frieze which represents the hunting of the Calydonian boar, which is represented, as is usual in the best time of Greek art, as an ordinary animal and no monster.

Perhaps earlier than 400 B.C. are certain groups found at Delos which represent respectively the carrying away of the Athenian girl Oreithyia by the wind-god Boreas, and the carrying off of the hunter Cephalus by the Goddess of the Dawn. These fine groups, full of energy, but unfortunately fragmentary, are supposed to have once adorned the roof of the great temple of Apollo at Delos. They are now preserved at Athens, and are the best examples we possess of the groups which frequently stood on the tops of the pediments of Greek temples.

Archæologists are now beginning to pay more attention to an interesting branch of Greek art which had until

Portraits. recently been neglected, that of sculptured portraits. The known portraits of the 5th century now include Pericles, Herodotus, Thucydides, Anacreon, Sophocles, Euripides, Socrates, and others. As might be expected in a time when style in sculpture was so strongly pronounced, these portraits, unless later unfaithful copies, are notably ideal. They represent the great men whom they portray not in the spirit of realism. Details are neglected, expression is not elaborated; the sculptor tries to represent what is permanent in his subject rather than what is temporary. Hence these portraits do not seem to belong to a particular time of life; they only represent a man in the perfection of physical force and mental energy. And the race or type is clearly shown through individual traits. In some cases it is still disputed whether statues of this age represent deities or mortals, so notable are the repose and dignity which even human figures acquire under the hands of

5th-century masters. The Pericles after Cresilas in the British Museum, and the athlete-portraits of Polycleitus are good examples.

It is now generally held, in consequence of evidence furnished by tombs, that the 5th century saw the end of the making of vases on a great scale at Athens for export to Italy and Sicily. And in fact **Athenian vases.** few things in the history of art are more remarkable than the rapidity with which vase-painting at Athens reached its highest point and passed it on the downward road. At the beginning of the century black-figured ware was scarcely out of fashion, and the masters of the severe red-figured style, Pamphæus, Epictetus, and their contemporaries, were in vogue. The schools of Euphronius, Hiero, and Duris belong to the age of the Persian wars. With the middle of the century the works of these makers are succeeded by unsigned vases of most beautiful design, some of them showing the influence of the great Thasian painter Polygnotus. In the later years of the century, when the empire of Athens was approaching its fall, drawing becomes laxer and more careless, and in the treatment of drapery we frequently note the over-elaboration of folds, the want of simplicity, which begins to mark contemporary sculpture. Unfortunately we cannot here illustrate these changes of style, which can only be satisfactorily followed in the vase rooms of the British Museum, or other treasuries of Greek art.

Period IV. 400-320 B.C.

Until about the year 1880, our knowledge of the great Greek sculptors of the 4th century was derived mostly from the statements of ancient writers and from Roman copies, or what were supposed to be copies, of their works. We are now in a far more satisfactory position. We now possess an original work of Praxiteles, and sculptures executed under the immediate direction of, if not from the hand of, other great sculptors of that age—Scopas, Timotheus, Damophon, and others. Among all the discoveries made at Olympia, none has become so familiar to the artistic world as that of the **Praxiteles.** Hermes of Praxiteles. It is the first time that we have become possessed of a first-rate Greek original by one of the greatest of sculptors. Hitherto almost all the statues in our museums have been either late copies of Greek works of art, or else the mere decorative sculpture of temples and tombs, which was by the ancients themselves but little regarded. But we can venture without misgiving to submit the new Hermes to the strictest examination, sure that in every line and touch we have the work of a great artist. This is more than we can say of any of the literary remains of antiquity—poem, play, or oration. Hermes is represented by the sculptor (Fig. 34) in the act of carrying the young child Dionysus to the nymphs who were charged with his rearing.

FIG. 34.—Hermes of Praxiteles, restored. Olympia, iii. 58.

On the journey he pauses and amuses himself by holding out to the child-god a bunch of grapes, and watching his eagerness to grasp them. To the modern eye the child is

not a success; only the latest art of Greece is at home in dealing with children. But the Hermes, strong without excessive muscular development, and graceful without leanness, is a model of physical formation, and his face expresses the perfection of health, natural endowment, and sweet nature. The statue can scarcely be called a work of religious art in the modern or Christian sense of the word religious, but from the Greek point of view it is religious, as embodying the result of the harmonious development of all human faculties and life in accordance with nature. The discovery of the Hermes has naturally set archæologists searching in the museums of Europe for other works which may from their likeness to it in various respects be set down as Praxitelean in character. In the case of many of the great sculptors of Greece—Cresilas, Silanion, Calamis, and others—it is of little use to search for copies of their works, since we have little really trustworthy evidence on which to base our inquiries. But in the case of Praxiteles we really stand on a safe level. Naturally it is impossible in these pages to give any sketch of the results, some almost certain, some very doubtful, of the researches of archæologists in quest of Praxitelean works. But we may mention a few works which have been claimed by good judges as coming from the master himself. Prof. Brunn claimed as work of Praxiteles a torso of a satyr in the Louvre, in scheme identical with the well-known satyr of the Capitol. Prof. Furtwängler puts in the same category a delicately beautiful head of Aphrodite at Petworth. And his translator, Mrs Strong, regards, with greater probability, the Aberdeen head of a young man in the British Museum as the actual work of Praxiteles. Certainly this last head does not suffer when placed beside the Olympian head of Hermes. At Mantinea has been found a basis whereon stood a group of Latona and her two children, Apollo and Artemis, made by Praxiteles. This base bears reliefs representing the musical contest of Apollo and Marsyas, with the Muses as spectators, reliefs very pleasing in style, and quite in the manner of Attic artists of the 4th century. But of course we must not ascribe them to the hand of Praxiteles himself; great sculptors did not themselves execute the reliefs which adorned temples and other monuments, but reserved them for their pupils. Yet the graceful figures of the Muses of Mantinea suggest how much was due to Praxiteles in determining the tone and character of Athenian art in relief in the 4th century. Exactly the same style which marks them belongs also to a mass of sepulchral monuments at Athens, and such works as the Sidonian sarcophagus of the Mourning Women, to be presently mentioned.

Excavation on the site of the temple of Athena Alea at Tegea has resulted in the recovery of works of the school of Scopas. Pausanias tells us that Scopas was the architect of the temple, and so important in the case of a Greek temple is the sculptural decoration, that we can scarcely doubt that the sculpture of the temple at Tegea was under the supervision of Scopas, especially as he was more noted as a sculptor than as an architect. In the pediments of the temple were represented two scenes from mythology, the hunting of the Calydonian boar, and the combat between Achilles and Telephus. To one or other of these scenes belong two heads of local marble discovered on the spot, which are very striking from their extraordinary life and animation. Unfortunately both are so much injured that they can scarcely be made intelligible except by the help of restoration; we therefore engrave one of them, the helmeted head, as restored by a German sculptor (Fig. 35). The strong bony frame of this head, and its depth from front to back, are not less noteworthy than the parted lips and deeply set and strongly shaded eye; the latter features

impart to the head a vividness of expression such as we have found in no previous work of Greek art, but which sets the key to the developments of art which take place in the Hellenistic age. The head of the Calydonian boar, which was found at the same time, is a curious work; the sculptor has transferred to the representation of a boar too much of his special style, and made it but little like an actual wild beast. Until these heads were found, Scopas was known to us, setting aside literary records, only as one of the sculptors who had worked at the Mausoleum. But it has now become possible to detect his style in many extant statues, such as the Meleager of the Vatican and the Hercules of the Lansdowne Gallery. It is also by no means unlikely that Scopas may have had a share in the carving of those sculptured pillars from the 4th-century temple of Artemis at Ephesus with which the spade of Mr Wood enriched the British Museum.

FIG. 35.—Head of warrior, restored: Tegea.

The interesting precinct of Æsculapius at Epidaurus has furnished us with specimens of the style of an Athenian contemporary of Scopas, who worked with him on the Mausoleum. An inscription *Timotheus, Bryaxis, Leochares, Damophon.* which records the sums spent on the temple of the Physician-god, informs us that the models for the sculptures of the pediments, and one set of acroteria or roof adornments, were the work of Timotheus. Of the pedimental figures and the acroteria considerable fragments have been recovered, and we may with confidence assume that the models for these at all events were by Timotheus. It is strange that the unsatisfactory arrangement whereby a noted sculptor makes models and some local workmen the figures enlarged from those models, should have been tolerated by so artistic a people as the Greeks. The subjects of the pediments appear to have been the common ones of battles between Greek and Amazon and between Lapith and Centaur. We possess fragments of some of the Amazon figures, one of which is here engraved (Fig. 36) striking downwards at an enemy. Their attitudes are vigorous and alert; but the work shows no delicacy of detail. Figures of Nereids riding on horses, which were found on the same site, may very probably be roof ornaments (acroteria) of the temple. We have also several figures of Victory, which probably were acroteria on some smaller temple, perhaps that of Artemis. A base found at Athens, sculptured with figures

of horsemen in relief, bears the name of Bryaxis, and was probably made by a pupil of his. Probable conjecture assigns to Leochares the originals copied in the Ganymedes of the Vatican, borne aloft by an eagle, and the noble statue of Alexander the Great at Munich. Thus we may fairly say that we are now acquainted with

FIG. 36.—Amazon from Epidaurus.

the work of all the great sculptors who worked on the Mausoleum—Scopas, Bryaxis, Leochares, and Timotheus; and are in a far more advantageous position than were the archæologists of 1880 for determining the artistic problems connected with that noblest of ancient tombs. As regards the plan and architecture of the Mausoleum, contributions have been made by Mr Oldfield (*Archæologia*, 1895-97), and Dr Adler (*Das Mausoleum*); but no generally accepted conclusion has been reached. Another great 4th-century artist, Damophon of Messene, is now known to us from his actual works. He set up in the

FIG. 37.—Head of Anytus: Lycosura.

all events in Hellenistic times. It is difficult to accept this view, because Damophon is spoken of by Pausanias as author of a statue of the City of Thebes, and of many works in the cities established in Peloponnesus at the time of the Theban hegemony

early in the 4th century. We prefer to retain Damophon as a sculptor of the 4th century, and even find no great difficulty in reconciling the style of his works with that date.

This may be the most appropriate place for mentioning the remarkable find made at Sidon in 1886 of a number of sarcophagi, which once doubtless contained the remains of kings of Sidon. They are now in the museum of Constantinople, and are admirably published by Hamdy Bey and T. Reinach (*Une nécropole royale à Sidon*, 1892-96). The sarcophagi in date cover a considerable period. The earlier are made on Egyptian models, the covers shaped roughly in the form of a human body or mummy. The later, however, are Greek in form, and are clearly the work of skilled Greek sculptors, who seem to have been employed by the grandees of Phœnicia in the adornment of their last resting-places. Four of these sarcophagi in particular claim attention, and in fact present us with examples of Greek art of the 5th and 4th centuries in several of its aspects. To the 5th century belong the tomb of the Satrap, the reliefs of which bring before us the activities and glories of some unknown king, and the Lycian sarcophagus, so called from its form, which resembles that of tombs found in Lycia, and which is also adorned with reliefs which have reference to the past deeds of the hero buried in the tomb, though these deeds are represented, not in the Oriental manner directly, but in the Greek manner, clad in mythological forms. To the 4th century belong two other sarcophagi. One of

Sarcophagi of Sidon.

these is called the Tomb of the Mourning Women. On all sides of it alike are ranged a series of beautiful female figures, separated by Ionic pillars, each in a somewhat different attitude, though all attitudes denoting grief (Fig. 38). The pediments at the ends of the cover are also closely connected with the mourning for the loss of a friend and protector, which is the theme of the whole decoration of the sarcophagus. We see depicted in them the telling of the news of the death, with the results in the mournful attitude of the seated figures. The mourning women must be taken, not as the representation of any persons in particular, but generally as the expression of the feeling of a city. Such figures are familiar to us in the art of the second Attic school; we could easily find parallels to the sarcophagus among the 4th-century sepulchral reliefs of Athens. We can scarcely be mistaken in attributing the workmanship of this beautiful sarcophagus to some sculptor trained in the school of Praxiteles. And it is a conjecture full of probability that it once contained the body of Strato, king of Sidon, who ruled about 380 B.C., and who was *proxenos* or public friend of the Athenians.

FIG. 38.—Tomb of mourning women: Sidon. Hamdy et Reinach, *Nécropole à Sidon*, Pl. 7.

More celebrated is the astonishing tomb called that of Alexander, though there can be no doubt that, although it commemorates the victories and exploits of Alexander, it was made not to hold his remains, but those of some ruler of Sidon who was high in his favour. Among all the monuments of antiquity which have come down to us,

frieze is now one of the treasures of the Royal Museums of Berlin, and it cannot fail to impress visitors by the size of the figures, the energy of the action, and the strong vein of sentiment which pervades the whole, giving it a certain air of modernity, though the subject is strange to the Christian world. In early Greek art the Giants where they oppose the Gods are represented as men armed in full panoply, "in shining armour, holding long spears in their hands," to use the phrase in which Hesiod describes them. But in the Pergamene frieze the Giants are strange compounds, having the heads and bodies of wild and fierce barbarians, sometimes also human legs, but sometimes in the place of legs two long serpents, the heads of which take with the Giants themselves a share in the battle. Sometimes also they are winged. The Gods appear in the forms which had been gradually made for them in the course of Greek history, but they are usually accompanied

FIG. 40.—Giant from great altar: Pergamon.

stands for the victory of Greek civilization over Gallic barbarism; and this meaning is made more emphatic because the Gods are obviously inferior in physical force to their opponents, indeed, a large proportion of the divine combatants are goddesses. Yet everywhere the Giants are overthrown, writhing in pain on the ground, or transfixed by the weapons of their opponents; everywhere the Gods are victorious, yet in the victory retain much of their divine calm. The piecing together of the frieze at Berlin has been a labour of many years, and is even yet incomplete. We still await a final and monumental publication of it. Some of the groups, however, have become familiar to students from photographs, especially the group which represents Zeus slaying his enemies with thunderbolts, and the group wherein Athena seizes by the hair an overthrown opponent, who is winged, while Victory runs to crown her, and beneath is seen Gaia, the earth-goddess who is the mother of the Giants, rising out of the ground, and mourning over her vanquished and tortured children. Another and smaller frieze which also decorated the altar-place gives us scenes from the history of Telephus, who opposed the landing of the army of Agamemnon in Asia Minor and was overthrown by Achilles. This frieze, which is quite fragmentary, is put together by Dr Schneider in the *Jahrbuch* of the German Archæological Institute for 1900.

Since the Renaissance Rome has continually produced a crop of works of Greek art of all periods, partly originals brought from Greece by conquering generals, partly copies

made by Greek artists for wealthy Roman amateurs. The extensive excavations and alterations which have taken place at Rome in recent years have been very fruitful in this way; the results may be found partly in the palace of the Conservatori on the Capitol, partly in the new museum of the Terme. Among recently

Rome.

found statues none excel in interest some bronzes of large size dating from the Hellenistic age. We engrave (Fig. 41) the figure of a seated boxer, in scale somewhat exceeding life. Attitude and gesture are expressive. Evidently the boxer has fought already, and is awaiting a further conflict. His face is cut and swollen; on his hands are the terrible *cæstus*, here made of leather, and not loaded with iron, like the *cæstus* described by Virgil. The figure is of astounding force; but though the face is brutal and the expression savage, in the sweep of the limbs there is nobility, even ideal beauty. To the last the Greek artist could not set aside his admiration for physical perfection. Another bronze figure of more than life-size is that of a king of the Hellenistic age standing leaning on a spear. He is absolutely nude, like the athletes of Polycleitus. Another large bronze presents us with a Hellenistic type of Dionysus.

FIG. 41.—Bronze boxer: Rome. *Ant. Denkmäler des Inst. Fl. 4.*

Sculpture of the Roman age has not in recent years been discovered to the same extent. We have gained rather by a closer and more exact study of monuments already known than from the discovery of fresh monuments. The columns of Trajan and of Antoninus have been re-published in a series of excellent photographic plates. Many provincial monuments, such as the Roman tomb at S. Rémy, the arch of Beneventum, the monument of Adam Klissi, have been more carefully published. Many additions have been made to our already vast series of Roman portraits, and the gigantic publication of Arndt on Greek and Roman portraits has for the first time put together the necessary materials for a more satisfactory arrangement of portraits, as well as for their identification. Unfortunately, at present the great mass of portraits, both Greek and Roman, have to be labelled "unknown person."

In Italian and other museums it has been the custom to assign names to portraits for reasons which will not bear investigation. Bernoulli's *Römische Ikonographie* is, however, a scientific work; a similar work by Bernoulli on Greek iconography is now in course of publication: the book of Visconti is quite out of date and untrustworthy.

The most important discovery at Pompeii, during the last quarter of a century, has been that of the *Domus Vettiorum*, a house whereof the walls are adorned with an unusually important series of paintings, partly scenes from Greek mythology, partly scenes which give us glimpses of daily life. Among the former are Achilles in Scyros, the punishment of Dirce, the death of Pentheus, Dædalus and Pasiphaë. Among the latter we especially note the series of scenes in which Cupids are represented as engaged in various kinds of manufacture and commerce, a Hellenistic fashion of introducing the actual in a manner

not too literal. Other paintings found at Rome range with or even excel those of Pompeii, notably the remarkable wall-paintings representing artificial gardens with shrubs and flowers, which have been found at Prima Porta.

The whole subject of Roman art has been recently discussed by Prof. Wickhoff of Vienna in an essay translated into English by Mrs Strong. This writer claims for the art of Italy and of Rome greater independence and more importance than had been conceded to it by other writers. He regards the art of the Augustan age as the last efflorescence of the Greek creative genius, which at that time had passed by a reaction against the strained and theatrical tendencies of the Pergamene school to a somewhat dry and insipid naturalism, a style of which the portraits of Augustus, the reliefs of the Ara Pacis at Rome, and some of the paintings of Pompeii are good examples. Against the jejuneness of this art the national spirit of Italy, which had for long been expressed in a series of portraits, lifelike if somewhat coarse, revolted towards the end of the 1st century. The result is to be observed in the portraits of the Flavian age, which are far more vivid than those of the Cæsars, as well as in the remarkable reliefs of the arch of Titus and the column of Trajan. In this national Roman art, Prof. Wickhoff does not hesitate to see illusionism, as opposed to the typical art of Greece, and the naturalism of the early empire. Its chief features are the attempt to produce a vivid and individual effect, often worked by very simple means, and the continuous method of representation of events, a method according to which successive scenes of a transaction follow one another without any separation, and the actors appear again and again in the same relief. Thus Trajan appears eighty-five times over in the continuous scroll of relief which adorns his column; and on Roman sarcophagi the successive scenes of a mythical tale follow one another without division. It was, according to Prof. Wickhoff, from illusionist Roman art that the earliest Christian art took its origin; hence its effects lasted far on into the Middle Ages. It is evidently impossible in this place to criticize these novel views; their importance lies in the fact that they are perhaps the first attempt to set forth the course of Roman art as a valuable development rather than as a mere process of degeneration; but most readers will think that Dr Wickhoff overvalues Roman, and undervalues Greek art. (P. G.)

Archangel. See ARCHANGELSK.

Archbald, a borough of Lackawanna county, Pennsylvania, U.S.A., in the anthracite coal region in the north-eastern part of the state, on several railways. Population (1890), 4032; (1900), 5396.

Arches, Court of the.—The court of the Arches is the court of appeal of the archbishop of Canterbury as metropolitan of the province of Canterbury from all the consistory and commissary courts in the province, and its decisions are in most cases appealable to the judicial committee of the Privy Council. (See *Ency. Brit.* vol. ii. p. 378.) The judge (known as the dean of the Arches) was until 1874 appointed by the archbishop of Canterbury by patent which, when confirmed by the dean and chapter of Canterbury, conferred the office for the life of the holder. He took the oaths of office required by the 127th canon. But by the Public Worship Regulation Act, 1874 (37 and 38 Vict. c. 85), the two archbishops were empowered, subject to the approval of the sovereign by sign-manual, from time to time to appoint a judge for the purpose of exercising jurisdiction under that Act, and it was enacted (sec. 7) that on a vacancy occurring in the office of dean of the Arches, the judge so to be appointed should become *ex officio* dean of the Arches. In this way the late Lord Penzance became dean on the retirement of Sir Robert Phillimore in 1875. Lord Penzance received in 1878 a supplemental patent as dean from Archbishop Tait, but did not otherwise fulfil the conditions observed on the appointment of his predecessors. On Lord Penzance's retirement in 1899, his successor, Sir Arthur Charles, was appointed dean by patent from the archbishop of Canterbury, and he took the oaths of office according to the practice before the Public Worship Regulation Act. He was subsequently and separately appointed judge under that Act.

Under the Clergy Discipline Act, 1892 (55 and 56 Vict. c. 32, sec. 4) an appeal lies from the judgment of a consistory court under that Act, in respect of fact by leave of the appellate court, and in respect of law without leave, to either the court of the Arches or the judicial committee of the Privy Council at the option of the appellant. Under the Benefices Act, 1898 (61 and 62 Vict. c. 48, sec. 3 (4)), the official principal of the archbishop is required to institute a presentee to a benefice if the tribunal constituted under that Act decides that there is no valid ground for refusing institution and the bishop of the diocese notwithstanding fails to institute him. For many years past there has been but little business in the court of Arches. On the rare occasions when a sitting of the court is necessary, it is held in the Library of Lambeth Palace, or at the Church House. (L. T. D.)

ARCHITECTURE.

I. MODERN.

BOTH in England and in the United States, the last quarter of the 19th century was a period of unusual interest and activity in architectural development. While other nations have been content to carry on their architecture, for the most part, on the old scholastic lines which had been prevalent since the Renaissance, in the two countries named there has been manifest a spirit of unrest, of critical inquiry into the basis and objects of architecture; an aspiration to make new and original creations in or applications of the art, without example in any other period in the modern history of architecture. In England, the "note"—heard with increasing shrillness of *crescendo* towards the very last year of the century—

has been the cry for originality, for throwing off the trammels of the past, for rendering architecture more truly a direct expression of the conditions of practical requirement and of structure. This was no doubt to some extent the effect of a reaction. During the greater part of the century architectural strength had been spent in revivals of past styles. First came the Greek revival, of which the best result was St George's Hall at Liverpool, and the worst the formation of the tower of St Pancras Church in London by piling three Greek temples or shrines one upon another. Then followed the Gothic revival, which gained an immense impetus from the fact that it coincided with the spiritual and ecclesiological revival of the English church—and indeed it is rather difficult to apportion cause and effect between

the spiritual and the architectural revival. At all events, *donec templa refecimus* was the motto of the day. The land was covered with modern mediæval churches, and with Gothic town halls and residences; and the business of restoring cathedrals was carried to an extent which deprived some of them of most of their value, and which an after generation has had to regret when regret was unavailing.

It was in 1869, just before the period we are here dealing with, that the great competition for the London

Gothic. Law Courts took place; and Street's building, completed a few years afterwards, was the last great national building erected in the revived Gothic style; as was observed shortly after its completion, it was "the grave of modern Gothic architecture," at least as regarded important secular buildings. Churches indeed, up to the close of the century, continued to be built, for the most part, in revived Gothic; but this was owing to special clerical influence, which saw in Gothic a style specially consecrated to church architecture, and would be satisfied, as a rule, with nothing else. Efforts have been made by architects to modify the mediæval church plan into something more practically suited to modern congregational worship, by a system of reducing the side aisles to mere narrow passages for access to the seats, thus retaining the architectural effect of the arcade, while keeping it out of the way of the seated congregation; and there have been occasional reversions to the ancient Christian basilica type of plan, or sometimes, as in the church in Davies Street, London, attempts to treat a church in a manner entirely independent of architectural precedent; but in the main, Gothic has continued to rule for churches. Apart from this special class of building, however, revived Gothic began to droop during the 'seventies. All had been copied that could be copied, and the result, to the architectural mind, was not satisfaction but satiety. Gothic began to be regarded as "played out." The immediate result, however, was not an organized attempt to think for ourselves, and make our own style, but a recourse to another class of precedent, represented in the type of early 18th-century building

which became known as "Queen Anne," and which, like Gothic before it, was now to be recommended as "essentially English," as in fact it is. It can hardly, however, be called an architectural style; it would have no right to figure in

FIG. 1.—Chelsea Vestry Hall—Example of Modern "Queen Anne." (J. M. Brydon.)

any work illustrating the great architectural styles of the world. It was, in fact, the last dying phase of the English Renaissance; the architecture of the classic order reduced to a threadbare condition, treated very simply

and in plain materials, in many cases shorn of its columnar features, and reflecting faithfully enough the prim rationalistic taste in literature and art of the England of the 18th century. Though not to be dignified as a *style*, it was, however, a recognizable and consistent *manner* in building; it made extensive use of brick, a material inexpensive and at the same time very well suited to the English climate and atmosphere; and it was generally carried out in very solid proportions, and with very good workmanship. To a generation tired of imitating a great style at second hand, this unpretending and simple model was a welcome relief, and led to the erection of a considerable number of modern buildings, dwelling-houses especially, the obvious aim of which was to look as like 18th-century buildings as possible. A typical example is the large London house by Mr Norman Shaw, at the corner of Queen's Gate and Imperial Institute Road. The Chelsea Vestry Hall (Fig. 1), by Mr Brydon, is a good example of a public building in the revived Queen Anne style.

A change of front from copying a great style like the mediæval, to copying what is at best a bastard one, if a style at all, might not seem to promise very much for the emancipation of modern architecture; yet there turned out to be one element of progress in it, resting on the fact that the comparatively simple detail of the 18th-century buildings formed a kind of vernacular of building workmanship, which could be comprehended and carried out by good artisans as a recognized tradition. Now, to reduce architecture to good sound building and good workmanship seemed to promise at any rate a better basis to work upon than the mere imitation of classic or mediæval detail; it might conceivably furnish a new starting-point. This was the element of life in the Queen Anne revival, and it had, as we shall see, an influence beyond the circle of the special revivers of the style. But almost concurrently with, or following hard upon, the "Queen Anne" movement arose the idea of a modern architecture, founded on a free and unfettered treatment of the materials of our earlier Renaissance architecture, as illustrated in buildings of the Stuart period. This new ideal was styled "free classic," and it gave the prevailing tone to English architecture for the last fifteen years of the century, though it had its commencement in certain characteristic buildings a good many years earlier than that. In 1873, for instance, there arose a comparatively small front in Leadenhall Street, under the name of "New Zealand Chambers" (Fig. 2), and designed by Mr Norman Shaw, R.A., which excited more attention, and had more influence on contemporary architecture, than many a building of far greater size and importance. This represented the playful and picturesque possibilities of "free classic." Its more restrained and refined achievements were early exemplified in Mr Bodley's design for the front of the London School Board Offices on the Thames Embankment;¹ a comparatively small building which also exercised a considerable influence. There were no details here, however, but what could be found in Stuart (or, as it is more often called, Jacobean) architecture, but the building, and the prominence of its architect's name, helped to draw attention to the possibilities of the style, and it has been discovered that free classic is

¹ The western half of the present front; the design was duplicated afterwards, on the extension of the building, but Mr Bodley originated it.

susceptible of a great deal of original treatment based on Renaissance elements. As an example, we may cite a street front built some twenty years later by another academician-architect; viz., the offices of the Chartered Accountants in the City, by Mr J. Belcher, A.R.A. More dignified and more monumental than New Zealand Chambers, more original than the School Board Offices, this front contains some details and a general treatment which may be said to be absolutely new; it affords another example of a piece of street architecture which attracted a great deal of attention, and has had an effect

painting, mosaic, &c.—in alliance with architecture, and of the architect and the decorative artist working together and in harmony. This is no more than what has long been understood and acted on in France, but it has been a new light to modern English architecture, in which, until a comparatively recent period, decorative painting was hardly thought of, and decorative sculpture, where it was introduced, was too often, or indeed generally, the mere work of some trading firm of masons. But of late years sculpture has taken a far more prominent place in connexion with architecture; it has become a habit with the best architects to rely largely on the introduction of appropriate and symbolic sculpture to add to the interest of their buildings, and to associate with them eminent sculptors, who, instead of regarding their work only in the light of isolated statues or groups for the exhibition room and the art gallery, are willing to give their best efforts to produce high-class sculpture for the decoration of an architectural design which forms the framework to it.

FIG. 2.—New Zealand Chambers. (R. Norman Shaw, R.A.)

quite disproportionate to its size and importance as a building; and it gives a general measure of the progress of the “free classic” idea. During the last decade of the century “free classic” has been almost the recognized style in English architecture, and has been illustrated in many town halls and other large and important buildings, among which the Imperial Institute is a prominent example.

Concurrently with this tendency towards a free classic style there has arisen another movement which has had a considerable influence already on English architecture, and which will probably have a further influence in the future, viz., an increased perception of the importance of decorative arts—sculpture,

The allied arts.

painting, mosaic, &c.—in alliance with architecture, and of the architect and the decorative artist working together and in harmony. This is no more than what has long been understood and acted on in France, but it has been a new light to modern English architecture, in which, until a comparatively recent period, decorative painting was hardly thought of, and decorative sculpture, where it was introduced, was too often, or indeed generally, the mere work of some trading firm of masons. But of late years sculpture has taken a far more prominent place in connexion with architecture; it has become a habit with the best architects to rely largely on the introduction of appropriate and symbolic sculpture to add to the interest of their buildings, and to associate with them eminent sculptors, who, instead of regarding their work only in the light of isolated statues or groups for the exhibition room and the art gallery, are willing to give their best efforts to produce high-class sculpture for the decoration of an architectural design which forms the framework to it.

Notice should be taken, however, of another movement in English architecture during the closing years of the 19th century. Reference has already been made to one idea which prompted the culture of the “Queen Anne” type of architecture: that it presented a simple vernacular of construction and detail, in which solid workmanship was a more prominent element than elaboration of what is known as architectural style. To a small group of clever and enthusiastic architects of the younger generation it appeared that this idea of reducing architecture to the common-sense of construction might be carried still further; that as all the revivals of styles since the Renaissance had failed to give permanent satisfaction and had tended to reduce architecture to a learned imitation of the work of former epochs, the real chance for giving life to architecture as a modern art was to throw aside all the conventionally accepted insignia of architectural style—columns, pilasters, cornices, buttresses, &c.—and to begin over again with mere workmanship—wall-building and carpentry—and trust that in process of time a new decorative detail would be evolved, indebted to no precedent. The building artisans, in fact, were collectively to take the place of the architect, and the form of the building to be evolved by a natural process of growth. This was a favourite idea also with William Morris, who

The craftsmanship ideal.

insisted that mediæval art—the only art which he recognized as of any value (Greek, Roman, and Renaissance being alike contemptible in his eyes)—was essentially an art of the people, and that in fact it was the modern architects who stood in the way of our having a genuine architecture of the 19th century. Considering how much of merely formal, conventional, and soulless architecture has been produced in our time under the guidance of the professional architect, it is impossible to deny that there is an element of truth in this reasoning; at all events, that there have been a good many modern architects who have done more harm than good to architecture. But when we come to follow out this reasoning to its logical results, it is

obvious that there are serious flaws in it. Morris's idea that mediæval architecture alone was worthy the name, we may, of course, dismiss at once; it was the prejudice of a man of genius whose sympathies, both in matters social and artistic, were narrow. Nor can we regard the mediæval cathedrals as artisan's architecture. The name of "architect" may have been unknown, but that the personage was present in some guise, the very individuality and variety of our English cathedrals attest. Peterborough front was no mere mason's conception.

of architecture of the past has, in fact, been evolved from the detail of preceding styles; and some of the ablest and most earnest architects of the present day are, indeed, urging the desirability of clinging to traditional forms in regard to detail, as a means of maintaining the continuity of the art. This does not by any means imply the absence of original architecture; there is scope for endless origination in the plan and the general design of a building. The Westminster Houses of Parliament (one of the greatest buildings of modern times) is a prominent example. The detail is a reproduction of Tudor detail, forced upon the architect by order of the Government; the plan and the general conception are absolutely original, and resemble those of no other pre-existing building in the world.

It is necessary to take account of all these movements of opinion and principle in English architecture to appreciate properly its position and prospects at the time with which we are here dealing. Turning

*In the
United
States.*

now from England to the United States, which, as already observed, is the only other important country in which there has been a general new movement in architecture, we find, singular to say, that the course of development has in America been almost the reverse of what has taken place in England. The rapidity of architectural development in America, it may be observed, during the last quarter of a century, has been something

astonishing; there is no parallel to it anywhere else. Some thirty years ago, or even less, the currently accepted architecture of the American Republic was little more than a bad repetition of the English Gothic and Classic types of revived architecture. At the present day no nation, except perhaps France, takes so keen an interest in architecture and produces so many noteworthy buildings; and it may be observed that in the States the public and the official authorities seem really to have some enthusiasm on the subject, and to desire fine buildings. But the stirring of the dry bones began in America where it ended in England. The first symptoms of an original spirit operating in American architecture showed themselves in domestic architecture, in town and country houses, the latter especially; and the form which the movement took was a desire to escape conventional architectural detail and to return to the simplest form of mere *building*; rock-faced masonry, sometimes of material picked up on the site; chimneys which were plain shafts of masonry or brickwork; woodwork simply hewn and squared; but the whole arranged with a view to picturesque effect (Figs. 3 and 4).

This form of American house became an incident in the course of modern architecture; it even had a recognizable influence on English architects. About the same time an impetus of a more special nature was given to American architecture by a man of genius, the late H. H. Richardson, who, falling back on Romanesque and Byzantine types of architecture as a somewhat unworked field, evolved from them a type of architectural treatment so distinctly his own (though its *origines* were of course quite traceable) that he came very near the credit of having personally invented a style; at all events he invented a manner, which was so largely admired and imitated that for some ten or fifteen

FIG. 8.—American Type of Country-house Architecture.

And when we come to consider modern conditions of building, it is perfectly obvious that with the complicated practical requirements of modern building, in regard to planning, heating, ventilation, &c., the planning of the whole in a complete set of drawings, before the building is begun, is an absolute necessity. We are no longer in mediæval times; modern conditions require the modern architect. The real cause of failure, as far as modern architecture is a failure, lies partly in the fact that it is practised too much as a profession or business, too little as an art; partly in the deadening

FIG. 4.—American Seaside Villa. (Bruce Price.)

effect of public indifference to art in Britain. If the public really desired great and impressive works of architecture they would have them; but neither the British public, nor its mouthpiece the Government, care anything about it. Their highest ambition is to get convenient and economical buildings. And as to the theory of the new school, that we should throw overboard all precedent in architectural detail, that is intellectually impossible. We are not made so that we can invent everything *de novo*, or escape the effect on our minds of what has preceded us; the attempt can only lead to baldness or eccentricity. Every great style

years American architecture showed a distinct tendency to become "Richardsonesque" (Fig. 5, see Plate). As with all architectural fashions, however, people got tired of this, and the influence of another very able American architect, the late R. Morris Hunt, who had received his educa-

FIG. 7.—American Modern High Building (American Surety Co., New York).

tion at the École des Beaux-Arts of France, coupled perhaps with the proverbial philo-Gallic tendencies of the modern American, led to the American architects, during the last decade of the century, throwing themselves almost entirely into the arms, as it were, of France; seeking their education as far as possible in Paris, and adopting the theory and practice of the École des

Beaux-Arts so completely that it is often impossible to distinguish their designs, and even their methods of drawing, from those of French architects brought up in the strictest régime of the "École." By this French movement the Americans have, on the one hand, shared the advantages and the influence of what is undoubtedly the most complete school of architectural training in the world; but, on the other hand, they have foregone the opportunity which might have been afforded them of developing a school or style of their own, influenced by the circumstances of their own requirements, climate, and materials. Fig. 6 (see Plate) shows an example of recent American architecture of the European classic type. Thus, in the two countries which during the last quarter of a century have shown the most activity and restlessness in their architectural aspirations, and given the most original thought to the subject, England has constantly tended towards throwing off the yoke of precedent and escaping from the limits of a scholastic style; while America, commencing her era of architectural emancipation with an attempt at first principles and simple but picturesque building, has ended by a pretty general adoption of the highly-developed scholastic system of another country. The contrast is certainly a curious one. Only one original contribution to the art has been made by America in recent days—one arising directly out of practical conditions, viz., the "high buildings" in cities; a form of architecture which may be said to be due directly to the fact that New York is built on a peninsula, and extension of the city is only possible vertically and not horizontally. The tower-like buildings, served internally by lifts, to which this condition of things has given rise (Fig. 7), form a really new contribution to architecture, and have been handled by some of the American architects in a very effective manner; though, unfortunately, the rage for rapid building in the cities of the States has led to the adoption of a system of running up such structures in the form of a steel framing, cased with a mere skin of masonry or terra cotta for appearance' sake, which in reality depends for its stability on the steel framing. This is not only a false system of architectural design, but may probably prove to be a dangerous form of building. It must be admitted, however, to be a new contribution to architecture, and renders New York, as seen from the harbour, a "towered city" in a sense not realized by the poet.

Some sketch of the state of architectural thought or endeavour in England seemed essential to the subject, since it is there that what may be called the philosophy of architecture has been most debated, and that thought has had the most obvious and most direct effect on architectural style and movement. That this has been the case has no doubt been largely due to the influence of Ruskin, who, though his architectural judgment was on many points faulty and absurd in the extreme, had at any rate the effect of setting people thinking—not without result. In other countries architecture continued to pursue, up to the close of the century, the scholastic ideal impressed upon it by the Renaissance, without exciting doubt or controversy unless in a very occasional and partial manner, and without any changes save those minor ones arising from changing habits of execution and use of material. In Germany there appears to be a certain tendency to a greater freedom in the use of the materials of classic architecture, a certain relaxation of the bonds of scholasticism; but it has hardly assumed such proportions as to be ranked as a new movement in architecture.

Turning from the critical to the historical aspect of the subject, we find that in England the chief activity has been in public buildings and in street architecture. As already observed, church architecture has for the most

part followed, under clerical influence, the old lines of the mediæval revival; and there have been comparatively fewer churches built than in the middle portion of the century, nor has the general interest in church architecture been of late by any means what it was during the earlier revival, the enthusiasm of which has in fact to a great extent burned itself out. There are, however, some incidents worth special notice. The building of a new cathedral is an event which stands alone in modern England. It is true that Truro Cathedral, designed by the late Pearson, R.A., is not completed, but it has been carried further towards

British examples; churches.

completion than was first hoped, and is perhaps the most remarkable and most successful example, in a scholastic sense, of revived Gothic, being internally almost (if one may say so) more mediæval than a mediæval cathedral itself, as far as detail is concerned, though not without original features, and externally showing the distinct impress of its architect's special feeling. One may regret that a great modern cathedral should not have been planned and designed on more modern lines; but it is a study in Gothic which speaks the thorough capacity and knowledge of its architect, and which no other country could have produced. Some of Mr Pearson's parish churches, as those of

FIG. 8.—Interior, St Clare's, Liverpool. (Leonard Stokes.)

Red Lion Square and Kilburn, London, are among the best and most striking modern buildings of their type. The addition of new naves to two mediæval churches—that of Bristol, by Street, that of St Saviour's, Southwark, by Blomfield, is an interesting achievement, and in these cases the use of revived Gothic was quite justified, for reasons of architectural consistency. In opposition to such work may be mentioned the curious and characteristic incident of the delivery of St Albans Abbey (now St Albans Cathedral), one of the most interesting and most valuable of the ancient mediæval monuments of the country, into the hands of a wealthy lawyer with a taste for playing the architect, the fact of his providing the funds being apparently accepted by public opinion as a quite sufficient

reason for allowing him to do what he liked with a building which is a national possession. There is probably no other civilized country in which such a proceeding would be possible. Among other events connected with the much-vexed question of restoration may be mentioned the repairing of the north transept of Westminster Abbey by Mr Pearson; in this case an excusable proceeding, as the archæological as well as architectural value of the façade had already been entirely destroyed by bad restoration earlier in the century, and Mr Pearson merely substituted good modern Gothic for bad. The taking down and rebuilding of the upper portion of the front of Peterborough Cathedral, rendered absolutely necessary on account of its structural condition, will be long remem-

bered on account of the opposition raised against it by archæologists, who were unable, or did not choose, to understand the practical necessity of the case. The last years of the 19th century witnessed the progress to an

FIG. 9.—Exterior, Modern English Church. (*James Brooks.*)

FIG. 11.—Staircase, Imperial Institute. (*Colcutt.*)

advanced stage of the most remarkable piece of English church architecture of the period, the Roman Catholic Cathedral at Westminster, by Mr Bentley; a building which is not a Gothic revival, but goes back to earlier (Byzantine) precedents; not, however, without a considerable element of novelty and originality in the design.

In ordinary church architecture, though there is still a good deal of mere imitation mediæval work carried out, we have not been without examples of a new and original application of Gothic materials. The interior of the church of St Clare, Liverpool, by Mr Leonard Stokes (Fig. 8), is a good example of the modified treatment of the three-aisled mediæval plan already referred to, the side aisles being reduced to passages; and also of the tendency in recent years to simplify the treatment of Gothic, in contrast to the florid and over-carved churches of the Gothic revival. The churches of Mr Brooks have shown many examples of a solid plain treatment of Gothic, yet with a great deal of character (Fig. 9); and the late J. D. Sedding built some showing great originality; among which the interior of his church of the Holy Redeemer, Clerkenwell, affords also an interesting example of the modern free treatment of forms derived from classic architecture.

with a solid masonry dome, instead of a huge dish-cover of glass and iron, there would have been little to find fault with in its general conception. It was

In the architecture of public buildings one of the earliest incidents in the period was the completion of the Albert Hall, which, though the work of an engineer, and

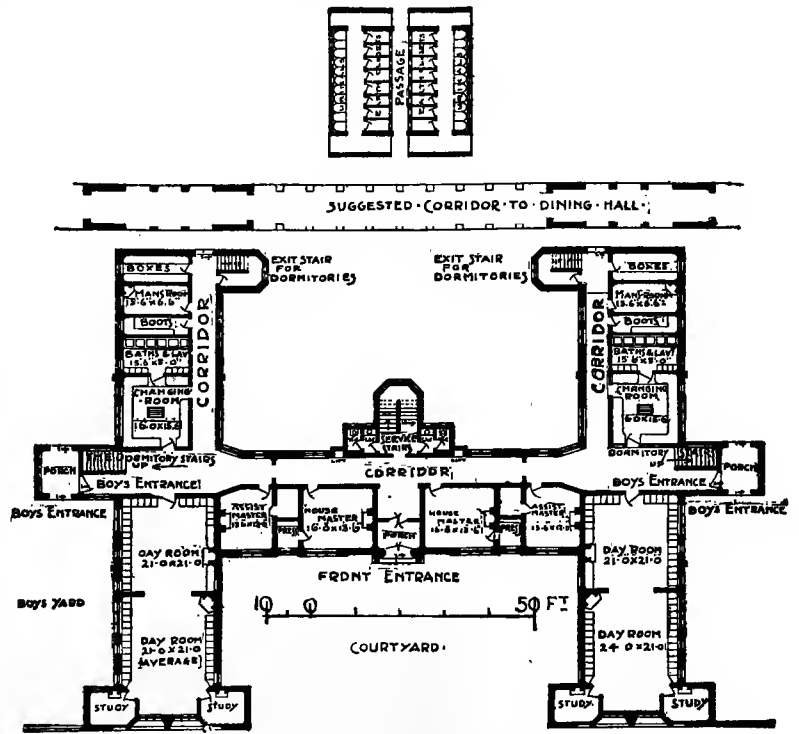

FIG. 12.—Plan of a Master's House, New Christ's Hospital. (Webb and Bell.)

FIG. 15.—Sheffield Town Hall. (Mountford.)

also the first modern English building of importance to be decorated externally with *Public buildings.* symbolical figure composition, in the shape of the large frieze in a coarse mosaic of terra cotta, which is carried round the upper portion of the exterior. Connected with this, both historically and in architectural grouping, is the Albert Memorial, the work of Scott, intended as a "shrine" on a great scale, which both for originality and beauty claims more credit than it has generally received. Its worst fault is that the angle piers are not adequate for the thrust of the arches, which are secured by concealed iron ties. Here again we had an early (modern) example of the sculptor working in harmony with the architect; and though there has been a great advance in

commonplace in detail, is in the main a fine and novel architectural conception, and a practical success (considering its abnormal size) as a building for musical performances. Had its constructor been bold enough to roof it

English sculpture during the last quarter of the century, much of that on the Albert Memorial still commands admiration; the colossal central figure, entirely out of scale with the rest, being unfortunately the weakest

portion of the work. The subject of the Government Offices in London forms in itself an important chapter in recent architectural history. The Home and Foreign Office block was finished in 1874; a sumptuous, but weak

The building was to stand between Whitehall and St James's Park, with a front both ways. The competition came to nothing, and the successful architects were eventually employed to build the new Admiralty as it now stands, a mean and commonplace building with no street frontage, in which economy was the main consideration, and totally discreditable to the greatest naval power in the world. In 1898-99 it was at last resolved to build a War Office and other Government Offices much needed, and an irregular site opposite the Horse Guards was selected for the War Office and one in Great George Street for the others. In this case there was no competition, but the Government selected two architects after inquiry as to their works ("classic" architecture being a *sine quâ non*); Mr Young for the War Office, and Mr Brydon for the Great George Street block. The War Office site is inadequate and totally unsymmetrical, the boundary of the building being settled by the boundary of the street curb, and the inner courtyards will be of very mean proportions compared with the great courtyard of the Home and Foreign Office. Both architects have produced grandiose designs, but in regard to the War Office at least the Government have thrown away a great opportunity. Unfortunately, throwing away great opportunities has been the history of the Government buildings ever since the Houses of Parliament, a really fine building, was completed.

FIG. 16.—Oxford Town Hall. (Hare.)

FIG. 17.—Northampton Institute. (Mountford.)

FIG. 18.—Cragside. (R. Norman Shaw, R.A.)

and ill-planned building designed by Scott, *invitâ Minervâ*, in a style alien to his own predilections. In 1884 took place the great competition for the War and Admiralty Offices conjointly, won by a commonplace but admirably drawn design, presenting some good points in planning.

grace. The competition produced some fine and striking designs, some of them perhaps more so than the selected one by Mr Aston Webb, whose fine plan, however, justified the selection. Another competition which excited general interest was that in 1894, for the rebuild-

There can only be further enumerated a few of the more important buildings carried out in England during the later years of the 19th century, and mention made of the general course which architecture has taken in regard to special classes of buildings. The Natural History Museum (Fig. 10, see Plate), completed in 1881 by Mr Alfred Waterhouse, may stand as a type of the taste for the employment of terra cotta, with all its dangerous facilities in ornamental detail, which that architect specially set the example of. Detail is certainly overdone here, but the building is strikingly original; a point not to be overlooked in these days of architectural copying. The Imperial Institute, the result of a competition among six selected architects, represents also a type of architecture which its architect, Mr Collcutt, may be said to have matured for himself, and which has been extensively imitated; a refined variety of free classic, always quiet and delicate in detail, though perhaps rather wanting in architectonic force (Fig. 11). The next great architectural competition was that for the completion of the South Kensington Museum, the bare brick exterior of which, waiting for architectural completion, had long been a national dis-

ing on a country site of Christ's Hospital Schools, also gained by Mr Webb (in collaboration with Mr Ingress Bell), by a design which, in its arrangement of schoolhouses in detached blocks (Fig. 12), but in a symmetrical grouping, opened up a new idea in public school planning, and struck a blow at the picturesque but insanitary quadrangle system. Among notable public buildings of the period ought to be mentioned Mr Norman Shaw's New Scotland Yard, built in a style neither classic nor Gothic, but par-

taking of the elements of both (Figs. 13 and 14, see Plate); a work which has perhaps been a little over-praised, just as it has been very superficially condemned, but which is a remarkable example of novel and picturesque design, though most of the details, taken separately, are imitative.

In recent years there has been a great movement for building town halls; towns rather vying with each other in this way. Of late nearly all of these have been carried

FIG. 19.—City Bank, Ludgate Hill. (Collcutt.)

out in some variety of free classic. Among the more important in point of scale is that of Sheffield, by Mr Mountford (Fig. 15); among smaller ones, those of Oxford, by Mr Hare (Fig. 16), and Colchester, by Mr Belcher, are particularly good examples of recent architecture of this class, the former distinguished also by an exceptionally good plan. The merit of excellent planning also belongs to Messrs Aston Webb and Ingress Bell's Birmingham Law Courts, one of the modern terra-cotta buildings of somewhat too florid detail, though picturesque as a whole. Among public halls the M'Ewan Hall at Edinburgh, completed in 1898 from the designs of Dr Rowand Anderson, deserves mention as one of the most original

and most carefully designed of recent buildings in Great Britain.

The various new buildings erected in connexion with the University of Oxford, those by Mr T. G. Jackson especially, form an important incident in modern English architecture. Mr Jackson has succeeded to a remarkable degree in designing new buildings which are in harmony with the old architecture of the university city; sometimes perhaps a little too imitative of it, but at any rate he has the credit of having added rather extensively to Oxford without spoiling it; while his school buildings in different parts of the country have a refinement and domesticity of feeling which is the true note of school

architecture. Among buildings of an educational class, the move in technical education has led to the erection of

Henman, combines architectural effect with the latest hygienic improvements, and is the first large hospital in Great Britain in which the system of mechanical ventilation has been completely and consistently carried out.

In theatre building there has been an immense improvement in regard to planning, ventilation, and fire-proof construction, but little to note in an architectural sense, since theatres in England are never designed by eminent architects, the financial and practical aspects being alone considered.

In domestic architecture the tendency has been to quit picturesque irregularity for a more formal and more dignified treatment. Such a house as Mr Norman Shaw's "Cragside," built in the earlier part of our period (Fig. 18), however its picturesque treatment may still be admired, would hardly be built now on a large scale; its architect himself has of late years shown a preference for a symmetrical and regular treatment of house architecture, sometimes to the extent of making the mansion look too like a barrack. In street architecture, however, the tendency has been towards a more characteristic and more picturesque treatment; nor is there any class of building in which the improvement in English architecture during the last quarter of a century has been more marked and more unquestionable. Many of the new residential streets in the west end of London present a really picturesque *ensemble*, and many shops and other commercial street buildings have been erected with admirable fronts from the designs of some of the best architects of the day. Mr Norman Shaw's building at the corner of St James's Street and Pall Mall was one of the first, and is still one of the best examples of modern street architecture. As later examples may be cited Mr Colcutt's City Bank in Ludgate Hill (Fig. 19), and Mr R. Blomfield's narrow house-front in Buckingham Gate (Fig. 20). The introduction of sculpture in street fronts is also beginning to receive attention; and a simple house-front recently erected in a London street, from the design of Mr Beresford Pite (Fig. 21, see Plate), is an excellent example of the use of sculpture in connexion with ordinary street architecture. It is significant of the increased attention accorded to street architecture, that the most important architectural event in England at the very close of the 19th century, was the outlay of £2000 by the London County Council, in

FIG. 20.—House, Buckingham Gate. (R. Blomfield.)

a good many large polytechnic and similar institutions, which in many cases have been well treated architecturally; the Northampton Institute at Clerkenwell (Fig. 17), by Mr Mountford, being perhaps one of the boldest and most effective of recent public buildings. In the building of hospitals and asylums much has been done, and great progress made in the direction of hygienic and practical planning and construction, but the tendency has been (perhaps rightly) towards making this practical efficiency the main consideration, and reducing architectural treatment to the simplest character. The well-known St Thomas's Hospital, at Lambeth, exemplifies the treatment of hospital architecture at the commencement of our period; the separate pavilion system had been already adopted on practical grounds, but the building is treated in a sumptuous architectural style, as if representing so many detached mansions; a treatment which would now be deprecated as an expenditure foreign to the main purpose of the building. One recent hospital, however, that at Birmingham, by Mr

fees to eight architects for designs for the front of a proposed new street.

Turning to the Continent, we find in France, still the leading artistic nation of the world, that the art of architecture has been in a most flourishing and most active state during the last quarter of a century. It is true that

there is not the same variety as in modern English architecture, nor have there been the same discussions and experiments in regard to the true aim and course of architecture which have excited so much interest in England; because the French architects, unlike the English, know exactly what they want. They have a "school" of architecture; they adhere to the scholastic or academic theory of architecture as an art founded on the study of classic models; and on this basis their architects receive the most thorough training of any in the world. This predominance of the academic theory deprives their architecture, no doubt, of a good deal of the element of variety and picturesqueness; a French architect *pur sang*, in fact, never attempts the picturesque, unless in a country residence, and then the results are such that one wishes the attempt had not been made. But, on the other hand, modern French architecture at its best has a dignity and a style about it which no other nation at present reaches, and which goes far to atone for a certain degree of sameness and repetition in its motives; and living under a Government which recognizes the importance of national architecture, and is willing to spend public money liberally on it (with the full approbation of its

important events in connexion with architecture, for even the temporary buildings erected for them showed an amount of architectural interest and originality which

FIG. 23.—Salle des Cariatides, Hôtel de Ville, Paris.

FIG. 25.—École de Médecine, Paris. (Ginain.)

public) the French architects have opportunities which English ones but seldom enjoy—the predominant aim with a British Government being to see how little they can spend on a public building. The two great Paris exhibitions of 1889 and 1900 may be regarded as im-

could be met with nowhere else, and which in each case left its mark behind it, though with a difference; for while in the 1889 exhibition the main object was to treat temporary structures—iron and concrete and terra cotta—in an undisguised but artistic manner, in those of the 1900 exhibition the effort was to create an architectural *coup d'œil* of apparently monumental structures of which the actual construction was disguised. In spite of some eccentricities, the amount of invention and originality shown in these temporary buildings was most remarkable; but fortunately the exhibition left something more permanent behind it in the shape of the two Art-palaces and the new bridge over the Seine. The two palaces are triumphs of modern classic architecture; the larger one

(by MM. Thomas, Louvet, and Deglane) is to some extent spoiled by the apparently unavoidable glass roof; the smaller one, by M. Girault, escapes this drawback, and, still more refined than its greater opposite, is one of the most beautiful buildings of modern times; while the

architectural pylons, with their accompanying sculpture, which flank the entries to the bridge, are worthy of the | in progress for many years, from the designs of the late M. Abadie, and in the year 1900 was still unfinished. In church architecture generally France has not shone very much during the latter part of the century; all her finest modern classic churches date from before the war. Among smaller French buildings of peculiar merit may be mentioned the Musée Galliera, in the Trocadéro quarter of Paris, designed by M. Ginain—a work of pure art in architecture such as we should nowadays look for in vain out of France; the École de Médecine, by the same refined architect (Fig. 25); and the chapel in Rue Jean Goujon (Guilbert), erected as a memorial to the victims of the bazaar fire, again a notable instance of a work of pure thought in architecture—a new conception out of old materials. The new Opéra Comique (Bernier) should also be mentioned (Fig. 26), the rather disappointing result of a competition which excited great interest at the time. Street architecture has been carried out of late in Paris in a sumptuous style (Fig. 27), with great stone fronts

FIG. 26.—Opéra Comique, Paris. (Bernier.)

best period of French Renaissance. Thus much, at least, has the 1900 exhibition done for architecture.

At the beginning of our period stands one of the most important of modern French buildings, the Paris Hôtel de Ville, commenced shortly after the war, from the designs of MM. Ballu and Deperthes, planned on an immense scale, and on the stateliest and most monumental lines (Figs. 22, 23). The central block is, externally, a restoration of the old Hôtel de Ville, the remainder carried out in an analogous but somewhat more modern style. The interior has been the scene of sumptuous pictorial decoration, in which all the first artists of the day were employed—unfortunately in too scattered a manner, and on no predominant or consistent scheme. During the period one of the most characteristic architectural efforts of the French has consisted in the erection of the various smaller Hôtels-de-ville or Mairies, in the city and suburban districts of the capital; as at Pantin, Lilas, Suresnes, and in various arrondissements within the city proper (Fig. 24, see Plate). Nothing shows the quality of modern French architecture better, or perhaps more favourably, than this series of district town halls; all have a distinctly municipal character and a certain family resemblance of style amid their diversity of details; all are refined specimens of pre-eminently civilized architecture. Among the greater architectural efforts of France during the last decade or two are the immense block of the new Sorbonne, by M. Nénot, a building sufficient in itself for an architectural reputation; and the great church of the Sacré Cœur, overlooking Paris from the hill of Montmartre, an erection of such monumental massiveness as we never see in modern England, which was

FIG. 27.—Example of Paris Street Architecture.

and a profusion of carved ornament, such as we know nothing of in England; and though there is a rather monotonous repetition of the same style and character

throughout the new or newly-built streets, it is impossible to deny the effect of palatial dignity they impart to the city. In the matter of country houses the French architect is less fortunate; when he attempts what he regards as the rural picturesque, his good taste seems entirely to desert him, and the *maison de campagne* (Fig. 28) is generally a mere riot of gimerack.

The great military success of Germany in 1870, and the founding of the German empire, gave, as is usual in

such crises, a decided impetus to public architecture, of which the central and most important visible sign is the German Houses of Parliament, by Professor *Germany.* Wallot, whose design was selected in a competition. There is something essentially German in the quality of this national building; classic architecture minus its refinement. The detail is coarse; the finish of the end pavilions of the principal front absolutely unmeaning—mere architectural rodomontade; the central

FIG. 29.—Interior, Houses of Parliament, Berlin. (Wallot.)

cupola of glass and iron, on a square plan, probably the ugliest central feature on any great building in Europe; and yet there is undeniable power about the whole thing; it is the characteristic product of a conquering nation not reticent in its triumph. The interior of the vestibule is shown in Fig. 29. The new cathedral at Berlin, by Professor Raschdorff, is the other most important German work of the period (Fig. 30); a building very striking and unusual in plan, but absolutely commonplace in its architectural detail; school classic of the most ordinary type, without even any of those elements of originality

which are to be found in the Houses of Parliament. A curious feature in the plan (Fig. 31) is that the building, alone of any cathedral we can recall, has its principal general entrance at the side, the end entrance being reserved for a special imperial cortège on special occasions, the cathedral also serving the second purpose of an imperial mausoleum. Theatre building has been carried on very largely in Germany, and among its productions the Lessing Theatre at Berlin (Fig. 32) (von der Hude and Henicke) is a favourable example of German classic at its best, besides being, like most modern German

FIG. 86.—Houses of Parliament, Budapest. (Steinhil.)

FIG. 87.—Plan of Parliament Houses, Budapest.

theatres, very well planned (Fig. 33). Hamburg has had its new municipal buildings (Herr Grotjan), a florid Renaissance building with a central tower, showing in its general effect and grouping a good deal of Gothic feeling. Mention may also be made of the new Law Courts at Leipzig (Herr Hoffmann), a building with no more charm

FIG. 28.—French "Maison de Campagne" (mild type).

character (Fig. 36, see Plate), in a style in which the Gothic element is prevalent, though the central feature is a dome. The plan (Fig. 37, see Plate) is obviously based on that of the Westminster building; the exterior design, however, has the merit of clearly indicating the position of the two Chambers as part of the architectural design, the want of which is the one serious defect of Barry's noble structure. In Italy modern architecture is at a very low ebb; the one great work which comes within our period has been the building of the façade to the Duomo at Florence, from the design of the late De Fabris, who did not live to see its completion. As the completion in modern times of a building of world-wide fame, it is a work of considerable interest, and, on the whole, not unworthy of its position; that it should harmonize quite satisfactorily with the ancient structure was hardly to be expected. It was probably the completion of this façade which led the city of Milan to start a great architectural competition, a few years since, for the erection of a new façade to its celebrated cathedral, not because the façade had never been completed, but because it had been spoiled and patched with bad 18th-century work. The ambition was a legitimate one, and the competition, open to all the world, excited the greatest interest; but the young Italian architect, Brentano, to whom the first premium was awarded, died shortly afterwards, and other causes, partly financial, led to the postponement of the

FIG. 34.—Interior of Leipzig Law Courts. (Hoffmann.)

about it, externally, than the Berlin Parliament Houses, but with some good interior effects (Fig. 34). The new Post Offices in Germany have been an important undertaking, and are, at all events, buildings of more mark than those in England. There has also been a great deal of new development in street architecture, which shows an immense variety, and a constantly evident determination to do something striking; but we find in it neither the dignity of Parisian street architecture nor the refinement of modern London work; there is an element of the bombastic about it.

No modern building on the European continent is more remarkable than the Brussels Law Courts, built in the early years of our period, from the designs of the late M. Poelaert, an original genius in architecture, who had the good fortune to be appreciated and given a free hand by his Government. The design is based on classic architecture, but with a treatment so completely individual as to remove it almost entirely from the category of imitative or revival architecture; somewhat fantastic it may be, but as an original architectural creation it stands almost alone among modern public buildings. In Vienna the scholastic classic style has been retained with much more purity and refinement than in the German capital (Fig. 35, see Plate). Budapest, on the other hand, which has almost sprung into existence since 1875 as the rival of the Austrian capital, has erected a great Parliament building of florid

scheme, though it is understood that there is still an intention of carrying out Brentano's design under the direction of the official architectural department of the city.

AUTHORITIES.—The literature of architecture as a modern art is limited, the most important publications of recent times being mainly devoted to the study and illustration of ancient architecture. The following, however, may be named:—JAMES FERGUSSON. *History of Modern Architecture* (2nd edition). London, John Murray, 1873.—T. G. JACKSON. *Modern Gothic Architecture*. London, H. S. King, 1873.—J. T. MICKLETHWAITE. *Modern Parish Churches*. London, 1874.—E. R. ROBSON. *School Architecture*. London, John Murray, 1874.—J. J. STEVENSON. *House*

FIG. 81.—Plan of Berlin Cathedral.

The real literature of modern architecture, however, is to be found mainly in the articles and illustrations in the best periodical architectural publications of various countries. Among these Italy has none worth mention, and France, with all her architectural enthusiasm, has had no first-class architectural periodical since the extinction, about 1890, of the *Revue générale de l'Architecture*, conducted for more than fifty years by the late César Daly, and in its day the first periodical of its class in the world. The following are the best publications at present:—*The Architectural Record* (quarterly). New York.—*The Architectural Review* (monthly). Boston, U.S.A.—*The Allgemeine Bauzeitung* (quarterly). Vienna.—*The Berlin Architekturwelt* (monthly).

II. RECENT ARCHÆOLOGICAL DISCOVERIES.

Archæological research since 1875 has not only enriched the museums of Europe with priceless treasures, but, by the adoption of a much more scientific system of excavation, has been able to complete and rectify the discoveries of earlier explorers, and to fill up the gaps in the history of the origin and development of the earlier architectural styles. In two of these—viz., the Egyptian and the Greek—the researches of Professor Flinders Petrie in Egypt, and of Dr Schliemann, Dr Dörpfeld, and Mr Homolle in Greece, have placed the archæological history of architecture on a surer and better-defined basis than heretofore.

Egyptian.

Taking the earliest structures first, we learn from Professor Flinders Petrie's work on *The Pyramids and Temples of Gizeh*, that the oldest pyramids known are those of Sakkara and Medum (Meidoun), and these were not only

FIG. 1.—Pyramid of Medum (Meidoun).

of different construction from any of the others, but when the latter was completed it reached the form afterwards adopted in the true pyramids. The kernel of the Sakkara and Medum pyramids belong to the class known as Mastaba tombs. The term mastaba (Arabic for "bench") has been given to the sloping-sided tombs, of about 76° angle and from

10 to 20 feet in height (Fig. 1). In their origin they are probably copies in stone of the crude brick dwellings of the Egyptians, the walls of which must be much thicker at the bottom than at the top, to carry the superincumbent weight. Both the pyramids above named are known as cumulative or superposed mastabas¹—i.e., successive enlargements have been made to them, having been after each completion again enlarged by another coat of rough masonry with another fine polished casing outside. The pyramid of Sakkara was never completed, and has retained the stepped form which these successive casings gave to it. In the Medum pyramid the tower-like appearance, at present, of the centre portion is due to two of the lower enlargements having fallen away (Fig. 2). Before the final casing the successive enlargements had resulted in seven steps, the outer angles of which were pyramidal; the last process was to add a smooth casing to one slope from base to top. The angle thus formed was about 52°. These two pyramids are the only ones built in this way; in all the others the full size was settled from the first, though a change from the original size seems to have been made during its construction, in the third pyramid of Menkaura.

From Professor Flinders Petrie's measurements of the Great Pyramids, the original dimensions have now been ascertained exactly. The external dimensions of the first pyramid, that of Khufu, are 755 ft. 8 in. as the mean of the four sides, with an extreme difference of 1.7 of an inch. The height from the level of the artificial pavement round the pyramid to the apex was 481 ft. 4 in., and the angle of casing, 51.52°. In the second pyramid, Khafra, the lowest course was in granite, and had a vertical base 11 in. high, against which the artificial pavement was laid. The side dimensions were 706 ft. 3 in. as a mean, with an extreme difference of 5 in. The height was 472 ft., and the angle of casing 53.10°. The third pyramid, Menkaura, was never quite completed, the mean length of the sides was 346 ft., the height 215 ft. and the angle 51.10°. The lower portion of this pyramid was cased with granite to about one-fourth up, and the rough surface of the granite casing was never worked off. Part of the outer casing still remains on the second pyramid. The casing stones were not simply triangular blocks filling up the angles formed by the receding steps, but from 7 to 10 feet in depth, so that their bedding must have begun at the bottom.

FIG. 2.—Pyramid of Medum.

In the course of his researches at Gizeh in 1881-82, Professor Flinders Petrie made a minute examination of the granite blocks inside the Great Pyramid, and of the debris in granite chips and diorite on the site of the workshops of the masons who built the Pyramids, and ascertained that the typical method of working hard stones, such as

granite, basalt, and diorite, was by means of bronze tools set with cutting points, probably of corundum, as the diamond is not known in Egypt, and that the masons employed straight and circular saws and tubular drills.

¹ It still retains a portion of its original casing at the top (see Fig. 2).

The pyramid of Medum, already mentioned, was built by Sneferu, the first king of the fourth dynasty, c. 3998-3969 B.C.; and on the east side Professor Petrie discovered a small temple attached to it, consisting of two chambers roofed over in stone with two steles and an altar between on the roof. Traces of other temples have since been found on the east side of the Great Pyramids; and from the temple of the second pyramid a causeway led down to the granite temple, known as the temple of the Sphinx (Fig. 3), the earliest temple known, and, according to Professor Petrie, built by Khafra after the completion of his pyramid. The temple, though now buried, was originally a free-standing building on the plain at the foot of the hill. The tablet referring to the restoration of the Sphinx by Khufu is now recognized as a forgery of the twentieth dynasty. No mention is made of the Sphinx on any monument of the old kingdom, and Professor Petrie places its date between the sixth and the tenth dynasties.

Of the famous Labyrinth built by Amenemhat III., c. 2622-2578 B.C., nothing remains but the site, about 1000 × 800 feet—the masses of buildings described by Lepsius are, according to Professor Petrie, the brick houses of a Roman village built on the site. The Hawara pyramid on the north side was erected by the same king. It was built in crude brick and coated with a fine limestone casing like the other pyramids; its dimensions are about 334 feet wide and 197 feet high. In the interior of this pyramid Professor Petrie discovered a pointed arch 3 feet in depth and composed of three rings of bricks, which was employed to take off the weight of the upper part of the pyramid from the roof of the tomb chamber. The Pyramid of Illahun, built by Usertasen II., c. 2684-2660 B.C., to the south-east of, and situated about a mile from the Labyrinth, was partly composed of solid rock about 40 feet high, isolated by the cutting away of the rock round it. The upper portion consisted of cross walls of stone, fitted in with crude

Pyramid of Khafra.

Sphinx.

Pyramid of Khufu.

Fig. 3.—Temple of the Sphinx.

brick and cased afterwards with limestone. It was near this pyramid that Professor Petrie discovered the town of Kahun, erected to house the overseers and workmen who built the pyramid, and deserted by them on its completion. The walls were all of crude brick, and where the rooms exceeded 8 or 9 feet in width columns of wood or stone were employed to assist in carrying the roof. The lower portion of a column fluted like those at Benihasan was found on its stone base.

The pyramidal form given to the stone pylons of Egyptian temples is now generally acknowledged to have been derived from the material in which the earlier examples were built, viz., crude brick, the raking sides arising from the fact that these crude brick walls are always, for reasons already given, much thicker at the bottom. Even at the present day the pigeon-houses built on the roof of the modern Egyptian dwelling-houses take the same shape, and in the distance are often mistaken for temples.

During 1894 and following years excavations have been carried out under the direction of Mr Naville at Deir-el-Bahri, the splendid temple built by Queen Hat'shepsut,

1516-1503 B.C., and by the removal of the superincumbent earth a great portion of the temple foundations have been exposed. In that part buried by the falling in of the rock above at the north-east end, the hypostyle hall and colonnade are almost perfect. Since the plan was measured by Professor Brune in 1866 and published by Mariette, with some incorrect alterations, the principal architectural discovery has been that of the great altar in the north-east court, the only complete example found in Egypt, its preservation being due to the falling in of the rock above. Professor Brune's restorations made in 1866-67, and published by Mariette, give an excellent idea of the aspect of this remarkable temple, which was built on a series of terraces; except that the later discoveries have shown the north-east corner to have been different in plan from the north-west corner.

In 1891-92 Professor Petrie excavated and uncovered the remains of the Palace of Khu-en-aten (Amen-hotep IV.), 1383-1365 B.C., who not only made changes in the religious worship of the country, but in the decoration of his palace departed from the conventional art of the period, and intro-

duced a reform therein. In the pavement and frescoes of the walls the subjects are selected from out-of-door life, and birds, insects, and water-plants are depicted with marvellous fidelity to nature. The temple of Luxor has also been cleared out under Mr Maspero, so that those portions of the plan which were covered over and hidden by modern buildings are now exposed.

Persian.

Mr Marcel Dieulafoy's excavations at Susa in 1884-86 have confirmed those made by Sir Kenneth Loftus in 1850 as regards the three great porticoes and the Apadana, or Hall of Columns of the Palace of Artaxerxes Mnemon. The walls enclosing the hall and flanking the porticoes, as conjectured by Fergusson, no longer existed, being probably built in unburnt brick; but the discovery of fragments of the pavement inside the hall and in the rear of the north and west porticoes, which stopped on the lines where the walls (16 feet thick) should have been found, is a sufficiently clear proof of their existence. The fourth or south side of the Apadana opened on to a court, and facing the hall, on the right and left of the court, were two walls, which were decorated with the famous frieze of archers now in the Louvre. The wall had apparently fallen down on its face, and thus preserved more or less intact this frieze, which was executed in enamel in bright colours on beton blocks. Farther to the south Mr Dieulafoy found the grand staircase leading to the palace similar to the well-known example at Persepolis, except that the walls were here decorated with enamelled beton blocks. At Persepolis in 1891 Mr Weld Blundell ascertained, firstly, that the drain which was supposed to run under the site of what in Fergusson's restoration should be a wall was carried between the wall and the first row of columns; secondly, that two of the vertical stone rain-water pipes rose above the pavement of the terrace, proving that they were brought down inside the wall from the roof above the Hall of Columns; and, thirdly, that the three porticoes were flanked by towers, the foundations of which were traced below the hard lime crust which had been mistaken for the solid rock, thus confirming Fergusson's restoration.

Greek.

Although the excavations made by Dr Schliemann in Troy, Mycenæ, and Tiryns have in the main an archæological rather than an architectural value, the discovery of the plan of the Palace of Tiryns has enabled Dr Dörpfeld to trace the origin of many of the characteristic features of Greek architecture. The propylæa or entrance gateways were of the same plan as that subsequently developed into the Hexastyle porticoes of the Propylæa at Athens and other sacred enclosures. In the megaron or men's hall of the palace, with its Portico-in-antis and vestibule, Dr Dörpfeld recognizes the model of the cella of the Greek Doric Temple. The researches revealed that the primitive construction consisted of a foundation wall about 3 feet in height, built in rubble masonry laid in clay mortar, and of such thickness as to suggest that the upper part of the walls was built in crude or unburnt brick. In order to protect the face of the antæ of the Portico-in-antis, and in conjunction with the two columns of the portico, to carry the architrave, vertical posts or planks of wood were employed, secured by wooden dowels to a stone base. The two columns of the Portico-in-antis were in timber, their

trace being shown on the stone bases still *in situ*, which were raised two inches above the pavement, a precaution taken to protect the base of a wooden column. This timber construction was afterwards copied in stone, and is the origin, according to Dr Dörpfeld, of the slightly projecting antæ employed afterwards decoratively in all Greek temples. Further evidence of the correctness of this theory has been found in the temple of Hera at Olympia, which was excavated by the German Government in 1875-85. Here the lower part of the walls was in masonry of small dimensions carrying a superstructure in crude brick, and the antæ were protected and strengthened by vertical posts of timber, traces of which were found on the stylobate or upper step. Here also, as in Tiryns, the doorposts of the entrance doorway were in timber. In the Heraion, however, that which at Tiryns constituted the megaron had become the cella of the temple, and a further development had taken place by the surrounding of the same with a peristyle of columns to protect the external wall of the cella, and probably its stucco face and painted decoration. The variety of profile shown in the stone capitals found on the site, and the fact that Pausanias mentions his having seen a wooden column in

FIG. 4.—The Theatre of Epidaurus.

the opisthodomus, have led to the conclusion that originally all the columns of this temple were in wood, being replaced gradually by copies in stone. Their wide intercolumniation proves also that the entablature was in wood, and the discovery of some of the terra-cotta tiles and antefixæ shows that the wooden roof was covered with tiles. The probable date of the foundation of the temple is placed by Dr Dörpfeld in the 11th cent. B.C.; four centuries, therefore, before the earliest stone temples known, viz., those of Apollo and of Zeus at Syracuse.

The excavations at Olympia have laid bare the whole site of the Altis or sacred enclosure, and some of the structures of later date round the same. It may be pointed out that the preservation and recovery of the famous statue of Hermes by Praxiteles is due to its having been thrown down by, and buried in, the clay of the crude brick walls of the cella; when that happened no one knows, but it is strange that so ephemeral a material as unburnt brick should, if our dates are correct, have been preserved for thirteen or fourteen centuries. The researches of Blouet and other explorers in the earlier part of the 19th century had made known to us the plan of the Temple of Zeus, which was Hexastyle Doric with thirteen columns in the flanks, and of the usual type, with pronaos, epinaos, and cella. The entire clearance of all the

superincumbent earth has, however, revealed many other features in the plan which bear out Pausanias' description. First, within the entrance to the cella were staircases leading to the galleries, "through which there is an approach to the image." On the pavement were seen the traces of the barrier across the cella between the second column on each side and of other barriers restricting the passage to the side aisles. In front of the pedestal which carried the famous chryselephantine statue of Zeus, by Phidias, were found the traces of the black stone paving with the raised margin of Parian marble to hold the oil which, according to Pausanias, was kept there to preserve the ivory, a precaution rendered necessary by the dampness of the Altis. The position of this sunk space filled with oil quite disposes of the hypæthron, and there is no doubt that in this temple the statue was lighted only through the open door.

In the Byzantine church, outside the Altis, have been recognized the lower parts of the walls of the workshop of Phidias, mentioned by Pausanias. It was of the same size as the cella of the temple.

In order to carry out systematically the explorations

FIG. 5.—Conjectural Restoration of the East Front of the Temple of Diana at Ephesus, by Dr Murray.

at Delphi, begun in 1891 by the French School at Athens, it was found necessary to expropriate the inhabitants of Kastri, a small village built on the sacred enclosure, providing accommodation for them elsewhere. This, combined with the labour involved in clearing away the superincumbent earth and the debris of the village, and conveying it some distance, necessarily delayed the work. Here, as at Olympia, the writings of Pausanias have been of the greatest value in the nomenclature of the various buildings and monuments the foundations of which were found on either side of the sacred way. This, owing to the steepness of the hill, winds round at a gentle slope from the entrance of the sacred enclosure at the south-east, rising across the same to the west and returning to the foot of the steep ascent leading to the raised terrace on which the Temple of Apollo was built. The excavations have exposed the whole of the peribolos or wall surrounding the temenos or sacred enclosure, the foundations of all the treasuries and votive monuments, and the terrace wall; the latter, carrying the platform of the temple, is one of the finest examples known of polygonal masonry. Comparatively little was found of the architectural features of the Temple of Apollo, but those of the several Treasuries are of importance in one

case, that of the Siphnians allowing of a more or less complete conjectural restoration. The Siphnian treasury is supposed to date from the end of the 6th cent. B.C.; in the magnificent carving of the architectural ornament it may be said to rival that of the Erechtheum. Although built in Parian marble, it was richly decorated in colour, of which vivid traces still exist. Among other finds were the remains of four caryatid figures of colossal size, each with a calathos or polos on the head; these, according to Mr Homolle, seem to have supported a tribune like the caryatid portico of the Erechtheum, and probably served as the prototype of the arephoroi of that building. Further remains have been found of the Sphinx of archaic character, and of the Ionic capital of early date which carried it, sufficient now to complete their restoration. The remains also of a triangular votive column were found, triangular in the sense that as it supported originally a tripod there were three caryatid figures at the top carrying the same; and the decorations of the column, with widely-projecting and finely-carved acanthus leaves, are grouped in triplets, which constitute the capital and base of the column. These acanthus leaves are the earliest known, and are certainly the most vigorous examples ever carved.

At Epidaurus, where excavations were systematically begun in 1881 by the Greek Archæological Society under Mr Kavvadias, the sacred temenos has been laid bare, exposing the plans of the stoa or colonnade where the patients were housed, of the temple of Asclepius (singular in having no epinaos), and of the famous Tholos by Polycleitus the Younger, a circular building with a peristyle of twenty-six Doric columns round the exterior, and a circle of fourteen Corinthian columns inside, the capitals of these columns in Parian marble being of great beauty and among the earliest Corinthian examples known.

The famous Theatre has also been cleared out, displaying a circular orchestra and the foundations of a stage of late date, which, from the remains found, seem to have been 12 feet high, with the front decorated with Ionic semi-detached columns, all the capitals having angle volutes (Fig. 4).

The researches made since 1885 on the Acropolis of Athens have resulted in discoveries of more value to the archæologist than to the architect. The foundations of the old Temple of Athene, destroyed by Xerxes in 479 B.C., have been found close to the Erechtheum, and below the level of the same were discovered two stone bases considered to have supported the wooden pillars of the House of Erechtheus. In 1884-86 Mr F. C. Penrose undertook for the Dilettanti Society a series of investigations relative to the Olympieion or temple of Zeus Olympios, which proved that the temple had eight columns in front and rear, and not ten, as had been thought, owing to a misreading of Vitruvius; that the fifteen columns which remain belong to the edifice designed by Cosutius, the Roman architect, 174 B.C., and that Hadrian's share in the work was confined to the completion of the structure, including the new columns in

the cella, the original examples having been carried away by Sulla for the decoration of the Temple of the Capitol at Rome. Mr Penrose arrived at his conclusions from the great beauty of the Corinthian capitals of the Peristyle, many of which he thought were of a purer type than any likely to have been carved during the reign of Augustus when the work of completion of Cossutius's temple was again taken up, and still less likely to be of Hadrian's time.

The main results of the late Mr Wood's discovery of the site and remains of the Temple of Diana at Ephesus were made known as far back as 1876. Since then the remains brought to England and placed in the British Museum have attracted the attention of many archaeologists, who have attempted to make restorations of the plan embodying the chief features. Amongst these, by far the most trustworthy and most important has been that put forward by Dr Murray in a communication to the Royal Institute of British Architects in 1895. The same paper contains drawings representing a restoration of the carved drum of one of the columns belonging to the archaic temple, built 560 B.C., of which Croesus contributed most of the cost. By a fortunate accident the lower part of this drum is inscribed with his name. The fragments found have been set up in the Museum, and are interesting as showing the first conception of a scheme of decoration which exists in no other Greek temple. The Ionic capital of this archaic temple was brought over by Mr Wood, and the oblong form of its abacus is an additional proof of the theory which is now held that the Ionic capital was originally what is known as a bracket-capital, copied from the oblong piece of timber placed on a pillar to support the wooden architrave of a portico.

Returning to the later Temple described by Pliny, the two most difficult problems were—(1) where to place the square sculptured pedestals, and (2) how to dispose of the thirty-six "columnæ cœlatæ" spoken of by Pliny. Dr Murray solves the problem by placing the square pedestals (the cornices of which range with the raised platform on which the temple was built), eight at the east and eight at the west end, on a stylobate of four steps, which were carried round the whole building. On these pedestals he places sixteen of the "columnæ cœlatæ"; of the remaining twenty he places eight at the east and eight at the west end behind those raised on the square pedestals, resting on the stylobate of the platform; and the remaining four he places in antæ to the pronaos and epinaos. The nine steps required to reach the platform (there were thirteen in all) Dr Murray puts between the first and second rows of columns of the east and west porticoes (Fig. 5). In determining the plan of the temple, he arranges a vestibule beyond the pronaos, the west wall of which was found by Mr Wood. Then follow the cella, with its double row of columns inside to assist in carrying the roof, and behind it the opisthodomus and the epinaos or posticum (Fig. 6).

The excavations made by the British School at Athens in 1890-91 at Megalopolis have exposed the principal portions of the theatre said by Pausanias to have been the largest in Greece, and have enabled the explorers to trace the plan of the Thersilion or Assembly Hall of the 10,000 Arcadians. The hall covered an area of 35,000 square feet, and is remarkable for its plan, inasmuch as the columns which crowned its roof and which were on three sides of the hall were placed so as to radiate towards the tribune, and thus form the least possible obstruction to the view from any portion of the hall. The bases of the columns, which alone remained *in situ*, proved also by their levels that the floor of the assembly hall sloped towards the tribune. The intercolumniation of the columns varied from 29 to 17 feet, which shows that they carried wooden beams only. The columns were probably

in stone, but no remains of any capitals were found. In front of the hall was a portico of sixteen Doric columns, fourteen in the front and one behind each of the angle columns.

The complete excavation of the temenos at Eleusis by the Archæological Society of Athens in 1883 has solved the problem relative to the exact plan of the Hall of the Mysteries. Three successive buildings have occupied the site, and additions and restorations were made to the third hall, designed about 420 B.C. by Ictinus, the architect of the Parthenon. The foundations of the third hall show that the building was 188 feet square, with forty-two

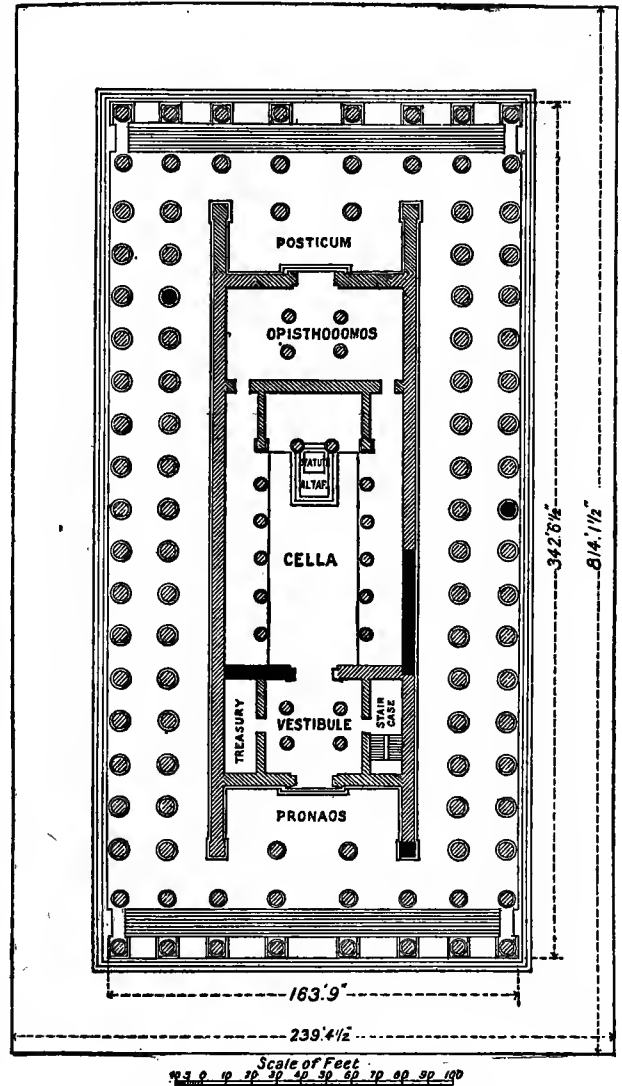

FIG. 6.—Plan of the Temple of Diana at Ephesus.

columns ranged in seven rows of six each; round the walls were rock-hewn steps for the spectators. The Doric portico of fourteen columns, twelve in front and two behind the angle columns, was added by Philon, the architect of the Arsenal of the Piræus, about 310 B.C. No architectural remains of the hall were found. The temenos was entered through two Propylæa, the outer one of which was hexastyle and similar in plan to the Propylæa at Athens.

The sanctuary of the Temple of Apollo in the island of Delos was explored by the Archæological Society of Athens in 1877-83, under the direction of Mr Homolle. The whole site has been cleared, revealing, as at Olympia and Delphi, the foundations of all the temples, treasuries, and other votive monuments. Of the temple of Apollo sufficient was found to enable a complete conjectural

restoration of it. It was of the Doric order, but the columns were not fluted.

In 1879-86 the German Government carried out excavations at Pergamon in Asia Minor, under the direction of Herr Humann. Although of comparatively late date, for the principal monuments of the acropolis were only commenced by Eumenes II., 191-159 B.C., the sculpture of the great altar of Zeus, now in the Berlin Museum and representing the battle of the Gods and the Giants, is of exceptional vigour and magnificence, and the splendour of the series of temples raised on successive terraces seems well to have merited the praise of Pliny, who calls it "the most celebrated town in Asia." The principal monument, of which the remains were found, was that of the great altar of Zeus, which was raised on a platform 93 x 90 feet, and 20 feet high, round which at a height of 8 feet from the level of the terrace was carried the great frieze of the "gigantomachia," 7 feet high. A wide flight of steps led up to the altar, which was surrounded by an Ionic peristyle open on the front and three sides; on the walls of the court enclosing the altar was a smaller frieze. On a terrace beyond were the remains of the Doric temple of Athene Polias, with a porticus round two sides of the court, and beyond, the famous Library and the Temple of Rome and Augustus. In the side of the hill was the Theatre, with the great Terrace, terminated at the north end by a beautiful Ionic temple.

Roman.

The immense difference between the levels of ancient and modern Rome, in some cases amounting to from 65 to 70 feet, and the extensive area of the archaeological stratum (at least 9 square miles), give some idea of the immense labour and cost of investigations in Rome. Since 1871, according to Professor Lanciani, an area of about 4 square miles has been turned up, with results of the greatest interest and value. Foremost amongst these must be placed the excavations on the Palatine, which have revealed the plans of the greater portions of the palaces built by succeeding emperors. The platform of the hill was selected by Augustus first for his imperial residence. Tiberius, Caligula, and Nero added considerably to it. The Flavian emperors united the various portions built by raising structures between those already erected, and rebuilt the House of Augustus, which had been destroyed by fire; and Septimius Severus added largely at the south-east angle of the hill. The excavations were begun by Napoleon III. in 1860, and since 1871 have been carried out by the Italian Government. The palace begun by Vespasian and completed by Domitian, being destined for state receptions and banquets, was in some respects the most magnificent. The throne room was 160 feet long and 120 feet wide, with a vault the clear span of which exceeded 100 feet. Twelve immense columns of pavonazetto marble and giallo antico assisted in carrying the vault, and flanked the great doorways and niches; the latter, with smaller columns of porphyry on the east side, held colossal statues or groups, many of which now enrich various museums.

Next in interest come the excavations made on the line of the Via Sacra, which since 1882 has been laid bare from the Forum to the Colosseum. Many of the buildings on either side have always been known; but the removal of the superincumbent earth has not only exposed the bases of the same, but brought to light the complete plans, and in some cases the architectural remains of other structures, such as the Basilica Julia, the Rostra on the Forum, the Temple of Vesta, the house of the Vestal virgins, the Porticus Margaritaria, and the temple of Venus and Rome with its surrounding Porticus, &c. Of these the most interesting was the "Atrium Vestæ," the house of the

Vestals, excavated in 1883-84, which has proved to be the most important example of domestic architecture yet found, surpassing in completeness any of the Pompeian houses in consequence of its having a great portion of the upper storey preserved. According to Dr Middleton, the house was evidently rebuilt by Hadrian on a much enlarged scale. It consisted of a large open peristyle measuring 200 feet by 72 feet in two storeys, with rooms in the rear, and at one end the tablinum covered over with a semicircular barrel vault. The whole house was richly ornamented, the floors and walls being covered with Oriental marbles, of which numerous remains were found. The upper part of the walls was decorated with mosaic of coloured glass tesserae. Staircases were found leading to the upper storey, in which the bedrooms and bathrooms were placed; the walls were lined with marble slabs in the lower part, and above were painted in brilliant colours with panels, wreaths, and garlands.

One of the most valuable discoveries made in Rome of late years is that relating to the date of the Pantheon, which has always been a much-contested point among archaeologists. In consequence of serious cracks in the dome which had allowed the rain-water to penetrate through the vault, Mr Chedanne, Grand Prix of the French Academy at Rome, was allowed to make use of the scaffolding which had been erected in 1892 and examine the structure of the vault. On taking out some of the bricks he found them stamped with dates of the time of Hadrian. This led to a further examination of bricks in other parts of the building, on which in every case Hadrian stamps were found, the dates extending from A.D. 115-125. This decided the question at once that the circular portion of the Pantheon was built by Hadrian. Further researches showed that 6 feet below the existing pavement was another pavement of marble which sloped from the centre to the circumference, belonging, therefore, to a circular area exposed to rain; and outside the walls of the existing building, concentric with them, and on the same level as this pavement, was a circular wall of masonry of early date surrounding this open area. A similar pavement was found under the Portico and, at a lower level 3 feet under this, was found another pavement, and a substructure in travertine masonry, larger and of different design. The results of these discoveries are considered to prove that—(1) the original Temple of Agrippa was rectangular; (2) the Portico of Agrippa faced the south instead of the north (which is the aspect of Hadrian's Portico); (3) the original Portico was decastyle, viz., with ten columns in front; (4) the rectangular temple on plan resembled the temple of Concord, the front being on the longer side; (5) not only were the columns of Agrippa's portico used again by Hadrian, but also portions of the entablature and pediment; and (6) in front of Agrippa's temple was an immense circular area surrounded by a wall. This latter suggests that Hadrian or his architect, having this site to build on, conceived the notion of covering the whole area and making the building circular.

Of the later discoveries at Pompeii, those made in 1894-95, when the House of the Vettii was excavated, are by far the most important. The house is comparatively small in size, but in the preservation of its peristyle and its richly-decorated walls it forms the most important representative of its class. It differs in plan from other examples in having no tablinum; the atrium opened directly on to the peristyle. The large room on the north side of the peristyle, richly decorated with cupids and Psyche, may possibly have served as the drawing- or sitting-room of the house.

Origin of the Pointed Arch.—The various theories put forward as to the origin of pointed-arch architecture and its introduction into

Europe through the Crusaders may be considered now as disposed of by the work of M. de Vogué on the churches of the Holy Land, from which it will be seen that they all date from a period long subsequent to the regular employment of the pointed arch and barrel vault in the south of France for constructional reasons. For proper consideration of the question the subject should be divided into two parts—(1) that which has to do with its immediate constructional object; and (2) its constant employment for almost every form of arch and vault during the Middle Ages. The earliest example of the pointed arch known is that found by Professor Flinders Petrie in the Pyramid of Hawara, 2622-2578 B.C. The second was that discovered in the drains of the palace of Khorsabad built by the Assyrians c. 721 B.C. In Egypt its first appearance is in the Nilometer of the Island of Roda, A.D. 861; and after the erection of the Mosque of Toulon, A.D. 879, it was always employed. From there it was probably imported into Sicily which the Saracens occupied from 941 to 1072. Unfortunately no example of that date remains; but when the Normans conquered Sicily, 1072, they employed the Mahomedan workmen, so that the Saracenic style lingers throughout the buildings erected in Sicily for more than a century. The pointed arch, therefore, was universally adopted in Sicily, and we find it in the church of S. Giovanni de' Leprosi outside Palermo, 1072, and in the Ponte dell' Ammiraglio, built in 1110, the arches of the bridge are of two orders, the lower ring of the arches being recessed slightly behind the upper ring. Of later buildings the church of S. Giovanni degli Eremiti and the Cappella Palatina, both built before 1132, and the church of La Martorana, completed 1143, are all built with pointed arches. Passing now to the south of France, in the church of St Stephen at Périgueux, the western bay, erected 1014, still preserves a portion of its dome and pendentives built on pointed arches. The churches of Brantôme, St Jean de Cole, and Cahors were all built with similar features before the close of the century, and the Cathedral of Angoulême (first bay), and the church of Fontevrault before 1130. It should be pointed out that in the domed churches of Périgord and Angoumois the setting out of the pendentives and its construction in horizontal courses is entirely different from Byzantine dome construction in the East. Throughout Provence the churches were vaulted with pointed-barrel vaults, all in the 11th century, the finest example being that of the church at Carcassonne, 1090.

In Palestine, prior to the crusades, all the doors and windows had circular arches, the vaults only, for constructional reasons, being pointed. The earliest churches built by the Crusaders in Palestine were those of Tortosa and Beyrout, in both of which the naves are covered with pointed-barrel vaults similar to that of Carcassonne, and probably carried out under the direction of the monks of Cluny. From 1142 onwards the Crusaders introduced the dome over the crossing of nave and transepts, pointed arches carrying pendentives and dome, and the construction of the latter is the same as that employed in Périgord, and quite different from that of the Byzantine dome and pendentives of the Greek churches. The arches of the naves of these churches are pointed, and of two orders, like the bridge already referred to near Palermo; and the masonry bears so close a resemblance to Sicilian work as to lead us to suppose that Sicilian masons, whose language was either Greek or Arabic, were taken over to Palestine, as they would be better able to direct the native labour of the country. The masons' marks found in the Holy Land are either French or Italian; English or German masons' marks have not been found. There is a natural tendency in M. de Vogué's work to ascribe to French masons the design and erection of all the Crusaders' churches; and in the more important, it is true, we recognize the genius of the French sculptor. The portals of the south doorway of the church of the Holy Sepulchre are identical with examples in the south of France (Fig. 7). On the other hand the mouldings of the west portal of the Church of the Resurrection at Nablús are of Early English section and associated with the dog-tooth ornament. The only characteristic difference between the Crusaders' churches and those in Europe are that the former have—(1) flat roofs over the aisles and sometimes over the nave, which were possible in the East; and (2) the exterior of the apses was occasionally polygonal, in imitation of those of the Greek Church.

A New Christian Style.—A second work by M. de Vogué on the

architecture of Central Syria, published in 1867, revealed the existence of a new Christian style of architecture, religious and secular, hitherto unknown, which, though developed by the Greek Christians of Palestine, is based more directly on the Roman remains in the country. The only parallel to it found in Europe is that which exists in Burgundy in the churches of Autun and Langres, based similarly on Roman work; but there is a difference of five or six centuries in date, and as these towns and villages in Central Syria were deserted during the Mahomedan invasion in the 7th century, and being in the centre of Syria were never even approached by the Crusaders, there can never have been any connexion between the two. M. de Vogué's book is not confined to Christian work. Many earlier buildings of Herodian and Roman work are illustrated in it, and amongst them the stone buildings of the Hauran, which, owing to the absence of timber, are entirely—roofs, doors, and windows—

FIG. 7.—South Doorway of the Church of the Holy Sepulchre, Jerusalem.

built in stone. These had been visited and described by Burckhart, the Rev. J. L. Porter, and other travellers; but it has only been from the engraved illustrations in M. de Vogué's book that a fair idea has been given of their design and remarkable construction.

St Mark's, Venice.—Discoveries in the archives of Venice since 1890 have led to a revised date being given for the construction of the five domes within the basilican church of St Mark's, Venice, restored only by Orseolo in 976. The late Professor Cattaneo arrived at the conclusion that these domes were not built till 1063. It follows, therefore, that the five-domed church of St Front at Périgueux, which was copied from it, is not the first domed church in France, as St Stephen's in Périgueux, and other domed churches, were built in the first half of the 11th century. A more careful examination of the so-called Latin church which stands on the western side of the five-domed church at Périgueux, has revealed features dating from the first half of the 11th century, so that this was the church burnt down in 1120. Moreover, the five-domed church is entirely in stone, so that no such conflagration could have taken place as is recounted in the chronicle. From the fact that the bodies of the saints were not brought back till 1171 to be placed in the new church of St Front, it is probable that it was

not commenced till 1160; and this is borne out by the excellence of the masonry throughout, which presented a marked contrast with that of St Stephen's, built in 1014. Instead of being the first domed church therefore, it was the last, of any magnitude.

The following additions require to be made to the glossary given in the ninth edition:—

APOPHYGE—(a) the inverted cavetto or concave sweep taken by the lower part of the shaft in the Ionic and Corinthian orders before its junction with the base. (b) The hollow or scotia beneath the Doric echinus forming the junction between the capital and the shaft.

ATRIUM—(a) the open court of a Roman house, surrounded by a colonnade or partially roofed over by projecting eaves. (b) The court in front of a church, surrounded by colonnades or arcades.

CELLA, the sanctuary of a Greek or Roman temple, enclosed by walls and entered from the pronaos=*πάρος* in Greek.

EPINAOS, the open vestibule behind the naos or cella, sometimes called the opisthodomus, as it was occasionally enclosed with metal grilles and contained the properties of the temple.

HELIX, term given to the spiral of the Ionic volute and the tendrils of the Corinthian capital.

OPISTHODOMUS (Greek, from *ὀπισθεν*, behind, and *δῶμος*, a house), an enclosed chamber behind the naos and entered from the epinaos, employed to store the treasury of the temple.

PORTICUS, a building with its roof supported by one or more rows of columns, either in one straight line or enclosing a space (Greek, *στώδα*).

STEREOBATE, the substructure of rough masonry beneath a temple.

STYLOBATE, the upper of the three steps on which the Greek temple stands; generally applied to the three steps.

TEMENOS, the sacred enclosure round a temple.

THOLOS, term given to Greek circular buildings with or without a peristyle.

VELARIUM, the curtain or awning extended above the auditorium of the Roman theatre to protect the spectators from sun or rain.

XO'ANON, a rude and primitive image carved in wood.

ZOOPHORUS, a continuous frieze sculptured in relief, with the figures of human beings and animals. (R. P. S.)

Arcot, a town of British India, which gives its name to two districts in the Madras presidency. The town has now lost its manufactures and trade, and preserves only a few mosques and tombs as traces of its former grandeur.

The district of NORTH ARCOT has an area of 7616 square miles. In 1891 its population was 2,180,487, being 286 persons per square mile; in 1901 the population was 2,208,391, showing an increase of 4 per cent. The administrative headquarters are at Chittur, but the largest towns are Vellore (the military station), Tirupati (a great religious centre), and Wallajapet and Kalahasti (the two chief places of trade). The land revenue and rates in 1897-98 were Rs.32,60,842, the incidence of assessment being Rs.2:7:0 per acre; the cultivated area was 828,396 acres, of which 366,245 were irrigated, including 49,783 from government canals; the number of police was 1284; the boys at school in 1896-97 numbered 42,509, being 26 per cent. of the male population of school-going age; the registered death-rate in 1897 was 20.2 per thousand.

The district of SOUTH ARCOT has an area of 5217 square miles. In 1891 its population was 2,162,851, being 414 persons per square mile; in 1901 the population was 2,350,365, showing an increase of 9 per cent. The administrative headquarters are at Cuddalore, close to the site of Fort St David. The land revenue and rates in 1897-98 were Rs.45,82,820, the incidence of assessment being Rs.2:7:9 per acre; the cultivated area was 1,456,961 acres, of which 470,353 were irrigated from tanks, &c., including 141,210 from government canals; the number of police was 963; the boys at school in 1896-97 numbered 36,464, being 22.5 per cent. of the male population of school-going age; the registered death-rate in 1897 was 21.2 per thousand. The principal crops in both districts are rice, millet, other food grains, oil-seeds, and indigo.

Arctic Ocean. See POLAR REGIONS.

Arctic Regions. See POLAR REGIONS.

Arcueil, a town of France, department of Seine, in the arrondissement of Sceaux, and $2\frac{1}{2}$ miles N.E. of that town, on the railway from Paris to Sceaux. It takes its name from a Roman aqueduct, the *Arcus Juliani*, some traces of which still remain. Two superimposed aqueducts now supply water to Paris. Starch, vermicelli, bottle capsules, patent leather, and other articles are manufactured. There are important quarries. Population (1881), 5529; (1891), 5863; (1896), 6418, (comm.) 6494.

Ardebil, or ARDABIL, chief town and seat of government of a district, or sub-province of the province of Azarbaiján, in north-western Persia, in lat. $38^{\circ} 14' N.$, long. $48^{\circ} 21' E.$, and at an elevation of 4500 feet. It is situated

on the Baluk Sú (fish-river), a tributary of the Kara Sú (Black river), which flows northwards to the Arras, and in a fertile plain bounded on the west by the Savalán Dágh, a volcanic mountain with an altitude of 15,792 feet (Russian triangulation). Ardebil has a population of about 10,000, a garrison of half a battalion of infantry, and post and telegraph offices. Its trade, principally in the hands of Armenians, is still important, but is chiefly a transit trade between Persia and Russia by way of Astara, a port on the Caspian 30 miles N.E. of Ardebil (Dr F. Sarre, "Reise von Ardebil," &c., in *Petermann's Mitteilungen*, September 1899). Plans and photographs of the shrine and mosques were taken in 1897 by Dr F. Sarre of Berlin.

European and Chinese merchants resided at Ardebil in the Middle Ages, and for a long time the city was a great emporium for Central Asian and Indian merchandise, which was forwarded to Europe by way of the Caucasus and the Volga, and also *via* Tabriz and Trebizond. Since the 16th century, when Persia fell under the sway of the Safavi dynasty, the place has been much frequented by pilgrims, who come to pay their devotions at the shrine of Shaikh Safi, the ancestor of Shah Ismail, who was the founder of the dynasty, and the shrine is a richly-endowed establishment, with mosques and college attached. It has also a fine library, containing many rare and valuable MSS. presented by Shah Abbas at the beginning of the 17th century; but most of these MSS. were carried off by the Russians in 1828, and are now in St Petersburg. The grand carpet, which had covered the floor of one of the mosques for three centuries, was purchased by a traveller some years ago for about one hundred pounds, and was finally acquired by the South Kensington Museum for many thousands.

Ardèche, a department of the S. of France, traversed by the Cevennes and watered by the Rhône and its affluent the Ardèche.

Area, 2145 square miles, with 31 cantons and 339 communes. The population declined to 375,472 in 1886 and 363,501 in 1896. In 1899 the births numbered 8465, of which 170 were illegitimate, the deaths 8437, and the marriages 2625. The chief towns are Privas (7843 inhabitants in 1896), Largentière, Tournon, and Annonay. In 1896 there were 1171 primary schools, with 61,178 pupils; 8 per cent. of the population was illiterate. The surface under cultivation comprised 938,499 acres, or more than three-fifths of the department, but the plough-land made up only 480,871 acres. The vine, attaining a fair range of cultivation, had 36,628 acres. In 1899 the wheat crop reached the value of £247,625, and the vine about a seventh more. Ardèche is one of the departments in which the mulberry grows most abundantly. The crop of leaves amounted in 1899 to nearly 73,000 cwts., and sericulture has developed in proportion, yielding 33,000 cwts. of cocoons, of the value of about £199,000. There were 25,000 sericulturists, and only Drôme and Gard have a greater number. The live stock in 1899 numbered 14,170 horses, 10,450 mules and asses, 97,760 cattle, 229,690 sheep, 102,140 pigs, and 128,580 goats. The mining production is inconsiderable, yielding in 1898, 50,000 tons of coal and 48,000 tons of iron. The working in metals realized in 1898 only some 23,000 tons of iron. The principal industries are paper manufacture (Annonay), tanning, and weaving.

Ardennes, a department in the N.E. of France, bordering on Belgium. It is covered with the wooded mountains of Ardennes, and traversed by the Meuse, the Semoy, and the Aisne.

Area, 2028 square miles, distributed among 31 cantons and 503 communes. The population decreased from 332,759 in 1886 to 315,589 in 1901. Births (1899), 6523, of which 492 were illegitimate; deaths, 6754; marriages, 2437. The principal towns are Mezières, which, with Charleville, has a population of more than 25,000 souls, Sedan, Rethel, Vouziers, and Rocroi. In 1896 there were 833 schools, with 43,815 pupils. Two per cent. of the population was illiterate. The total surface under cultivation comprised 1,224,455 acres, but the forests alone occupied 271,700 acres, and the plough-land was confined to 669,370 acres. The climate does not allow the cultivation of the vine. In 1899 wheat yielded a value of £748,678. Oats also gave excellent returns. Among the industrial cultures, beetroot is alone deserving of notice, producing in 1898, 2,090,585 cwts. In 1899 the live stock amounted to 47,370 horses, 109,040 cattle, 271,950 sheep, and 49,890 pigs. There are no coal-pits in the department of Ardennes, but iron-mines are found between Mezières and Rethel. The valley of the Meuse produces enormous quantities of slate. The working of metals (nails, bolts, machines) is highly developed all along the valley of the Meuse (Monthermé, Revin, Givet), yielding in 1898, 96,000 tons of cast iron and of iron, and 46,000 tons of steel, of the value of £995,000. The produce of the other metals amounts to the value of £255,000. Sedan is celebrated for the making of cloth. In the production of sugar, Ardennes takes the eighth rank among the departments, yielding in 1898, 255,893 cwts.

Ardglass, a village in the county of Down, Ireland, 7 miles S.S.E. of Downpatrick, with which it is now connected by a light railway. It is noted for its herring fisheries, the quantity caught in 1899 having been 15,519 cwt., valued at £5744. Population, 554.

Ardmore, a town of Chickasaw Nation, Indian Territory, U.S.A., situated on the Gulf, Colorado, and Santa Fé railway, at an altitude of 870 feet. Like other towns of this territory, it has no corporate existence, nor are any lots owned in fee by the occupants, with the exception of those lying within the right of way of the railway. The site was originally a squatter's claim, and lots are held by quit-claim deeds or leases under it. The population consists almost entirely of whites, the Indians keeping remote from the railway and large towns. The adjacent region is a rich farming country, producing cotton, grain, and cattle, with the shipping of which the town is mainly concerned. Population (1900), 5681.

Ardrossan, a seaport, burgh of barony, and police burgh of Ayrshire, Scotland, 14½ miles N.N.W. of Ayr by water. It has stations on the Glasgow and South-Western and Lanarkshire and Ayrshire railways. The dock accommodation has been greatly extended. In 1898 the port register contained 63 vessels of 25,129 tons; and the tonnage entered was, in 1888, 2429 vessels of 247,425 tons; 1898, 3440 vessels of 734,320 tons; cleared in 1888, 2347 vessels of 243,398 tons, and in 1898, 3393 vessels of 737,155 tons. Imports were valued at £66,540 in 1888, and £463,015 in 1898; exports at £12,919 in 1888, and £202,068 in 1898. In 1898, 477,082 tons of coal were exported and 60,351 tons of iron. One of the public schools is an academy. Population (1881), 4098; (1891), 5294; (1901), 5933.

Arecibo.—A city near the west end of the north coast of Porto Rico, founded in 1788. It commands the trade of the adjacent portions of the island, and ships large quantities of sugar and coffee. Near by are the famous caverns of Consejo. The harbour is poor. Population (1899), 8008.

Arendal, or ARNDAL, a seaport town of Norway, co. Nedenäs, on the S. coast, 36 miles N.E. from Christian-sand. It possesses a relatively large commercial fleet (212 vessels of 117,250 tons aggregate), principally en-

gaged in exporting timber (2 to 2½ million cubic feet annually to Great Britain), wood-pulp, sealskins, and felspar. In 1879 Arendal ranked second (after Christiania) as a ship-owning port; in 1899 it had dropped to the fifth place. In and near the town are factories for wood-pulp, paper, cotton, and joinery; and at Fevig, 8 miles to the north-east, a shipbuilding yard and engineering works. Population (1875), 4132; (1891), 4578; including suburbs (1899), about 10,000.

Arequipa, a coast department of southern Peru, containing seven provinces, Arequipa, Camana, Islay, Unión, Caylloma, Condesuyos, and Castilla. Its area occupies 21,947 square miles and its population in 1896 was officially estimated at 229,007. The capital, Arequipa, has a population of 35,000. The foreign trade of the town is carried on by the port of Mollendo, distant ninety miles, with which it is connected by rail (107 miles); the exports are mainly sheep's wool and alpaca, coca leaves, and borate of lime.

Arezzo, a town and episcopal see of Tuscany, capital of the province of Arezzo, 55 miles S.E. from Florence, Italy. The church of St Francis (1322) contains frescoes by Piero della Francesca and Spinello Aretino. Other notable edifices are the churches of SS. Annunziata and Sta Maria della Pieve (11th-14th cent.), the town hall (now converted into a jail), the ceramic Museum Funghini, the house in which Petrarch was born, the house of Vasari, and the municipal museum. There are a technical school and an academy of sciences, arts, and letters. Silks, gunpowder, pottery, and macaroni are manufactured, and tanning and printing are carried on. Population: commune (1881) 38,950, (1901) 44,350; province (1881) 238,744, (1901) 272,359.

Argao.—A town of 34,000 inhabitants, on the east coast of Cebu, Philippine Islands, in latitude 10° 3' N. It was founded in 1608. Its products are rice, Indian corn, and cacao. The latter is of superior quality and is produced in large quantities. A limited amount of cotton is raised and woven into cloth. The language is Cebu-Visayan.

Argentan, chief town of arrondissement, department of Orne, France, 27 miles N.N.W. of Alençon, on railway from Caen to Mans. One of the two principal churches contains fine wood-carving and 16th-century glass. Manufactures include stained glass. Oolitic limestone, quarried in the vicinity, is used in the construction of local buildings. The historian Mezeray and Charlotte Corday were born here. Population (1876), 4831, (comm.) 5365; (1896), 5070; (1901), 6291.

Argenteuil, a town of France, department of Seine-et-Oise, arrondissement of Versailles, 3¼ miles N.W. of outer circle of Paris, on railway from Paris to Mantes. Asparagus and figs are cultivated in the district, and heavy iron goods, chemical products, and plaster are manufactured. At CHOIX-DU-DÉSERT, between Argenteuil and Epernay, a large tumulus was opened in 1866, and found to contain over 200 skeletons, and a large quantity of arms and utensils. Population (1881), 9456; (1891), 11,362; (1896), 13,847; (1901), 17,424.

Argentine, a city of Wyandotte county, Kansas, U.S.A., situated in the eastern part of the state, five miles west of Kansas City, Missouri, on the south bank of the Kansas and just above its mouth, in 39° 04' N. lat. and 94° 38' W. long., at an altitude of 750 feet. Its streets run irregularly up the steep face of the river bluffs. It is entered by the Atchison, Topeka, and Santa Fé railway. Its chief business is the smelting of ores of the precious metals, lead, and copper from mines in the Rocky Mountains. Population (1890), 4732; (1900), 5878.

ARGENTINE REPUBLIC.

I. GEOGRAPHY AND STATISTICS

THE only considerable portion of the Argentine inland frontier which has not been in dispute in recent years is that formed by the lower waters of the river

Uruguay, separating it from the Uruguayan Republic and the southern portion of Brazil.

Boundaries. In accordance with a treaty of 1889 between the Argentine Republic and Brazil, and the arbitration award made by President Cleveland of the United States in 1894, the boundary line leaves the Uruguay river at its confluence with the Pequiry, and after ascending this stream northwards passes in a straight line to the source of the San Antonio, which it descends to its confluence with the Iguassu, and thence to the confluence of the Iguassu and Paraná. From this point the Argentine and Paraguayan republics are continuous. The boundary, by treaty of 3rd February 1876, follows the course of the Paraná to its junction with the Paraguay, which it ascends as far as the mouth of the Pilcomayo river. Formerly the Argentine Republic claimed territory north of the Pilcomayo, while the Paraguayan Republic asserted that the Bermejo was the boundary river; but by the treaty of 1876 and the arbitration award of President Hayes of the United States, given on 13th November 1878, the frontier line ascends the Pilcomayo as far as the frontier of Bolivia. The Argentine-Bolivian boundary (demarcated in accordance with the treaty of 1889) starts from the point where the Pilcomayo cuts the parallel of 22° S. lat., and runs due west to the Tarija, which it descends to the Juntas de San Antonio, whence it ascends the Bermejo. Leaving this river it proceeds to the Quiaca ravine, and thence to a point on the San Juan river opposite Esmoraca. After ascending the San Juan, it runs to the Cerro de Granados, to Incahuasi, and to Sapalegui on the Chilean frontier. The Argentine-Chilian frontier is still, for the most part, undetermined. On 17th April 1896 an agreement was signed providing for its delimitation as far south as the parallel of 52° S. lat., "the crests of the Andes that form the watershed" being stated as defining the boundary line. From 23° to 26° 52' 45" S. lat. the demarcation has been carried out, but in its continuation southwards disputes arose which were referred for arbitration to the British Government. At a point in 52° S. lat. the boundary (in accordance with a treaty with Chile, made in 1881) runs eastwards till it reaches the meridian of 70° W. long., and then south-eastwards to Cape Dungeness, at the eastern entrance of the Strait of Magellan. On the opposite side of the strait, which, by the treaty, is neutralized and free to the ships of all nations, the boundary lies in the meridian of 68° 34' W. long. from Cape Espiritu Santo to Beagle Channel, and then follows the channel to the Atlantic. The portion of Tierra del Fuego, and some small islands, including Staten Island, lying to the east of this line, belong to the Argentine Republic; the land and islands to the west and south belong to Chile.

Climate.—In the riparian provinces of Buenos Ayres and Santa Fé there are great areas of almost flat land, which consists of deep, rich loam formed from the alluvial deposits of the Rio de La Plata and the Rio Paraná, and which for stock-breeding and agricultural purposes cannot be surpassed. A temperate climate is not the least of the many advantages this section of the country can claim, for an average rainfall of some 34 inches provides abundant moisture for vegetation, and the many days of bright sunshine ensure the ripening of the cereal crops. The southern portion of the province of Cordova, closely resembling the provinces of Buenos Ayres and Santa Fé, likewise contains large areas of arable

land. These three provinces have other important features. In the south of Buenos Ayres is the Sierra Ventana, an extensive mountain range; the north-east of Santa Fé contains much valuable timber; in the northern and eastern sections of Cordova are great mountainous areas, the mineral wealth of which was worked by the early Spanish settlers. The climate of the Andean provinces of Mendoza and San Juan is eminently suitable for the cultivation of the vine. The valleys of the Andes open out at Mendoza into plains requiring only irrigation to produce abundant vegetation; the rivers, supplied by the melting snows at the higher elevations, provide the necessary water, and every year the area of cultivation increases. On these plains there is a rainfall of only six inches annually, snow rarely falls, and frosts are never severe. To the north of San Juan are the provinces of La Rioja and Catamarca, mountainous and heavily wooded, and intersected

MAP OF THE ARGENTINE REPUBLIC.

with well-watered fertile valleys. Between Cordova and Tucuman are great saline plains covered with a white alkaline crust, which glitters in the sunlight like an inland sea. At Tucuman tropical vegetation appears, although frosts occur regularly in winter, not however of sufficient severity to prevent the growth of the sugarcane. Salta and Jujuy, situated farther north amongst the wooded spurs of the lower Andean ranges, possess a climate tropical in the valleys, temperate on the higher plateau. To the north-east of Salta, and bordering on the republic of Bolivia, is the territory known as the Chaco, where the characteristic features are dense tropical forest interspersed with open, park-like grasslands. Still farther to the east, and adjoining Paraguay and Brazil, is the territory of the Misiones, covered with tropical jungle and watered by the river Uruguay, which passes in enormous volume over the Iguassu Falls and ultimately forms with the Rio Paraná, the great estuary of the river Plate. The southern

territories of Argentina, comprising the basin of the Rio Negro, the district of Neuquen, and the little-known land of Patagonia, through which the Chubut, Santa Cruz, and Gallegos rivers flow to the Atlantic, are of a very different character (see PATAGONIA). From Neuquen southwards along the eastern slopes of the Andes lie valleys of great fertility, with magnificent timber on the mountain sides, and a series of great lakes beginning at Nahuelhuapi, the headwaters of the Rio Limay, extends some 500 miles towards the Strait of Magellan. In the centre of Patagonia, where the steppes open out into rolling grass-land, heavy snowstorms and a low temperature generally prevail during the long winter, from May to the end of September. Near the Atlantic seaboard the climate again becomes more temperate. From Chubut to the Strait of Magellan snow falls frequently in winter, but not, as a rule, in sufficient quantities to interfere seriously with pastoral and agricultural industry.

Harbours.—In spite of some natural disadvantages Buenos Ayres remains, and will probably long remain, the principal port of Argentina, on account of the convenient and commanding position it holds for the river trade. Rosario and Santa Fé are centres of great grain-growing districts, and large quantities of wheat are annually shipped from them direct to Europe. Six hundred miles to the south of Buenos Ayres is the port of Bahia Blanca, with a shipping trade which might be largely increased by a comparatively small expenditure on the harbour works. Still farther to the south, and only some 20 miles distant from the mouth of the Rio Negro, is the natural harbour of San Blas. Near the Chubut river is Port Madrin, and between that place and the Strait of Magellan are harbours at the mouths of the Santa Cruz and Gallegos rivers.

Area and Population.—The subjoined table shows the area and population of the republic, and its provinces and territories.

from France, 2119 from Russia, and 2024 from Austria. In 1897, 27,593 availed themselves of the immigration laws with respect to taking up public lands. Owing to the buying up of accessible land by corporations and speculators the central and southern provinces have, so far, not attracted colonists.

Chief Towns.—The principal towns are as follows:—

	Population.		Population.
Buenos Ayres (1900)	824,308	Corrientes	16,129
Rosario	91,669	Chivilcoy	14,632
Cordova	47,609	Guaqueguaychú	13,282
La Plata	45,410	San Nicolas	12,550
Tucuman	34,305	Concordia	11,695
Mendoza	28,302	Rio Cuarto	10,825
Paraná	24,098	San Juan	10,410
Santa Fé	22,244	Barracas al Sur	10,186
Salta	16,672		

The present constitution of the Argentine Republic dates from 25th September 1860. The legislative power is vested in a Congress of two chambers—the Senate, composed of members (two from each province and two from the capital) elected by the provincial legislatures for a term of nine years, and the Chamber of Deputies, elected for four years by direct vote of the people, one deputy for every 20,000 inhabitants. To the Chamber of Deputies exclusively belongs the initiation of all laws relating to the raising of money and the conscription of troops. It has also the exclusive right to impeach the president, vice-president, Cabinet ministers, and federal judges before the Senate. The executive power is exercised by the president, elected by presidential electors from each province chosen by direct vote of the people. The president and vice-president are voted for by separate tickets. The system closely resembles that followed in the United States. The president must be a born citizen of the Argentine Republic, a Roman Catholic, not under thirty years of age, and must have an annual income of at least \$2000. His term of office is six years, and neither he nor the vice-president is eligible for the next presidential term. All laws are sanctioned and promulgated by the president, who is invested with the veto power, which can be overruled only by a two-thirds vote. The president, with the advice and consent of the Senate, appoints judges, diplomatic agents, governors of territories, and officers of the army and navy above the rank of colonel. All other officers and officials he appoints and promotes without the consent of the Senate. The Cabinet is composed of five ministers—the heads of the Government departments of the interior; foreign affairs; finance; war and marine; and justice, worship, and education. They are appointed by and may be removed by the president.

Provincial Government.—The provinces, under the constitution, retain all the powers not delegated to the Federal Government. Each province enacts its own constitution, which must be republican in form and in harmony with that of the nation. Each elects its governor, legislators, and provincial functionaries of all classes, without the intervention of the Federal Government. Each may conclude with the knowledge of the Federal Congress such partial treaties as may be necessary for the administration of justice, the regulation of financial interests, or the carrying out of public works. Each may promote by means of protective laws its own industries, may regulate immigration into its territories, and deal with similar local economic questions.

Justice.—Justice is administered by a Supreme Federal Court of five judges and an attorney-general, which is also a court of appeal, and by a number of inferior and local courts. Each state has also its own judicial system. Trial by jury is established by the constitution, but never practised. Civil and criminal courts are both corrupt and dilatory. In May 1899 the minister of justice stated in the Chamber of Deputies that the machinery of the courts in the country was antiquated, unwieldy, and incapable of performing its duties; that 50,000 cases were then waiting decision in the minor courts, and 10,000 in the federal division; and that a reconstruction of the judiciary and the judicial system had become necessary. In June 1899 he sent his project for the reorganization of the legal procedure to Congress, but no action has yet been taken beyond referring the Bill to a committee for examination and report.

In 1869 the population was 1,830,214, showing an average annual increase up to 1895 of 4.98 per cent. Of the total population in 1895, 2,088,919 were males and 1,865,992 females. The foreign element numbered 1,004,527, of whom 492,636 were Italian, 198,685 Spanish, 94,098 French, 48,650 Uruguayan, 24,725 Brazilian, 21,788 British, 20,594 Chilean, 17,143 German, 15,047 Russian, 14,789 Swiss, 14,562 Paraguayan, and 12,803 Austrian, many other nationalities being represented by smaller numbers.

Immigration and Emigration.—In the 43 years, 1857-99, 2,564,391 immigrants entered, and 882,599 emigrants departed from the ports of the republic. In the 10 years, 1880-89, the arrivals and departures were respectively 1,020,907 and 175,038; in 1890-99, 928,865 and 552,175. In 1899 the immigrants by ocean steamers numbered 84,442, and the emigrants 38,397. In 1900 the numbers were respectively 84,851 and 38,334. In 1900 there were 52,143 immigrants from Italy, 20,383 from Spain, 3160

Administrative Divisions.	Area, Square Miles.	Pop. 1895.	Pop. per Square Mile.

Santa Cruz	109,142	1,058	...
Tierra del Fuego	8,298	477	...
Total	1,113,846	3,954,911	3
Population not in census		60,000	
Indian population		30,000	
Total		90,000	
Grand total		4,044,911	

Religion.—The Argentine constitution recognizes the Roman Catholic religion as that of the state, but tolerates all other religions. The state pays the clergy, builds churches, &c., controls all ecclesiastical appointments, and decides on the passing or rejection of all decrees of the Holy See. In 1895 there were 1019 Catholic churches, or one for every 4000 inhabitants. There were also sixty-eight Protestant churches, three masonic halls, one Spiritualists' church, and one Russian Orthodox church. Of the Protestant churches twenty-five are in the territory of Chubut, which was largely colonized from Wales. In 1895 the population was divided as follows, according to religion:—

	Argentine.	Foreign.	Total.
Catholics . . .	2,944,397	976,739	3,921,136
Protestants . . .	5,597	21,158	26,755
Jews	195	5,890	6,085
Others	190	745	935
Total	2,950,379	1,004,532	3,954,911

From this it appears that 991 per 1000 are Catholics, 7 per 1000 are Protestants, and 2 per 1000 are Jews, the Jews being entirely of Russian origin, sent into the republic since 1891 by the Jewish Colonization Association.

Education.—The number of schools and colleges in 1899 was 3884, and of professors and teachers 11,001. The number of pupils under instruction was 280,930. Of these 192,060 attended elementary schools, 66,399 private establishments, 13,313 normal schools, and the remainder the higher educational course at the universities and at the various national advanced colleges. The national colleges are sixteen in number, and there are normal schools, a school of mines, a college of agriculture, two military schools (one with 125 cadets, the other for the instruction of non-commissioned officers), and three naval schools (one for officers and two for artificers and mechanics). The national universities are at Buenos Ayres and Cordova, and provincial universities are at La Plata, Santa Fé, and Paraná. The total number under instruction represents only 7 per cent. of the population, as compared with 23 per cent. in the United States and 20·3 per cent. in the United Kingdom. The cost of education to the state in 1899 was extremely heavy, no less a sum than £1,000,000 being devoted nominally to that purpose, an average of nearly £5 for each pupil attending the public educational institutions.

The Army.—The regular army, at the beginning of 1899, consisted of 1463 officers and 12,867 non-commissioned officers and men. In the ranks were then serving 2157 recruits of twenty years of age, drawn under the conscription law in connexion with the liability of Argentine citizens to be called upon for military service. The army comprised one regiment of engineers, two of mountain artillery, six of light artillery, twelve of infantry, eleven of cavalry, and two of Andean sharpshooters. There is also the president's escort. On 31st December 1898 the number of men enrolled in the National Guard, including the entire male population between the ages of eighteen and forty-five years, with certain exceptions, was 233,945 on the list for active service, 90,924 on the reserve list, and 13,780 on the territorial list; 5323 men liable to service were excused on special grounds. The total number of men the Government can call to arms to assist the regular troops is, therefore, 343,972. Under Law No. 3318 all youths of the age of twenty years are required to undergo a regular training and to serve two years in the army, if necessary. In 1898 the number of youths coming under this category was 34,000; but of these only 12,000 underwent the authorized instruction of sixty days with the colours, the remainder not being called out from motives of economy. The main body of the National Guard is paraded and drilled on all holidays and Sundays, attendance being compulsory for two months in every year until a citizen is twenty-five years of age. The number of horses in service in 1899 was 14,432, and of mules 4169. The artillery armament is from Krupp.

The Navy.—A marked development has taken place in the navy since 1874, when the Government ordered from British ship-builders two ironclads, four monitors, and two gunboats. In 1881 the *Almirante Brown* was purchased in England, and in 1886 the *Patagonia* and *Argentina* were added to the list. In 1892 the *Independencia* and *Libertad* were acquired, then the cruiser *25 de Mayo*, and the *9 de Julio*. The fear of war with Chile induced the purchase of the *Buenos Ayres* in 1896, of the *Garibaldi* in 1897, and of the *San Martín*, *Puerrypedon*, and *General Belgrano* in 1898. A torpedo division was also created with four first-class sea-going torpedo boats, two torpedo gunboats, and twenty-one torpedo boats. At La Plata there is a dock for the use of the torpedo division, and on the river Tigre a slip and workshops for repairs have been erected. A school-ship, the *Sarmiento*, has also been added to the navy list. The officers on the list in 1899 numbered 640 of all ranks and classes, and the petty officers and seamen 5105. A naval-port is being constructed at Belgrano, some 27 miles from

Bahia Blanca, for the use of the men-of-war, and there will be sufficient draught of water at this port to admit the docking of vessels up to 12,000 tons. The estimated cost of the construction of the new port exceeds £1,000,000. The machine guns and rifles now in use in the navy are all of the most recent pattern.

Finance.—The revenue of the republic is derived mainly from customs and excise, and the largest branch of expenditure is the service of the debt. In 1878 the revenue amounted to the equivalent of £3,680,000; in 1881, to £4,260,000, the expenditure in the latter year reaching the amount of £5,670,000. The following table shows approximately the revenue and expenditure in 1893 and onwards, conversions being made at the rate of \$5.04 to £1 for gold, and at the average rate of each year for paper. These average rates are shown in the last column of the table. For the years 1900 and 1901 the budget estimates are given:—

Year.	Revenue.	Expenditure.	Paper Dollars to £1.
	£	£	
1893	7,592,880	8,493,220	16·32
1894	6,995,940	6,973,760	17·85
1895	7,555,450	9,479,310	17·50
1896	8,677,140	12,034,200	14·86
1897	10,223,040	12,187,530	14·61
1898	18,672,668	24,044,245	12·95
1899	14,503,140	15,325,230	11·29
1900	12,859,000	12,996,100	11·36
1901	13,078,000	12,975,000	11·36

The abnormal increase of revenue and expenditure in 1898 and 1899 was due to the warlike preparations made on account of the boundary disagreement with Chile. In 1900 a 10 per cent. additional tax, which had been imposed on imports, was abolished to the extent of one-half, the remaining half being made applicable to the formation of a fund for the conversion of the paper money.

The debt of the republic in 1889 amounted to about £24,000,000, and in the following year financial difficulties arose. In 1891 a funding loan, limited to £7,630,680, was issued, and the proceeds were applied to the service of external loans and obligations. In 1893 the Romero arrangement was made between the National Government and the bondholders for the suspension of amortization and the temporary reduction of interest. The payment of full interest was resumed in 1898. In the years 1896-99 the issue of railway guarantee rescission bonds amounting to £11,607,100 was authorized for the purpose of settling railway guarantees in arrears; and in 1897-1900 the issue of bonds amounting to £20,284,600 was authorized, that arrangements might be made between the provinces and municipalities and their creditors. A considerable amount of the public debt arose from national mortgage bank *cedulas*, for which the Government had made itself responsible. In the year 1900 the outstanding and authorized debt of the republic was as follows:—

External debt—	£
Original national loans	45,738,708
Assumed provincial, &c.	31,891,657
National <i>cedulas</i>	9,945,143
Total external	87,575,508
Internal debt—	
\$ 6,375,000 gold }	9,896,384
98,751,300 paper }	
Floating debt, &c.—	
\$23,862,751 gold }	5,564,000
9,012,804 paper }	
Paper currency, \$291,326,263	25,600,000

The total obligations of the nation—external, internal, floating, and currency—thus amount to over £128,000,000.

According to an estimate given in the twenty-seventh annual report of the Foreign Bondholders' Council the cost of the service of the whole debt (exclusive of expenses) in 1900 amounted to £6,301,419.

The paper currency forms an important part of the internal debt. By the emission of vast sums of paper money President Celman entered on the course which led to the financial ruin of Argentina, and by further emissions, in reality neither more nor less than forced loans, subsequent presidents hastened the collapse. The assumption by the National Government of the provincial external indebtedness was only an act of justice. These provincial loans were contracted under the law of 3rd November 1887, an Act more commonly known as the *Free Banking Law*. The various provinces made loans abroad to the amount of £27,000,000, and deposited the specie with the National Government through the *Caisse de Conversion*, the gold to remain intact as security for the value of the notes issued by the provincial banks. In return for the gold deposited in the *Caisse de Conversion* the provinces were entitled to receive internal gold bonds bearing 4½ per cent.

interest, the bonds remaining in the custody of the Caisse de Conversion, which was authorized to attend to the annual service. But President Celman sold the gold specie, and the provincial bank notes immediately lost their value. The National Government has to some extent made good the loss caused by the action of Celman.

Minerals.—The principal mineral deposits of the republic are found in the provinces of San Juan, La Rioja, Mendoza, Jujuy, Salta, San Luis, and Catamarca, and in the territories of Santa Cruz, Chubut, Pampa, Neuquen, Tierra del Fuego, and Rio Negro, the richest being that of Jujuy. Gold and silver are found in many places, but the only rich deposits now being worked are in the Famatina region in La Rioja. Lead is found in some veins in La Rioja, Cordova, Mendoza, and San Luis. Copper has been discovered in the provinces of San Juan, La Rioja, Cordova, Catamarca, Mendoza, Salta, and Jujuy. Most of the ore contains considerable quantities of gold and silver. Iron, of poor quality, has been found in Mendoza, Cordova, La Rioja, and San Juan, but there are no smelting works in the country. Coal has been discovered in the department of San Rafael in Mendoza, in Neuquen, the Arroyo Malo, and San Juan in the district Morado. Some small petroleum springs have also been discovered in the department of Anta in the province of Salta, and near the town of Oran.

Agriculture and Stock-raising.—In 1878 the production of wheat was insufficient for home consumption, the amount of maize grown barely covered local necessities, and the only market for live stock was in the *saladero* establishments where the meat was turned into jerked beef for the Brazilian and Cuban markets. But three years later the actual economic development began. In 1881 President Roca offered for public purchase by auction the lands in the south-west of the province of Buenos Ayres, the Pampa Central, and the Neuquen district, these lands having been rendered habitable after the campaign of 1878 against the Indians. The upset-price was £80 sterling per square league of 6669 acres, and, as the lands were quickly sold, an expansion of the pastoral industry immediately ensued. The demand for animals for stock-breeding purposes sent up prices, and this acted as a stimulus to other branches of trade, so that, as peace under the Roca régime seemed assured, a steady flow of immigration from Italy set in. The development of the pastoral industry of Argentina since those days has been remarkable. In 1878 the number of cattle was 12,000,000; of sheep, 65,000,000; and of horses, 4,000,000; in 1899 the numbers were—cattle, 25,000,000; sheep, 89,000,000; and horses, about 4,500,000. Originally the cattle were nearly all of the long-horned Spanish breed and of little value for their meat, except to the *saladero* establishments. Gradually Durham and Hereford stock were introduced to improve the native breeds, with results so satisfactory that now herds of three-quarters bred cattle are to be found in all parts of the country. Not only has the breed of cattle been improved, but the system of grazing has completely altered. Vast areas of land (probably 8,000,000 acres) have been ploughed and sown with lucerne, and magnificent permanent pasturage has been created where there were coarse and hard grasses in former days. In 1889 the first shipment of Argentine cattle, consisting altogether of 1930 steers, was sent to England. The results of these first experiments were not encouraging, owing mainly to the poor class of animals, but the exporters persevered, and the business steadily grew in value and importance until in 1898 the number of live cattle shipped was 130,351. In 1899 the number fell to 103,566, of which 83,364 were shipped to England, 3290 to France, and 11,688 to Brazil. Large quantities of frozen meat were exported in 1899, profitable prices being realized. Dairy farming is making rapid strides, and the development of sheep-farming has been remarkable. In 1878, 65,000,000 sheep yielded 230,000,000 pounds' weight of wool, or an average per sheep of about 3½ pounds. In the season 1899-1900 the wool exports weighed 420,000,000 pounds, and averaged more than 5 pounds per sheep. The extra weight of fleece was owing to the very great improvement due to the large importation of rams from Europe and Australia. The export, moreover, of live sheep and of frozen mutton to Europe has become an important factor in the trade of Argentina. In 1892 the number of live sheep shipped for foreign ports was 40,000; in 1898 the export reached a total of 619,378; and in 1899, 462,013. In 1892 the frozen mutton exported was 25,500 tons, and this had increased in 1898 to 29,776 tons.

The advance made in agricultural industry is also of very great importance. In 1872 the cultivated area was about 1,430,000 acres; in 1888, 6,074,000 acres; in 1895, 12,083,000 acres; in 1899, 16,055,000 acres. In 1899 the wheat exports exceeded 50,000,000 bushels, and the maize 40,000,000 bushels. The area under wheat in 1899 was 5,500,000 acres; maize, 6,000,000 acres; linseed, 200,000 acres. The farming industry is not, however, on a satisfactory basis. No national lands in accessible districts are available for the application of a homestead law, and the farmer too often has no interest in the land beyond the growing crops, a percentage of the harvest being the rent charged by the owner of the property. This system is mischievous, since, if a few consecutive

bad seasons occur, the farmer moves to some more favoured spot. The principal wheat and maize-producing districts lie in the provinces of Santa Fé, Buenos Ayres, Cordova, and Entre Rios, and the average yield of wheat throughout the country in 1899 was, in round numbers, 12 bushels to the acre. Little attention is paid to methods of cultivation, and the farmer has no resources to help him if the cereal crops fail. In the Andean provinces of Mendoza, San Juan, Catamarca, and La Rioja viticulture is widely practised, and the area of the vineyards now exceeds 150,000 acres. Wine is manufactured in large quantities, but the output is not yet sufficient to meet the home demand. In the province of Tucuman the main industry is sugar-growing and manufacture. In 1899 the production of sugar was 110,000 tons, the total consumption of Argentina being estimated at 80,000 tons annually. The sugar manufacture, however, is a protected and bounty-fed industry. Other products are tobacco, olives, castor-oil, and fruit and vegetables for export to Brazilian markets.

The pastoral and agricultural industries have been hampered by fluctuations in the value of the currency, farm products being sold at a gold value for the equivalent in paper, while labourers are paid in currency. The existing system of taxation also presses heavily upon the provinces, as may be seen from the fact that the national, provincial, and municipal exactions together amount to £7 per head of population, while the total value of the exports in 1898 was only £6 in round numbers.

Manufactures.—Manufacturing enterprise in Argentina, in spite of the protection afforded by a high tariff, does not make any substantial progress. The reason put forward is the lack of coal or other available cheap fuel. At Cordova a central power station for the distribution of electricity obtained from water-power was erected in 1897; but so far very little use of this convenience has been made by factories. In Buenos Ayres several companies have established stations for distributing electric power generated by steam; but the cost is high, and the power has hitherto only been applied for lighting and for the electric tramways.

Commerce.—The rapid development of the foreign trade of the republic since 1881 is shown in the following table, the values of imports and exports being given in pounds sterling for the years named. In the period 1886-90 the trade was abnormally inflated, the average annual imports during the five years being of the value of £25,919,000, and of the exports £17,813,000.

Year.	Imports.	Exports.
	£	£
1881	11,100,000	11,580,000
1886	19,100,000	14,000,000
1891	13,442,000	20,644,000
1896	22,433,000	23,360,000
1898	21,486,000	26,766,000
1899	23,360,000	36,980,000
1900	22,697,000	30,920,000

The principal imports are textiles and raw materials, valued in 1900 at £7,519,570; iron and iron goods, £3,810,810; food stuffs, £2,090,670; glass and earthenware, £1,778,700. The values of the principal groups of exports were—pastoral products, £14,250,800; agricultural products, £15,485,200; forest products, £441,700; various, £701,800. Of the pastoral products the more important exports were—ox-hides, 3,359,460 in number; horse-hides, 120,100 in number; sheep-skins, 28,200 tons; wool, 112,105 tons; tallow, 353,880 cwt.; foreign wethers, 2,372,970 in number. The agricultural produce exported comprised 2,042,164 tons of wheat and 740,625 tons of maize. Of the imports in 1900 84 per cent. in value came from the United Kingdom, 14 per cent. from Germany, 13 per cent. from Italy, 12 per cent. from the United States, and 9 per cent. from France. Of the exports 15 per cent. in value were shipped to the United Kingdom, 13 per cent. to Germany, 12 per cent. to France, and 11 per cent. to Belgium. More than half the foreign trade of the republic goes through the port of Buenos Ayres.

The commercial community has been passing through a most difficult period. Between 1880 and 1890 immense sums of European capital were invested in railways and other undertakings. The Mortgage Bank of the province of Buenos Ayres lent money recklessly in the form of *cedulas* nominally secured on landed property, credit was given far and wide, and the import trade rapidly developed. In 1890 a financial crisis came, credit contracted, the value of property depreciated, and imports decreased. The constant fluctuations in the value of the currency were also an adverse factor. But recent commercial statistics indicate that the volume of trade is once more increasing. Credit is now sounder than for several years, and shows signs of further improvement. Many of the larger retailers now import their wares direct from Europe, and thus save the intermediate commission charges. Present difficulties arise mainly from the appreciation of the currency and recent additions to taxation. In consequence of these two factors

the expenses of a trading establishment are now, with a premium on gold of only 127 per cent., greater than they were when the premium stood at 300 per cent.

Shipping and Navigation.—The shipping under the Argentine flag in 1898 consisted of 1416 sailing ships of a total tonnage of 118,894 tons and 222 steamships of 36,323 tons. The shipping entered at Argentine ports in the foreign trade in 1891 had a total tonnage of 5,275,094; in 1896, 7,115,467; in 1897, 6,185,062; in 1898, 6,555,128; in 1899, 6,939,567.

Railways.—The rapid development of the railway system is indicated by the following figures, which show the length of line open in various years from 1880:—

Year.	Miles Open.	Year.	Miles Open.
1880	1,435	1895	8,887
1885	2,820	1898	9,885
1890	5,745	1899	10,285

The trans-Andean line is open to Santa Rosa, but 46 miles are required to unite the Argentine and Chilean sections.

In 1900 the capital invested in the railways amounted to £105,323,324, of which £10,991,750 corresponded with the state lines, and the remainder with the private lines. In the course of 1900 the railways carried 17,898,961 passengers and 12,719,297 tons of goods, the average working expenses of all the lines in operation being (1898) 62 per cent. of the gross receipts.

In consequence of the action of competing undertakings, the companies, without any National Government guarantee on the capital they employed, were compelled to extend their works, and expansion was only checked when the financial crisis of 1890 destroyed for a time the credit of Argentina in the money markets of Europe. The concessions granted during the tenure of office of President Roca from 1880 to 1886 had the specific object of uniting outlying districts with the capital, and could be justified on political as well as economic grounds. Those issued broadcast by President Celman had no such *raison d'être* and were simply political jobs, which brought the guaranteed railway system into disrepute.

Tramways.—In 1895 there were in operation 460 miles of tramways, 36 miles in construction and 32 miles projected. These lines had a capital of \$84,000,000 paper, and in 1894 carried 88,306,866 passengers. In 1895 there were 179 stage-coach companies travelling over 11,940 miles of road.

Telegraphs.—In 1896 the Argentine Republic had 25,345 miles of telegraph lines and 1237 offices. The national telegraph lines had a length of 11,023 miles with 23,572 miles of wire; the railway lines, 7070 miles with 18,717 miles of wire; companies' lines, 4428 miles with 7462 miles of wire; other lines, 2824 miles with 9309 miles of wire. The despatches sent numbered 4,953,887.

Posts.—The Argentine Republic joined the Postal Union in 1878. In four years the national post offices handled mail pieces to the following numbers:—In 1894, 127,564,667 pieces; 1895, 142,436,240; 1896, 177,641,001; 1897, 190,506,860. In 1897 the internal correspondence amounted to 167,634,383 letters and papers, and the foreign to 22,872,487. In 1897 there were 1716 post offices. The revenue derived from the post offices, including the telegraphs, in 1897 was \$15,257,966; the expenditures, \$30,347,390.

Credit.—By law of 16th October 1891 the old National Bank was placed in liquidation, and the Banco de la Nacion Argentina was opened. Within the republic there are many other banks, both state and private. The National and Provincial Hypothecary Banks, in the spendthrift period between 1886 and 1890, exercised a disastrous influence on Argentine credit. The fundamental principle of these mortgage banks was sound enough, the idea being that the bonds issued (*cedulas*) should be a first charge on real estate of approved value, and that their face value should not represent more than 75 per cent. of the approved value of the property. But in the "boom" of 1887-89 *cedulas* were issued on the nominal value of property and through political influence, so that many millions of dollars were obtained on waste and worthless lands. When the true condition of affairs came to light it was found that *cedulas* amounting to some \$400,000,000 had been issued by the Provincial Hypothecary Bank, and to about \$120,000,000 by the National Bank. In the case of the Provincial Bank the security of the lands mortgaged was found to represent only about 10 per cent. of the nominal value of the *cedulas* issued. The guarantee of the Provincial Government had been attached to these bonds, but the province was in a bankrupt condition. Unfortunately, the *cedulas* had been largely bought in Europe under the impression that they were secured upon valuable real estate. When their price fell, nearly all landowners in possession of valuable properties and owing money to the bank at once bought up the bonds at depreciated values and cancelled their indebtedness. The bank was, therefore, left with only the mortgages that

were worthless, and practically the \$250,000,000 of *cedulas* now outstanding in Europe and Argentina are without intrinsic value. By careful management the affairs of the National Hypothecary Bank were brought to a fairly sound financial condition, but this was in great part owing to the fact that the charter of the bank practically confined all mortgages to the municipality of Buenos Ayres, where property has steadily risen in value for some years past.

The development of the resources of Argentina is effected largely by means of foreign capital. In a consular report of July 1900, the foreign capital invested in undertakings within the country is estimated at £122,865,000, of which £119,018,000 is for railways and tramways, and the interest annually paid to capitalists outside the republic is put at about £4,900,000.

The paper money in circulation on 31st December 1899 amounted to \$291,326,000, or about £25,600,000, gold being at a premium of 127 per cent. On 4th November of that year a law was passed for the conversion of the paper currency into gold dollars at the rate of 44 cents gold per paper dollar, provision being made for the formation of a conversion fund. In April 1900 the fund amounted to \$3,200,000 gold, or £640,000. It is anticipated that five years must elapse before the fund can reach an amount sufficient for an attempt to carry out the conversion.

The metric system has been nominally compulsory since 1887, but the old Argentine system is not yet abandoned.

II. RECENT HISTORY.

The history of Argentina since the time of its emancipation from Spain is a confused, wearisome story of political intrigues, party struggles, civil wars, and military revolutions. In 1875 the temporary lull led many people to believe that the period of civil strife was at an end and that no new revolutionary movements would be attempted for a long time to come. These sanguine expectations were not destined to be realized. During the presidency of Dr Avellaneda, who had succeeded Sarmiento in the office of chief magistrate, political feeling in the city and province of Buenos Ayres began to show unmistakable signs of forcing to an issue the question as to what position Buenos Ayres was to hold for the future in regard to the remaining provinces of the confederation. Before retiring from office, the President endeavoured to secure the election of General Julio Roca as his successor, and on this point hinged the principal political events of 1879, leading to the civil war of 1880, by which the power of Buenos Ayres was crushed. When, in 1879, the people of Buenos Ayres perceived that

the decentralization party had determined to leave no stone unturned to secure the election of General Roca, and so make sure that the provinces became the dominant element in the political situation, an agitation was immediately set on foot. Mass meetings were held and a committee was appointed for the purpose of considering what action should be taken to defeat the ambitious designs of the provincials. Under the direction of this committee, the association known as the "Tiro Nacional" was formed, with the avowed object of training the able-bodied citizens of Buenos Ayres in military exercises and creating a volunteer army, ready for service, if called upon, to resist by force the pretensions of their opponents. The establishment of the Tiro Nacional was enthusiastically received by all classes in Buenos Ayres, the men turning out regularly to drill and the women aiding the movement by collecting subscriptions for the purpose of armament and other necessities. On the 13th of February, 1880, the Minister of War, Dr Pellegrini, summoned the principal military officers connected with the Tiro Nacional, and warned them that as officers of the national army they owed obedience to the National Government and would be severely punished if concerned in any revolutionary outbreak directed against the constituted authorities. The reply to this threat was the immediate resignation from the army of all the officers connected with the Tiro Nacional. Two days later, the National Government occupied with a strong force of infantry and artillery the parade ground at Palermo used by the Buenos Ayres volunteers for drill purposes. A great meeting of the citizens was then called and marched through the streets. President Avellaneda, finding his position insecure, made a compromise and ordered the troops to be withdrawn. Negotiations were now opened between the National Government and the provincial authorities for the disarmament of the city and province of Buenos Ayres, but without result. Matters became still further strained on account of outrages committed by the national troops, and the gradual development of the situation brought about such violent bitterness of feeling between the two factions that an appeal to arms became inevitable.

In the month of March, 1880, President Avellaneda and his Ministers left Buenos Ayres, and this act was considered tantamount to a declaration of war. The National Government and the twelve provinces, forming the Cordova League, were on one side; the province and city of Buenos Ayres and the province of Corrientes on the other. The National Government troops were well armed with Remington rifles, provided with abundant ammunition, equipped with artillery, and supported by the fleet. In the city and province of Buenos Ayres plenty of volunteers offered their services, and an army of some 30,000 men was quickly raised, but they were armed with old-fashioned weapons and there was only a limited supply of ammunition. Feverish attempts were made to remedy the lack of warlike stores, but difficulty was experienced on account of the fleet blockading the entrance to the river. After several skirmishes, the contending armies met in force on the 20th of July, 1880, in the outskirts of Buenos Ayres, General Roca commanding the national troops. Two days' fighting took place, and the Buenos Ayres forces were finally outmatched at all points. On the 23rd of July the surrender of the city was demanded and obtained. The terms of the surrender were that all the principal men of the revolution should be removed from positions of authority, all Government *employés* implicated in the movement dismissed, and the forces in the province and city of Buenos Ayres at once disarmed and disbanded. The power of Buenos Ayres was thus completely broken and at the mercy of the Cordova League,

represented by their favourite candidate for the presidency, General Julio Roca. Buenos Ayres was no longer in a position to take any active part in the nomination of a successor to President Avellaneda, and the official candidate, General Roca, was declared to be duly elected without opposition. He assumed office in October, 1880. Hitherto, General Roca had been regarded only in his capacity of a soldier, and not from the point of view of an administrator. In the campaign against the Indians in the south-west of the province of Buenos Ayres and the valley of the Rio Negro and the Neuquen district, he had gained much prestige; the victory over the forces at Buenos Ayres added to his fame, and secured his authority in the outlying provincial centres. One of the first most notable acts of the Roca Administration was to declare the city of Buenos Ayres the property of the National Government, and no longer under the control of the provincial authorities. Some compensation was granted to the province in consideration of this change, but nothing that was given could adequately represent the political loss which it suffered. A further blow was dealt at its supremacy in 1884, when the town of La Plata was declared to be the provincial capital, and the Provincial Government was moved to that place.

Considering the circumstances in which General Roca assumed office, it must be admitted that he showed great moderation, and that on the whole his administration was fairly successful. Public affairs were conducted quietly so far as the National Government was concerned, and the influence and prestige of Roca throughout the provinces acted as a deterrent to *pronunciamentos* and outbreaks against the provincial authorities. The danger of these internal dissensions was permanently lessened, though by no means entirely removed, by the extension of railways. Unfortunately, the last two years of Roca's administration were characterized by two grave errors, which subsequently caused widespread suffering and distress throughout the country. The first of these mistakes was a measure making the currency inconvertible, which was adopted without any consideration as to its effect on the national credit. The second was the nomination of Dr Miguel Juarez Celman for the presidential term commencing in October, 1886. The nomination was brought about by the Cordova clique, and Roca lacked the moral courage to oppose the decision of this group, though he was well aware that Celman, who was his brother-in-law, was neither intellectually nor morally fitted for the post. No sooner had President Juarez Celman come into power, towards the close of 1886, than the respectable portion of the community began to feel alarmed at the methods practised by the new president in his conduct of public affairs. At first it was hoped that the influence of General Roca would serve to check any serious extravagances on the part of Celman. This hope, however, was doomed to disappointment, and before many months had elapsed it was clear that the President would listen to no prudent counsels from Roca or any one else. The men of the old Cordova League became dominant in all branches of the Government, and carpet-bagging politicians occupied every official post. In their hurry to obtain wealth, this crowd of office-mongers from the provinces lent themselves to all kinds of bribery and corruption. The public credit was pledged at home and abroad to fill the pockets of the adventurers, and the wildest excesses were committed under the guise of administrative acts. What followed in the second and third years of the Celman Administration can only adequately be described as a debauchery of the national honour, of the national resources, of the rights of Argentines as citizens of the Republic. Buenos Ayres was still prostrate under the crushing blow of the misfortunes

of 1880, and lacked the strength and power of organization necessary to raise any effective protest against the proceedings of Celman and his friends when the true character of these proceedings was first understood. The conduct of public affairs, however, at length became so scandalous that action on the part of the more sober-minded and more conservative sections was seen to be absolutely imperative if the country was to be saved from speedy and certain ruin. In 1889, the association of the "Union Civica" was founded, and the organization undertaken by Dr Leandro Alem, Dr Aristobulo del Valle, Dr Vicente Lopez, Dr Lucio Lopez, and other leading citizens. Mass meetings were held in Buenos Ayres, and Dr del Valle, a most able orator, clearly explained the terrible danger threatening the Republic in consequence of the irresponsible and corrupt character of the Administration. Subsidiary clubs affiliated to the central association were formed throughout the length and breadth of the country, and millions of leaflets and pamphlets were distributed broadcast to explain the importance of the movement. President Celman underrated the strength of the new opposition and relied upon his armed forces promptly to suppress any sign of open hostility. No change was made in official methods, and the condition of affairs drifted from bad to worse until the temper of the people, so long and so sorely tried, showed plainly that the situation had become insufferable. The Union Civica then decided to make a bold bid for freedom by attempting forcibly to eject Celman and his clique from office.

On the night of the 26th of July, 1890, the Union Civica called its members to arms. It was joined by some regiments of the regular army, and received the support of the fleet. Barricades were thrown up in the principal streets, and the surrounding houses were occupied by the insurgents. Two days of desultory street fighting ensued, during which the fleet began to bombard the city, but was compelled to desist by the interference of foreign men-of-war, on the ground that the bombardment was causing unnecessary damage to the life and property of non-combatants. A suspension of hostilities then took place and negotiations were opened between the contending parties. Celman, acting under the advice of General Roca, who recognized the strength of public opinion in the outbreak and foresaw a more powerful movement looming in the distance, placed his resignation in the hands of Congress on the 31st of July. A scene of immense enthusiasm followed, and Buenos Ayres was *en fête* for the following three days. Vice-President Carlos Pellegrini succeeded to the office vacated by Juarez Celman and to the administrative confusion resulting from the iniquitous methods of conducting public affairs during the previous four years.

Great expectations were formed of the ability of President Pellegrini to establish a sound Administration and to introduce a system of government ensuring the peace and progress of the Republic. General Roca tendered his services for the duties of Minister of the Interior, and his influence in the provinces was of very great assistance to the national authorities. Dr Vicente Lopez undertook the post of Minister of Finance, an onerous task in view of the financial complications resulting from the previous reckless extravagance. In short, all the most respectable elements in the country showed willingness to co-operate in the restoration of a normal condition of affairs and the establishment of political order, but the result did not come up to public expectation. Pellegrini proved a failure. Of great natural intelligence, and with the advantages of a sound education at Harrow, combined with much charm of manner and widespread personal popularity, he showed himself during his term of office merely a

politician, with no genuine statesmanlike qualities. The new Government made no attempt to initiate a strong policy of reform in administration or finance; it became a Government of expedients, drifting helplessly on a sea of financial troubles, and seeking merely to prevent serious political disturbances. This unsatisfactory state of affairs aroused the hostility of the Radical wing of the Union Civica, and Dr Alem preached far and wide the doctrine of opposition to the Government and the necessity of reform in the methods of administering the country. The more conservative section of the Union Civica refused to join in this opposition movement, and Dr Alem was arrested and exiled.

In 1892, Pellegrini's term of office expired and a successor had to be chosen. General Bartolome Mitre was proposed by the Buenos Ayres faction as their candidate. He had been absent from Argentina on a journey to Europe, and it was on his return in April, 1891, when a popular reception was given to him at which 50,000 persons attended, that he had formally accepted the candidacy for the presidential office. His partisans found themselves confronted by a compact provincial party who proposed to put forward General Roca, or, failing his acceptance, some other representative to oppose the Buenos Ayres candidate. There was no doubt that if both sides persisted in the struggle on the lines indicated a civil war must inevitably result. General Mitre disapproved of any measures likely to involve bloodshed and sought to effect a compromise. A meeting between him and General Roca resulted in an *acuerdo*, by which the two generals agreed to support a neutral candidate having no direct connexion with either of the political parties. The final selection for the candidacy fell upon Dr Saenz Peña, a Judge of the Supreme Court, and a man universally respected, who had never taken part in political life. In May, 1892, the presidential elections were held; Dr Saenz Peña was declared duly elected, and Señor Uriburu, then Argentine Minister in Chili, was chosen as Vice-President.

The idea of President Saenz Peña was to conduct the government on common-sense and business-like lines. He had no political training, no political party in Congress to support him; he was simply a straightforward, honourable man trying to do his duty in a position which had been forced upon him, and was in no sense of the word of his own seeking. No sooner was he installed in office than difficulties began to crop up on all sides, and he quickly discovered that no help could be expected from the two political factions which had brought him into power to suit their own convenience. To govern without a majority in Congress was a practical impossibility, and before twelve months of the presidential term had run public affairs had drifted to a deadlock. This was the opportunity of Dr Alem, the Radical leader of the Union Civica, and he was not slow to profit by the occasion. Embittered by his treatment in 1892, he openly preached the advisability of an armed rising and the overthrow of the existing Administration. The unscrupulous acts of corruption on the part of Dr Julio Costa, then Governor of the province of Buenos Ayres, strengthened the movement. A number of officers of the naval and military forces agreed to lend assistance to the revolutionary outbreak, and towards the end of July, 1893, matters came to a head. The population of the province of Buenos Ayres assembled in armed bodies with the avowed intention of turning the Governor out of office and electing in his stead a man who would give them a just Administration. At the commencement of the movement, Governor Costa imagined himself strong enough to hold his own with the aid of his police and several battalions of provincial troops quartered at La Plata; but as the insurrection spread he

appealed for aid to the National Government. President Saenz Peña professed to doubt his authority to interfere in provincial affairs, and deliberated for many days before he took action in the matter. Eventually, the intervention of the National Government was decided upon, and troops were despatched to the scene of the disturbance; but there was no serious fighting. Negotiations were soon opened, and resulted in the resignation of Governor Costa and the dispersal of the armed insurrectionary forces.

While these political disturbances were in progress in Buenos Ayres, another revolutionary rising took place in the province of Santa Fé. Dr Alem, preaching his gospel of a reform of the national Administration, induced a number of his co-religionists of the Union Cívica to take up arms. Several military and naval officers joined the movement, and a gunboat and one or two torpedo boats were seized by the insurgents. The scene of the insurrection was the vicinity of Rosario, and this city was in possession of the insurgents for a few days. After a few skirmishes, the revolt was suppressed by the national authorities in September, 1893, and Dr Alem and the other conspirators were captured. He and his civilian friends were sentenced to banishment to Staten Island during the pleasure of the Federal Government, and were immediately transported to that isolated spot. Of the naval and military officers, some were condemned to be shot and the others to serve various terms of imprisonment. This severity on the part of the Court-martial brought about fresh troubles. President Saenz Peña was determined that the sentences should be carried out. Congress was equally decided that the death penalty should not be inflicted. The Ministry at first supported the President in a half-hearted manner and then deserted him as the opposition in the Chambers gathered strength. The struggle between Congress and the Executive continued for some weeks, the former refusing to vote the Budget or any supplies unless the President conformed to the desires of the Chambers in the matter of the officers implicated in the Santa Fé outbreak. On the 21st of January, 1895, the President found his position no longer tenable, and preferred to resign rather than act against his convictions. That the government of Dr Saenz Peña was weak and vacillating is not to be gainsaid; but he himself was honest in his intention of doing his duty in the trust confided to him, and the chief cause of his unpopularity was probably the fact that he belonged to no distinct political party and consequently commanded no following among the members of Congress. His resignation was at once accepted by the Chambers, and the Vice-President, Dr Uriburu, became President of the Republic for the remainder of the period of six years for which Dr Saenz Peña had been elected in 1892.

President Uriburu was neither a politician nor a statesman; he had spent the greater portion of his life abroad in the Argentine diplomatic service, and could count on no political following in his own country. It was, indeed, on account of his belonging to no political party that he had been elected Vice-President. During his term of office the boundary question with Chile was the subject which chiefly attracted public attention. Internal politics were dwarfed in comparison with this important issue. The strain on both Governments was extremely severe. On both sides, from time to time, the populace clamoured for an appeal to arms. The resources of both countries were squandered in military preparations, and the National Guards were called out and constantly drilled in order to be ready in case of an emergency. In August, 1898, matters reached a climax. The choice lay between war and arbitration. The tendency of both nations was to decide the dispute by force of arms, but wiser counsels finally prevailed

and arbitration was agreed upon. The question of the Puña of Atacama was referred to a tribunal composed of the United States Minister to Argentina, one Argentine and one Chilean delegate; that of the southern territory in Patagonia was referred to the British Crown. The decision of the representative of the United States was given in April, 1899. Although the Chileans professed to be dissatisfied with the award, no active opposition was raised and the terms were duly notified. Up to the end of 1900 the decision of the Arbitration Commission appointed by the British Government had not been given. Further details regarding certain points were required, and, in order to obtain these, Argentine and Chilean expeditions were sent to Patagonia. In view of the occupation of Ultima Esperanza, part of the disputed territory, by Argentine colonists, the Governments of Chile and Argentina signed a protocol on 27th December agreeing to take no aggressive action, and to instruct the local authorities to maintain the previous position. No other boundary disputes can now arise, as the question with Brazil was settled by the award of President Cleveland in 1894, and subsequently accepted and ratified by the Argentine and Brazilian Governments.

In 1898 there was again a presidential election. Public opinion, excited by the prospect of a war with Chile, naturally supported the candidature of General Roca, and he was elected without opposition (12th October, 1898). Before he had been many weeks in office he arranged to meet the President of the Chilean Republic in the Strait of Magellan, and held a conference with him which confirmed the amicable solution of the frontier question. In his Message to Congress on the 1st of May, 1899, General Roca spoke strongly of the immediate necessity of a reform in the methods of administering justice, the expediency of a revision of the electoral law, and the imperative need of a reconstruction of the Department of Public Instruction. Justice, he said, had come to so low a level as to be practically non-existent. Of the necessity of electoral reform the following may serve as an illustration:—In March, 1899, elections were held for Deputies for the Provincial Chamber of Buenos Ayres, and resulted in the return of a substantial majority opposed to the Governor. They were at once annulled, and at the new elections the supporters of the Governor had a decided majority. On 31st August of the same year, President Roca sent to Congress a series of proposals for dealing with the currency question and certain branches of finance connected with the national revenue and expenditure. The scheme included the conversion of the currency at the rate of 44 cents gold for each paper dollar. The President declared that he was determined to make every effort to reduce the national expenditure, adding that the object of fixing the rate of the relation of gold to currency was to do away with the violent fluctuations in the value of the paper dollar, which caused so much damage to commerce and all classes of industry. In spite of the adverse feeling which prevailed in many quarters, the Conversion Bills were passed by the Senate and the Chamber of Deputies, and became law on 6th November.

In 1900 considerable anxiety was caused in Argentina by what was regarded as the aggressive attitude of Chile towards Bolivia. Dr Campos Salles, the President of Brazil, paid a visit to Buenos Ayres in October and was very warmly received. The result of the conversations between the two Presidents was an understanding that instructions should be sent to all Argentine and Brazilian representatives abroad to lose no opportunity to advocate the maintenance of peace in South America, and to discountenance the idea of any South American Government acquiring an extension of territory by force of arms.

The city and province of Buenos Ayres have been rapidly recovering by natural causes the political predominance which they lost in 1880. Representation in the Argentine Congress is accorded to the various provinces in proportion to their population. Until 1895 the number of seats in the Chamber of Deputies was based upon the census of 1869, which gave the provinces a large majority over the city and province of Buenos Ayres. Under the census of 1895 the increase of population in Buenos Ayres entitled the capital and province to a greater number of seats, and no fewer than 47 members for city and province together

are returned out of the total number of 116 for the whole Republic.

The chief political question agitating the people of Argentina is that of heavy protective duties as against a moderate tariff—practically, protection *versus* free trade. The farmers of all classes, agricultural and pastoral, demand a reduction of the tariff; while the manufacturers of sugar and other articles, which thrive only in consequence of the prohibitive duties, use all their political influence to maintain the existing system.

(C. E. A.)

Argenton, a town of France, in the arrondissement of Châteauroux, department of Indre, on the R. Creuse, 18 miles S.S.W. of Châteauroux on the railway to Le Blanc. Excellent wine is produced; tanning, the manufacture of boots and shoes, and linen goods, are leading industries. The actual site of the ancient *Argentomagus* lies a little to the north, and is occupied by St MARCEL. Population (1881), 5167; (1891), 5503; (1901), 6281, (comm.) 5978.

Argon.—For more than a hundred years before 1894 it had been supposed that the composition of the atmosphere was thoroughly known. Beyond variable quantities of moisture and traces of carbonic acid, hydrogen, ammonia, &c., the only constituents recognized were nitrogen and oxygen. The analysis of air was conducted by determining the amount of oxygen present and assuming the remainder to be nitrogen. Since the time of Cavendish no one seemed even to have asked the question whether the residue was, in truth, all capable of conversion into nitric acid.

The manner in which this condition of complacent ignorance came to be disturbed, is instructive. Observations undertaken mainly in the interest of Prout's law, and extending over many years, had been conducted to determine afresh the densities of the principal gases—hydrogen, oxygen, and nitrogen. In the latter case, the first preparations were according to the convenient method devised by Vernon Harcourt, in which air charged with ammonia is passed over red-hot copper. Under the influence of the heat the atmospheric oxygen unites with the hydrogen of the ammonia, and when the excess of the latter is removed with sulphuric acid, the gas properly desiccated should be pure nitrogen, derived in part from the ammonia, but principally from the air. A few concordant determinations of density having been effected, the question was at first regarded as disposed of, until the thought occurred that it might be desirable to try also the more usual method of preparation in which the oxygen is removed by actual oxidation of copper without the aid of ammonia. Determinations made thus were equally concordant among themselves, but the resulting density was about $\frac{1}{1000}$ part greater than that found by Harcourt's method (Rayleigh, *Nature*, vol. xlvi. p. 512, 1892). Subsequently when oxygen was substituted for air in the first method, so that all (instead of about one-seventh part) of the nitrogen was derived from ammonia, the difference rose to one-half per cent. Further experiment only brought out more clearly the diversity of the gases hitherto assumed to be identical. Whatever were the means employed to rid air of accompanying oxygen, a uniform value of the density was arrived at, and this value was one-half per cent. greater than that appertaining to nitrogen extracted from compounds such as nitrous oxide, ammonia, and ammonium nitrite. No impurity, consisting of any known substance, could be discovered capable of explaining an excessive weight in the one case, or a deficiency in the other. Storage for eight months did not disturb the density of the chemically extracted gas, nor had the silent electric

discharge any influence upon either quality. ("On an Anomaly encountered in determining the Density of Nitrogen Gas," *Proc. Roy. Soc.*, April 1894.)

At this stage it became clear that the complication depended upon some hitherto unknown body, and probability inclined to the existence of a gas in the atmosphere heavier than nitrogen, and remaining unacted upon during the removal of the oxygen—a conclusion afterwards fully established by Rayleigh and Ramsay. The question which now pressed was as to the character of the evidence for the universally accepted view that the so-called nitrogen of the atmosphere was all of one kind, that the nitrogen of the air was the same as the nitrogen of nitre. Reference to Cavendish showed that he had already raised this question in the most distinct manner, and indeed, to a certain extent, resolved it. In his memoir of 1788 he writes:—

As far as the experiments hitherto published extend, we scarcely know more of the phlogisticated part of our atmosphere than that it is not diminished by lime-water, caustic alkalies, or nitrous air; that it is unfit to support fire or maintain life in animals; and that its specific gravity is not much less than that of common air; so that, though the nitrous acid, by being united to phlogiston, is converted into air possessed of these properties, and consequently, though it was reasonable to suppose, that part at least of the phlogisticated air of the atmosphere consists of this acid united to phlogiston, yet it may fairly be doubted whether the whole is of this kind, or whether there are not in reality many different substances confounded together by us under the name of phlogisticated air. I therefore made an experiment to determine whether the whole of a given portion of the phlogisticated air of the atmosphere could be reduced to nitrous acid, or whether there was not a part of a different nature to the rest which would refuse to undergo that change. The foregoing experiments, indeed, in some measure decided this point, as much the greatest part of air let up into the tube lost its elasticity; yet, as some remained unabsorbed, it did not appear for certain whether that was of the same nature as the rest or not. For this purpose I diminished a similar mixture of dephlogisticated [oxygen] and common air, in the same manner as before [by sparks over alkali], till it was reduced to a small part of its original bulk. I then, in order to decompose as much as I could of the phlogisticated air [nitrogen] which remained in the tube, added some dephlogisticated air to it and continued the spark until no further diminution took place. Having by these means condensed as much as I could of the phlogisticated air, I let up some solution of liver of sulphur to absorb the dephlogisticated air; after which only a small bubble of air remained unabsorbed, which certainly was not more than $\frac{1}{100}$ of the bulk of the dephlogisticated air let up into the tube; so that, if there be any part of the dephlogisticated air of our atmosphere which differs from the rest, and cannot be reduced to nitrous acid, we may safely conclude that it is not more than $\frac{1}{100}$ part of the whole.

Although, as was natural, Cavendish was satisfied with his result, and does not decide whether the small residue was genuine, it is probable that his residue was really of a different kind from the main bulk of the "phlogisticated air," and contained the gas afterwards named Argon.

The announcement to the British Association in 1894 by Rayleigh and Ramsay of a new gas in the atmosphere was received with a good deal of scepticism. Some doubted the discovery of a new gas altogether, while others denied that it was present in the atmosphere. Yet there was

nothing inconsistent with any previously ascertained fact in the asserted presence of 1 per cent. of a non-oxidizable gas about half as heavy again as nitrogen. The nearest approach to a difficulty lay in the behaviour of liquid air, from which it was supposed, as the event proved erroneously, that such a constituent would separate itself in the solid form. The evidence of the existence of a new gas (named Argon on account of its chemical inertness), and a statement of many of its properties, were communicated to the Royal Society (see *Phil. Trans.* clxxxvi. p. 187) by the discoverers in January 1895. The isolation of the new substance by removal of nitrogen from air was effected

Fig. 1.

by two distinct methods. Of these the first is merely a development of that of Cavendish. The gases were contained in a test-tube A (Fig. 1) standing over a large quantity of weak alkali B, and the current was conveyed in wires insulated by U-shaped glass tubes CC passing through the liquid and round the mouth of the test-tube. The inner platinum ends DD of the wire may be sealed into the glass insulating tubes, but reliance should not be placed upon these sealings. In order to secure tightness in spite of cracks, mercury was placed in the bends. With a battery of five Grove cells and a Ruhmkorff coil of medium size, a somewhat short spark, or arc, of about 5 mm. was found to be more favourable than a longer one. When the mixed gases were in the right proportion, the rate of absorption was about 30 c.c. per hour, about thirty times as fast as Cavendish could work with the electrical machine of his day. Where it is available, an alternating

electric current is much superior to a battery and break. This combination, introduced by Spottiswoode, allows the absorption in the apparatus of Fig. 1 to be raised to about 80 c.c. per hour, and the method is very convenient for the purification of small quantities of Argon and for determinations of the amount present in various samples of gas, *e.g.*, in the gases expelled from solution in water. A convenient adjunct to this apparatus is a small voltmeter, with the aid of which oxygen or hydrogen can be introduced at pleasure. The gradual elimination of the nitrogen is tested at a moment's notice with a miniature spectroscope. For this purpose a small Leyden jar is connected as usual to the secondary terminals, and if necessary the force of the discharge is moderated by the insertion of resistance in the primary circuit. When with a fairly wide slit the yellow line is no longer visible, the residual nitrogen may be considered to have fallen below 2 or 3 per cent. During this stage the oxygen should be in considerable excess. When the yellow line of nitrogen has disappeared, and no further contraction seems to be in progress, the oxygen may be removed by cautious introduction of hydrogen. The spectrum may now be

Fig. 2.

further examined with a more powerful instrument. The most conspicuous group in the Argon spectrum at atmospheric pressure is that first recorded by Schuster (Fig. 2). Water vapour and excess of oxygen in moderation do not interfere seriously with its visibility. It is of interest to note that the Argon spectrum may be fully developed by operating upon a miniature scale, starting with only 5 c.c. of air (*Phil. Mag.* vol. i. p. 103, 1901).

The development of Cavendish's method upon a large scale involves arrangements different from what would at first be expected. The transformer working from a public supply should give about 6000 volts on open circuit, although when the electric flame is established the voltage on the platinum is only from 1600 to 2000. No sufficient advantage is attained by raising the pressure of the gases above atmosphere, but a capacious vessel is necessary. This may consist of a glass sphere of 50 litres' capacity, into the neck of which, presented downwards, the necessary tubes are fitted. The whole of the interior surface is washed with a fountain of alkali, kept in circulation by means of a small centrifugal pump. In this apparatus, and with about one horse-power utilized at the transformer, the absorption of gas is 21 litres per hour ("The Oxidation of Nitrogen Gas," *Trans. Chem. Soc.*, 1897).

In one experiment, specially undertaken for the sake of measurement, the total air employed was 9250 c.c., and the oxygen consumed, manipulated with the aid of partially de-aerated water, amounted to 10,820 c.c. The oxygen contained in the air would be 1942 c.c.; so that the quantities of atmospheric nitrogen and of total oxygen which enter into combination would be 7308 c.c. and 12,762 c.c. respectively. This corresponds to $N + 1.75 O$, the oxygen being decidedly in excess of the proportion

required to form nitrous acid. The Argon ultimately found was 75.0 c.c., or a little more than 1 per cent. of the atmospheric nitrogen used. A subsequent determination over mercury by Kellas (*Proc. Roy. Soc.* lix. p. 66, 1895) gave 1.186 c.c. as the amount of Argon present in 100 c.c. of mixed atmospheric nitrogen and Argon. In the earlier stages of the inquiry, when it was important to meet the doubts which had been expressed as to the presence of the new gas in the atmosphere, blank experiments were executed in which air was replaced by nitrogen from ammonium nitrite. The residual Argon, derived doubtless from the water used to manipulate the gases, was but a small fraction of what would have been obtained from a corresponding quantity of air.

The other method by which nitrogen may be absorbed on a considerable scale is by the aid of magnesium. The metal in the form of thin turnings is charged into hard glass or iron tubes heated to a full red in a combustion furnace. Into this air, previously deprived of oxygen by red-hot copper and thoroughly dried, is led in a continuous stream. At this temperature the nitrogen combines with the magnesium, and thus the Argon is concentrated. A still more potent absorption is afforded by calcium, prepared *in situ* by heating a mixture of magnesium dust with thoroughly dehydrated quick-lime. The density of Argon, prepared and purified by magnesium, was found by Professor Ramsay to be 19.941 on the O = 16 scale. The volume actually weighed was 163 c.c. Subsequently large-scale operations with the same apparatus as had been used for the principal gases gave an almost identical result (19.940) for Argon prepared with oxygen.

Argon is soluble in water at 12° C. to about 4.0 per cent., that is, it is about 2½ times more soluble than nitrogen. We should thus expect to find it in increased proportion in the dissolved gases of rain-water. Experiment has confirmed this anticipation. The weight of a mixture of Argon and nitrogen prepared from the dissolved gases showed an excess of 24 mg. over the weight of true nitrogen, the corresponding excess for the atmospheric mixture being only 11 mg. Argon is contained in the gases liberated by many thermal springs, but not in special quantity. The gas collected from the King's Spring at Bath gave only one-half per cent., *i.e.*, half the atmospheric proportion.

The most remarkable physical property of Argon relates to the constant known as the ratio of specific heats. When a gas is warmed one degree, the heat which must be supplied depends upon whether the operation is conducted at a constant volume or at a constant pressure, being greater in the latter case. The ratio of specific heats of the principal gases is .14, which, according to the kinetic theory, is an indication that an important fraction of the energy absorbed is devoted to rotation or vibration. If, as for Boscovitch points, the whole energy is translatory, the ratio of specific heats must be 1.67. This is precisely the number found from the velocity of sound in Argon as determined by Kundt's method, and it leaves no room for any sensible energy of rotatory or vibrational motion. The same value had previously been found for mercury vapour by Kundt and Warburg, and had been regarded as confirmatory of the monatomic character attributed on chemical grounds to the mercury molecule. It may be added that helium has the same character as Argon in respect of specific heats (*Ramsay, Proc. Roy. Soc.* l. p. 86, 1895).

The refractivity of Argon is .961 of that of air. This low refractivity is noteworthy as strongly antagonistic to the view at one time favoured by eminent chemists that Argon was a condensed form of nitrogen represented by N₂. The viscosity of Argon is 1.21, referred to air, some-

what higher than for oxygen, which stands at the head of the list of the principal gases ("On some Physical Properties of Argon and Helium," *Proc. Roy. Soc.* vol. lix. p. 198, 1896).

The spectrum shows remarkable peculiarities. According to circumstances, the colour of the light obtained from a Plücker vacuum tube changes "from red to a rich steel blue," to use the words of Crookes, who first described the phenomenon. A third spectrum is distinguished by Eder and Valenta. The red spectrum is obtained at moderately low pressures (5 mm.) by the use of a Ruhmkorff coil without a jar or air-gap. The red lines at 7056 and 6965 (Crookes) are characteristic. The blue spectrum is best seen at a somewhat lower pressure (1 mm. to 2.5 mm.), and usually requires a Leyden jar to be connected to the secondary terminals. In some conditions very small causes effect a transition from the one spectrum to the other. The course of electrical events attending the operation of a Ruhmkorff coil being extremely complicated, special interest attaches to some experiments conducted by Trowbridge and Richards, in which the source of power was a secondary battery of 5000 cells. At a pressure of 1 mm. the red glow of Argon was readily obtained with a voltage of 2000, but not with much less. After the discharge was once started, the difference of potentials at the terminals of the tube varied from 630 volts upwards.

The introduction of a capacity between the terminals of the Geissler tube, for example two plates of metal 1600 sq. cm. in area separated by a glass plate 1 cm. thick, made no difference in the red glow so long as the connexions were good and the condenser was quiet. As soon as a spark-gap was introduced, or the condenser began to emit the humming sound peculiar to it, the beautiful blue glow so characteristic of Argon immediately appeared. (*Phil. Mag.* xliii. p. 77, 1897.)

The behaviour of Argon at low temperatures was investigated by Olszewski (*Phil. Trans.*, 1895, p. 253). The following results are extracted from the table given by him:—

Name.	Critical Temperature, Cent.	Critical Pressure, Atmos.	Boiling Point, Cent.	Freezing Point, Cent.
Nitrogen .	-146.0	35.0	-194.4	-214.0
Argon .	-121.0	50.6	-187.0	-189.6
Oxygen .	-118.8	50.8	-182.7	?

The smallness of the interval between the boiling and freezing points is noteworthy.

From the manner of its preparation it was clear at an early stage that Argon would not combine with magnesium or calcium at a red heat, nor under the influence of the electric discharge with oxygen, hydrogen, or nitrogen. Numerous other attempts to induce combination also failed. Nor does it appear that any well-defined compound of Argon has yet been prepared. It was found, however, by Berthelot that under the influence of the silent electric discharge, a mixture of benzole vapour and Argon underwent contraction, with formation of a gummy product from which the Argon could be recovered.

The facts detailed in the original memoir led to the conclusion that Argon was an element or a mixture of elements, but the question between these alternatives was left open. The behaviour on liquefaction, however, seemed to prove that in the latter case either the proportion of the subordinate constituents was small, or else that the various constituents were but little contrasted. An attempt, somewhat later, by Ramsay and Collie to separate Argon by diffusion into two parts, which should have different densities or refractivities, led to no distinct effect. More recently Ramsay and Travers have obtained evidence of the existence in the atmosphere of three new gases,

besides helium, to which have been assigned the names of Neon, Krypton, and Xenon. These gases agree with Argon in respect of the ratio of the specific heats and in being non-oxidizable under the electric spark. As originally defined, Argon included small proportions of these gases, but it is now preferable to limit the name to the principal constituent and to regard the newer gases as "companions of Argon." The physical constants associated with the name will scarcely be changed, since the proportion of the "companions" is so small. Professor Ramsay considers that probably the volume of all of them taken together does not exceed $\frac{1}{400}$ th part of that of the Argon. The latest information with respect to the physical properties of these gases is conveyed in the following table (*Proc. Roy. Soc.* 67, p. 331, 1900):—

	Helium.	Neon.	Argon.	Krypton.	Xenon.
Refractivities (air=1)	·1238	·2345	·968	1·449	2·364
Densities (O=16)	1·98	9·97	19·96	40·88	64
Boiling-points at 760 mm.	?	?	86·9° abs.	121·33° abs.	163·9° abs.
Critical temper- atures	?	below 68° abs.	155·6° abs.	210·5° abs.	287·7° abs.
Critical pres- sures	?	?	40·2 metres.	41·24 metres.	43·5 metres.
Weight of 1 c.c. of liquid	?	?	1·212 gm.	2·155 gm.	3·52 gm.

The glow obtained in vacuum tubes is highly characteristic, whether as seen directly or as analysed by the spectroscope. (R.)

Argos.—Recent investigation has added considerably to our knowledge concerning the Argive Heræum or Heraion, the temple of Hera, which stood, according to Pausanias, "on one of the lower slopes of Eubœa." The term Eubœa did not designate the eminence upon which the Heræum is placed, or the mountain-top behind the Heræum only, but, as Pausanias distinctly indicates, the group of foothills of the hilly district adjoining the mountain. When once we admit that this designated not only the mountain, which is 532 metres high, but also the hilly district adjoining it, the general scale of distance for this site grows larger. The territory of the Heræum was divided into three parts, namely Eubœa, Akraia, and Prosymna. Pausanias tells us that the Heræum is 15 stadia from Mycenæ. Strabo, on the other hand, says that the Heræum was 40 stadia from Argos and 10 from Mycenæ. Both authors underestimate the distance from Mycenæ, which is about 25 stadia, or a little more than 3 miles, while the distance from Argos is 45 stadia, or a little more than 5 miles. The distance from the Heræum to the ancient Midea is slightly greater than to Mycenæ, while that from the Heræum to Tiryns is about 6 miles. The Argive Heræum was the most important centre of Hera and Juno worship in the ancient world; it always remained the chief sanctuary of the Argive district, and was in all probability the earliest site of civilized life in the country inhabited by the Argive people. In fact, whereas the site of Hissarlik, the ancient Troy, is not in Greece proper, but in Asia Minor, and can thus not furnish the most direct evidence for the earliest Hellenic civilization as such; and whereas Tiryns, Mycenæ, and the city of Argos, each represent only one definite period in the successive stages of civilization, the Argive Heræum, holding the central site of early civilization in Greece proper, not only retained its importance during the three periods marked by the supremacy of Tiryns, Mycenæ, and

the city of Argos, but in all probability antedated them as a centre of civilized Argive life. These conditions alone account for the extreme archæological importance of this ancient sanctuary.

According to tradition the Heræum was founded by Phoroneus at least thirteen generations before Agamemnon and the Achæans ruled. It is highly probable that before it became important merely as a temple, it was the fortified centre uniting the Argive people dwelling in the plain, the citadel which was superseded in this function by Tiryns. There is ample evidence to show that it was the chief sanctuary during the Tirynthian period. When Mycenæ was built under the Perseides it was still the chief sanctuary for that centre, which superseded Tiryns in its dominance over the district, and which this temple clearly antedated in construction. According to the *Dictis Cretensis*, it was at this Heræum that Agamemnon assembled the leaders before setting out for Troy. In the period of Dorian supremacy, in spite of the new cults which were introduced by these people, the Heræum maintained its supreme importance: it was here that the tablets recording the succession of priestesses were kept which served as a chronological standard for the Argive people, and even far beyond their borders; and it was here that Pheidon deposited the *obeliskoi* when he introduced coinage into Greece.

We learn from Strabo that the Heræum was the joint sanctuary for Mycenæ and Argos. But in the 5th century the city of Argos vanquished the Mycenæans, and from that time onwards the city of Argos becomes the political centre of the district, while the Heræum remains the religious centre. And when in the year 423 B.C., through the negligence of the priestess Chryseis, the old temple was burnt down, the Argives erected a splendid new temple, built by Eupolemos, in which was placed the great gold and ivory statue of Hera, by the sculptor Polycleitus, the contemporary and rival of Phidias, which was one of the most perfect works of sculpture in antiquity. Pausanias describes the temple and its contents (ii. 17), and in his time he still saw the ruins of the older burnt temple above the temple of Eupolemos.

All these facts have been verified and illustrated by the excavations of the American Archæological Institute and School of Athens, which were carried on from 1892 to 1895. In 1854 Rhangabé made tentative excavations on this site, digging a trench along the north and east sides of the second temple. Of these excavations no trace was to be seen when those of 1892 were begun. The excavations have shown that the sanctuary, instead of consisting of but one temple with the ruins of the older one above it, contained at least eleven separate buildings, occupying an area of about 300 metres by 100 metres.

On the uppermost terrace, defined by the great Cyclopean supporting wall, exactly as described by Pausanias, the excavations revealed a layer of ashes and charred wood, below which were found numerous objects of earliest date, together with some remains of the walls resting on a polygonal platform—all forming part of the earliest temple. Immediately adjoining the Cyclopean wall and below it were found traces of small houses of the rudest, earliest masonry which are pre-Mycenæan, if not pre-Cyclopean.

We then descend to the second terrace, in the centre of which the substructure of the great second temple was revealed, together with so much of the walls, as well as the several architectural members forming the superstructure, that it will be possible for the architects to design a complete restoration of the temple. On northern side of this terrace, between the second temple and the Cyclopean supporting wall, a long stoa or colonnade runs from east to west abutting at the west end in structures which evidently contained a well-house and waterworks; while at the eastern end of this stoa a number of chambers were erected against the hill, in front of which were placed statues and inscriptions, the bases for which are still extant. At the easternmost end of this second terrace a large hall with three rows of columns in the interior, with a porch and entrance at the west end facing the temple, is built upon elaborate supporting walls of good masonry.

Below the second terrace at the south-west end a large and complicated building, with an open courtyard surrounded on three

sides by a colonnade and with chambers opening out towards the north, may have served as a gymnasium or a sanatorium. It is of good early Greek architecture, earlier than the second temple. A curious, ruder building to the north of this and to the west of the second terrace is probably of much earlier date, perhaps of the Mycenaean period, and may have served as propylaea.

Immediately below the second temple, at the foot of the elevation on which this temple stands, towards the south, and thus facing the city of Argos, a splendid stoa or colonnade, to which large flights of steps lead, was erected about the time of the building of the second temple. It is a part of the great plan to give worthy access to the temple from the city of Argos. To the east of this large flights of steps lead up to the temple proper.

At the western extremity of the whole site, immediately beside the river bed, we again have a huge stoa running round two sides of a square, which was no doubt connected with the functions of this sanctuary as a health resort, especially for women, the goddess Hera presiding over and protecting married life and childbirth.

Finally, immediately to the north of this western stoa there is an extensive house of Roman times also connected with baths.

While the buildings give archæological evidence for every period of Greek life and history from the pre-Mycenaean period down to Roman times, the topography itself shows that the Heræum must have been constructed before Mycenæ and without any regard to it. The foothills which it occupies form the western boundary to the Argive plain as it stretches down towards the sea in the Gulf of Nauplia. While it was thus probably chosen as the earliest site for a citadel facing the sea, its further relation points towards Tiryns and Midea. It could not have been built as the sanctuary of Mycenæ, which was placed farther up towards the north-west in the hills, and could not be seen from the Heræum, its inhabitants again

PLAN OF THE HERÆUM (surveyed and drawn by Edward L. Tilton).

I, Old Temple; II, Stoa; III, Stoa; IV, East Building; V, 5th-Century Temple; VI, South Stoa; VII, West Building; VIII, North-West Building; IX, Roman Building; X, Lower Stoa; XI, Phylakeion; A, B, C, D, E, F, Cisterns.

not being able to see their sanctuary. The west building, the traces of bridges and roads, show that at one time it did hold some relation to Mycenæ; but this was long after its foundation or the building of the huge Cyclopean supporting wall which is coeval with the walls of Tiryns, these again being earlier than those of Mycenæ. There are, moreover, traces of still more primitive walls, built of rude small stones placed one upon the other without mortar, which are in character earlier than those of Tiryns, and have their parallel in the lowest layers of Hissarlik.

Bearing out the evidence of tradition as well as architecture, the numerous finds of individual objects in terracotta figurines, vases, bronzes, engraved stones, &c., point to organized civilized life on this site many generations before Mycenæ was built, *à fortiori* before the life as depicted by Homer flourished—nay, before, as tradition has it, under Prætus the walls of Tiryns were erected. We are aided in forming some estimate of the chronological sequence preceding the Mycenaean age, as suggested by the finds of the Heræum, in the new distribution which Dörpfeld has been led to make of the chronological stratification of Hissarlik in his most recent excavations

of that site. For the layer, which he now assigns to the Mycenaean period, is the sixth stratum from below. Now, as some of the remains at the Heræum correspond to the two lowest layers of Hissarlik, the evidence of the Argive temple leads us far beyond the date assigned to the Mycenaean age, and at least into the second millennium B.C. (see also MYCENÆAN CIVILIZATION).

This sanctuary still holds a position of central importance as illustrating the art of the highest period in Greek history, namely, the art of the 5th century B.C. under the great sculptor Polycleitus. Though the excavations in the second temple have clearly revealed the outlines of the base upon which the great gold and ivory statue of Hera stood, it is needless to say that no trace of the statue itself has been found. From Pausanias we learn that "the image of Hera is seated and is of colossal size: it is made of gold and ivory, and is the work of Polycleitus." Based on the computations made by the architect of the American excavations, Mr Tilton, on the ground of the height of the nave, the total height of the image, including the base and the top of the throne, would be about 8 metres, the seated figure of the goddess herself about 5.50 metres.

It is probable that the face, neck, arms, and feet were of ivory, while the rest of the figure was draped in gold. Like the Olympian Zeus of Phidias, Hera was seated on an elaborately decorated throne, holding in her left hand the sceptre, surmounted in her case by the cuckoo (as that of Zeus had an eagle), and in her right, instead of an elaborate figure of Victory (such as the Athene Parthenos and the Olympian Zeus held), simply a pomegranate. The crown was adorned with figures of Graces and the Seasons. A Roman imperial coin of Antoninus Pius shows us on a reduced scale the general composition of the figure; while Antoninus Argive coins of the 5th century give a fairly adequate rendering of the head. A further attempt has been made to identify the head in a beautiful marble bust in the British Museum hitherto known as Bacchus (Waldstein, *Journal of Hellenic Studies*, vol. xxi. 1901, pp. 30 seq.).

We also learn from Pausanias that the temple was decorated with "sculptures over the columns, representing some the birth of Zeus and the battle of the gods and giants, others the Trojan war and the taking of Ilium." It was formerly supposed that the phrase "over the columns" pointed to the existence of sculptured metopes, but no pedimental groups. Finds made in the excavations, however, have shown that the temple also had pedimental groups. Besides numerous fragments of nude and draped figures belonging to pedimental statues, a well-preserved and very beautiful head of a female divinity, probably Hera, as well as a draped female torso of excellent workmanship, both belonging to the pediments, have been discovered. Of the metopes also a great number of fragments have been found, together with two almost complete metopes, the one containing the torso of a nude warrior in perfect preservation, as well as ten well-preserved heads. These statues bear the same relation to the sculptor Polycleitus which the Parthenon marbles hold to Phidias; and the excavations have thus yielded most important material for the illustration of the Argive art of Polycleitus in the 5th century B.C.

See the official publication of the *Excavations of the Argive Heraeum*; WALDSTEIN: *Excavations of the American School of Athens at the Heraion of Argos*, 1892; and numerous reports and articles in the *American Archaeological Journal* since 1892.

Argostoli. See GREECE (IONIAN ISLANDS).

Argyll, George John Douglas Campbell, 8TH DUKE OF (1823-1900), British statesman, was born 30th April 1823, and succeeded his father, the 7th duke, in April 1847. He had then already obtained notice as a writer of pamphlets on the disruption of the Church of Scotland, which he strove to avert, and he rapidly became prominent on the Liberal side in Parliamentary politics. He was a frequent and eloquent speaker in the House of Lords, and sat as Lord Privy Seal (1852) and Postmaster-General (1855) in the Cabinets of Lord Aberdeen and Lord Palmerston. In Mr Gladstone's Cabinet of 1868 he was Secretary of State for India and infelicitously signalized his term of office by his refusal, against the advice of the Indian Government, to promise the Ameer of Afghanistan support against Russian aggression, a course which threw that ruler into the arms of Russia and was followed by the second Afghan war. With all the duke's activity and disposition to assert himself, this seems the only memorable political act recorded of him, except his resignation of the office of Lord Privy Seal, which he held in Mr Gladstone's Administration of 1880, from his inability to assent to the Irish land legislation of 1881. He opposed the Home Rule Bill with equal vigour, though Mr Gladstone subsequently stated that, among all the old colleagues who dissented from his course, the duke was the only one whose personal

relations with him remained entirely unchanged. Detached from party, the duke took an independent position, and for many years spoke his mind with great freedom in letters to the *Times* on public questions, especially such as concerned the rights or interests of landowners. He was no less active on scientific questions in their relation to religion, which he earnestly strove to reconcile with the progress of discovery. With this aim he published *The Reign of Law* (1866), *Primeval Man* (1869), *The Unity of Nature* (1884), and numerous essays in literary and scientific journals. He also wrote on the Eastern Question, with especial reference to India, the history and antiquities of Iona, patronage in the Church of Scotland, and many other subjects. The duke died 24th April 1900. He was thrice married: first (1844) to a daughter of the second duke of Sutherland (d. 1878); secondly (1881) to a daughter of Bishop Claughton of St Albans (d. 1894); and thirdly (1895) to Ina Erskine McNeill. His eldest son, then marquess of Lorne (b. 1845), married in 1871 the Princess Louise, fourth daughter of H.M. Queen Victoria. Few men of the duke's era displayed more versatility, and as an orator he ranked very high; but his treatment of the various themes he handled, if always impressive, was rarely conclusive; and while doing something to illustrate every subject and promote every cause which he made his own, and retaining for a generation before he died the deepest public respect—due not only to his career as a public man, but also to his position as the foremost Scottish noble, and the father-in-law of one of his Sovereign's daughters—he can hardly be said to have left any abiding reputation either as politician, thinker, or man of science. (R. G.)

Argyllshire, a maritime Highland county of W. Scotland, embracing a number of the Hebrides or Western Isles, bounded on the N. by Inverness, on the E. by Perth and Dumbarton, Loch Long and the Firth of Clyde, on the S. by the Irish Sea, and on the W. by the Atlantic. It is the second largest county in Scotland.

Area and Population.—In 1891 the Argyll parts of the parishes of Kilmallie and Small Isles were transferred to Inverness-shire. According to the latest official estimate the area of the county (foreshore excluded) is 2,025,154 acres, or about 3165 square miles. The population was in 1881, 76,440; in 1891, 75,003—on the above area, 74,085, of whom 36,292 were males and 37,793 females; on the old area, taking land only (2,056,402 acres or 3213.1 square miles), the number of persons to the square mile in 1891 was 23, and the number of acres to the person 27.4. In the registration county the population decreased between 1881 and 1891 by 1.8 per cent. Between 1881 and 1891 the excess of births over deaths was 6588, and the decrease of the resident population 1451. In 1901 the population was 73,665, a decline of 420. The following table gives particulars of births, deaths, and marriages in 1880, 1890, and 1899:—

Year.	Marriages.	Births.	Deaths.	Percentage of Illegitimato.
1880	299*	2108	1557	7.9
1890	282	1803	1360	6.66
1899	303	1749	1338	7.6

The birth-rate, death-rate, and marriage-rate were all below those for Scotland. The following table gives the birth-rate, death-rate, and marriage-rate per thousand of the population for a series of years:—

	1880.	1881-90.	1890.	1891-98.	1899.
Birth-rate . . .	26.13	25.24	22.69	22.09	22.46
Death-rate . . .	19.30	17.01	17.11	16.63	17.18
Marriage-rate . .	3.71	3.88	3.54	3.86	3.89

In 1891 the number of Gaelic-speaking persons in the county was 36,014, of whom 5998 spoke Gaelic only, and there were 52 foreigners. Valuation in 1889-90, £431,554; in 1899-1900, £439,975.

Administration.—The county returns a member to parliament. Inveraray (735) and Campbeltown (8234) are royal burghs, and

Oban (5374) is a parliamentary burgh; all three belong to the Argyll group of parliamentary burghs. Dunoon, with Kinn and Hunter's Quay, is the principal police burgh (6772). There are 39 civil parishes, 26 of which are divided among four combinations of Islay, Lochgilphead, Lorn, and Mull, with poorhouses at Oban, Lochgilphead, Bowmore, and Campbeltown. The number of paupers and dependants in May 1899 was 2383. Argyllshire is a sheriffdom, and there are resident sheriffs-substitute at Inveraray, Campbeltown, Oban, and Fort-William, and courts are held also at Tobermory, Lochgilphead, Bowmore in Islay, and Dunoon.

Education.—Forty-six school boards manage 159 schools, which had an average attendance of 11,117 in 1898-99, while 10 voluntary schools, of which 4 are Episcopal and 2 Roman Catholic, had 677. Campbeltown, Dunoon, and Oban have secondary schools, Tarbert public school has a secondary department, and 19 other schools earned grants in 1898 for giving higher education. Part of the "residue" grant is spent by the county council in subsidizing navigation and other classes in various schools, short courses in agriculture for farmers, and in providing bursaries.

Agriculture.—The greater part of the soil is moor or moss, in-susceptible of cultivation, and utilized as grouse and deer forest. The acreage under crops in 1898 was only 6.6 per cent. of the whole. Argyllshire is one of the crofting counties, but crofting is by no means universal. It is predominant in the island of Tiree and the western district of the mainland, but elsewhere farms of moderate size are the rule. In 1895 the average size of the 3272 holdings was 41 acres; the percentage under 5 acres was 32.64; between 5 and 50 acres 47.10, and over 50 acres 20.26. The number of farms between 50 and 100 acres was 304; between 100 and 300, 305; between 300 and 500, 30; and over 500, 24. Oats are the principal corn crop, only about 1500 acres of barley being sown, and there is no wheat at all. Besides stock-raising there is a good deal of dairying in Kintyre, the leading agricultural district. The following table gives the principal acreages at intervals of five years from 1880:—

Year.	Area under Crops.	Corn Crops.	Green Crops.	Clover.	Perman-ent Pasture.	Fallow.
1880	119,219	23,548	12,761	20,180	61,097	1597
1885	124,797	22,830	11,673	25,112	63,866	1816
1890	133,005	21,486	11,282	27,328	72,389	505
1895	134,063	20,444	10,644	26,999	75,222	725
1899	134,709	19,912	10,348	27,807	76,137	460

The following table gives particulars of the live stock during the same years:—

Year.	Total Horses.	Total Cattle.	Cows or Heifers in Milk or Calf.	Sheep.	Pigs.
1880	7204	59,976	22,385	1,021,948	3758
1885	6930	62,235	23,106	1,000,653	4645
1890	6662	59,627	22,747	1,008,279	4981
1895	7025	60,005	22,446	1,026,712	4905
1899	6367	61,698	22,888	984,304	4285

The acreage under wood in 1895 was 48,412, of which 2068 had been planted since 1881. From the commencement of the operation of the Crofters' Act in 1886 down to the end of 1898, 1097 applications to fix fair rent were dealt with by the Commission, and rents amounting to £6949 were reduced to £4825, and of £12,075 of arrears £7548 were cancelled. The Commissioners have dealt with 146 applications for enlargement of holdings, and have added 4663 acres to existing crofts. At the census of 1891 the number of persons engaged in agriculture was 8234 men and 900 women. Deer forests covered 232,698 acres in 1899, an increase of 16,000 since 1883, and their annual value was £7434.

Industries and Trade.—Coarse woollens are still made for home use. The following table gives particulars of the mineral industry for 1885 and 1895; the figures showing the output of coal cover Dumfries as well as Argyll:—

Year.	Coal.		Slate.		Granite.	
	Tons.	Value.	Tons.	Value.	Tons.	Value.
1885	105,733	£24,671	17,938	£25,364		
1895	113,945	£28,486	34,340	£60,977	37,211	£13,401
1899	154,786	£58,690	30,580	£62,440	66,128	£19,156

Fishing is the most important industry. Argyllshire ports and creeks are represented in four fishery districts, but as the Rothesay district comprises only a few Argyll ports, statistics may best be given for the fishery districts of Inveraray and

Campbeltown, which are exclusively Argyll, and Fort-William, which has 19 Argyll ports out of 26. The following table gives particulars of these three districts in 1890, 1898, and 1899:—

Year.	Boats.			Value of Gear.	Resident Fishermen and Boys.	Total Value of all Fish.
	No.	Tons.	Value.			
1890	1537	6622	£35,807	£31,189	4122	£105,175
1898	1062	4367	£20,000	£20,823	2570	£87,929
1899	1023	3716	£20,225	£20,682	3464	£101,066

£82,902 of the total value of fish in 1899 was the value of herrings only; £6992 the value of shell-fish. In the greater part of the districts the herring fishing is an autumn one. The Lochfyne fishing, which is the most important, lasts from June to January. White fishing is carried on at one or other of the ports all the year round. The number of persons employed in the three districts in connexion with the various branches of the sea fisheries in 1898 was 3873. The railway mileage has been increased by about 56 miles since 1875, and a light railway (18½ m.) from Loch Long to Loch Fyne has been sanctioned.

(w. w.)

Argyrokaströ, or ERGERI, a town of Turkey, on the river Drina in South Albania (Epirus). It is the chief town of the sanjak of the same name, which is one of the four composing the vilâyet of Janina as reduced by the annexation of Thessaly to Greece. Its population numbers 9000.

Arica or **San Marcos de Arica**, a town and port in the Chilean province of Tacna and capital of the department of Arica, situated in 18° 28' 8" S. lat. and 70° 20' 46" W. long. Its population in 1895 was 2853. It is the centre of a great mining district, and is connected with Tacna by rail. The territory of Arica and of Tacna fell into Chilean hands during the war of 1879 with Peru. In 1898, 295 vessels of 493,447 tons entered, and 296 of 494,784 tons cleared. The customs dues on imports into Arica in 1897 were 144,713 pesos (gold), and in 1898, 99,084.

Ariège, a department in the S. of France, resting on the Pyrenees and watered by the Ariège.

Area, 1893 square miles. The population declined to 237,619 in 1886 and 219,641 in 1896. Births in 1899, 4004, of which 149 were illegitimate; deaths, 4374; marriages, 1543. The chief towns are Foix, Pamiers, and St Giron. In 1896 the schools numbered 776, with 32,000 pupils. Eight per cent. of the population was illiterate. The area cultivated was 917,839 acres, of which 353,269 acres was plough-land. The mountains give very good pasture. In 1899 wheat yielded a return of the value of £225,037. Maize is also a profitable culture, as are likewise potatoes, which gave a return of 2,035,145 cwts. in 1898. Among the industrial cultures flax is the only noteworthy one. In 1899 the live stock numbered 573,560 head. Ariège produced in 1898 26,000 tons of iron ore, and 23,000 tons of copper, argentiferous lead, and manganese (mines of Nicdessos). The metallurgic industry yielded 48,000 tons of iron, cast-iron, and steel, of the value of £304,000. The other industries, with the exception of the manufacture of paper, are inconsiderable.

Arish. See ARABIA.

Aristides, Apology of.—Until 1878 our knowledge of Aristides was confined to the statement of Eusebius that he was an Athenian philosopher who presented an apology "concerning the faith" to the Emperor Hadrian. In that year, however, the Mechitarists of S. Lazzaro at Venice published a fragment in Armenian from the beginning of the apology; and in 1889 Dr Rendel Harris found the whole of it in a Syriac version on Mount Sinai. While his edition was

passing through the press, it was observed by the present writer that all the while the work had been in our hands in Greek, though in a slightly abbreviated form, as it had been imbedded as a speech in a religious novel written about the 6th century and entitled "The Life of Barlaam and Josaphat." The discovery of the Syriac version reopened the question of the date of the work. For although its *title* there corresponds to that given by the Armenian fragment and by Eusebius, it begins with a formal inscription to "the Emperor Titus Hadrianus Antoninus Augustus Pius": and Dr R. Harris is followed by Harnack and others in supposing that it was only through a careless reading of this inscription that the work was supposed to have been addressed to Hadrian. If this be the case, it must be placed somewhere in the long reign of Antoninus Pius (138-161). There are, however, no internal grounds for rejecting the thrice-attested dedication to Hadrian his predecessor, and the picture of primitive Christian life which is here found points to the earlier rather than to the later date. It is possible that the apology was read to Hadrian in person when he visited Athens, and that the Syriac inscription was prefixed by a scribe on the analogy of Justin's Apology, a mistake being made in the amplification of Hadrian's name.

The Apology opens thus: "I, O king, by the providence of God came into the world; and having beheld the heaven, and the earth, and the sea, the sun and moon, and all besides, I marvelled at their orderly disposition; and seeing the world and all things in it, that it is moved by compulsion, I understood that He that moveth and governeth it is God. For whatsoever moveth is stronger than that which is moved, and whatsoever governeth is stronger than that which is governed." Having briefly spoken of the divine nature in the terms of Greek philosophy, Aristides proceeds to ask which of all the races of men have at all partaken of the truth about God. Here we have the first attempt at a systematic comparison of ancient religions. For the purpose of his inquiry he adopts an obvious threefold division into idolaters, Jews, and Christians. Idolaters, or, as he more gently terms them in addressing the Emperor, "those who worship what among you are said to be gods," he subdivides into the three great world-civilizations—Chaldeans, Greeks, and Egyptians. He chooses this order so as to work up to a climax of error and absurdity in heathen worship. The direct nature-worship of the Chaldeans is shown to be false, because its objects are works of the Creator, fashioned for the use of men. They obey fixed laws and have no power over themselves. "The Greeks have erred worse than the Chaldeans . . . calling those gods who are no gods, according to their evil lusts, in order that having these as advocates of their wickedness they may commit adultery, and plunder and kill, and do the worst of deeds." The gods of Olympus are challenged one by one, and shown to be either vile or helpless, or both at once. A heaven of quarrelling divinities cannot inspire a reasonable worship. These gods are not even respectable: how can they be adorable? "The Egyptians have erred worse than all the nations; for they were not content with the worships of the Chaldeans and Greeks, but introduced, moreover, as gods even brute beasts of the dry land and of the waters, and plants and herbs. . . . Though they see their gods eaten by others and by men, and burned, and slain, and rotting, they do not understand concerning them that they are no gods."

Throughout the whole of the argument there is strong common-sense and a stern severity unrelieved by conscious humour. Aristides is engaged in a real contest;

he strikes hard blows, and gives no quarter. He cannot see, as Justin and Clement see, a striving after truth, a feeling after God, in the older religions, or even in the philosophies of Greece. He has no patience with attempts to find a deeper meaning in the stories of the gods. "Do they say that one nature underlies these diverse forms? Then why does god hate god, or god kill god? Do they say that the histories are mythical? Then the gods themselves are myths, and nothing more."

The Jews are briefly treated. After a reference to their descent from Abraham and their sojourn in Egypt, Aristides praises them for their worship of the one God, the Almighty Creator; but blames them as worshipping angels, and observing "sabbaths and new moons, and the unleavened bread, and the great fast, and circumcision, and cleanness of meats." He then proceeds to the description of the Christians. He begins with a statement which, when purged of glosses by a comparison of the three forms in which it survives, reads thus: "Now the Christians reckon their race from the Lord Jesus Christ; and He is confessed to be the Son of God Most High. Having by the Holy Spirit come down from heaven, and having been born of a Hebrew virgin, He took flesh and appeared unto men, to call them back from their error of many gods; and having completed His wonderful dispensation, He was pierced by the Jews, and after three days He revived and went up to heaven. And the glory of His coming thou canst learn, O king, from that which is called among them the evangelic scripture, if thou wilt read it. He had twelve disciples, who after His ascent into heaven went forth into the provinces of the world and taught His greatness; whence they who at this day believe their preaching are called Christians." This passage contains striking correspondences with the second section of the Apostles' Creed. The attribution of the Crucifixion to the Jews appears in several 2nd-century documents; Justin actually uses the words "He was pierced by you" in his dialogue with Trypho the Jew.

"These are they," he proceeds, "who beyond all the nations of the earth have found the truth: for they know God as Creator and Maker of all things, and they worship no other god beside Him; for they have His commandments graven on their hearts, and these they keep in expectation of the world to come. . . . Whatsoever they would not should be done unto them they do not to another. . . . He that hath supplieth him that hath not without grudging: if they see a stranger they bring him under their roof, and rejoice over him, as over a brother indeed, for they call not one another brethren after the flesh, but after the spirit. They are ready for Christ's sake to give up their own lives; for His commandments they securely keep, living holily and righteously, according as the Lord their God hath commanded them, giving thanks to Him at all hours, over all their food and drink, and the rest of their good things." This simple description is fuller in the Syriac, but the additional details must be accepted with caution: for while it is likely that the monk who appropriated the Greek may have cut it down to meet the exigencies of his romance, it is the habit of certain Syriac translators to elaborate their originals. After asserting that "this is the way of truth," and again referring for further information to "the writings of the Christians," he says: "And truly this is a new race, and there is something divine mingled with it." At the close we have a passage which is found only in the Syriac, but which is shown by internal evidence to contain original elements: "The Greeks, because they practise foul things . . . turn the ridicule of their foulness upon the Christians." This is

an allusion to the charges of Thyestean banquets and other immoralities, which the early apologists constantly rebut. "But the Christians offer up prayers for them, that they may turn from their error; and when one of them turns, he is ashamed before the Christians of the deeds that were done by him, and he confesses to God, saying: 'In ignorance I did these things'; and he cleanses his heart, and his sins are forgiven him, because he did them in ignorance in former time, when he was blaspheming the true knowledge of the Christians."

These last words point to the use in the composition of this Apology of a lost apocryphal work of very early date, *The Preaching of Peter*. This book is known to us chiefly by quotations in Clement of Alexandria: it was widely circulated, and at one time claimed a place within the Canon. It was used by the Gnostic Heracleon and probably by the unknown writer of the epistle to Diognetus. From the fragments which survive we see that it contained: (1) a description of the nature of God, which closely corresponds with Arist. i., followed by (2) a warning not to worship according to the Greeks, with an exposure of various forms of idolatry; (3) a warning not to worship according to the Jews—although they alone think they know the true God—for they worship angels and are superstitious about moons and sabbaths, and feasts, comp. Arist. xiv.; (4) a description of the Christians as being "a third race," and worshipping God in "a new way" through Christ; (5) a proof of Christianity from Jewish prophecy; (6) a promise of forgiveness to Jews and Gentiles who should turn to Christ, because they had sinned "in ignorance" in the former time. Now all these points, except the proof from Jewish prophecy, are taken up and worked out by Aristides with a frequent use of the actual language of *The Preaching of Peter*. A criterion is thus given us for the reconstruction of the Apology, where the Greek which we have has been abbreviated, and we are enabled to claim with certainty some passages of the Syriac which might otherwise be suspected as interpolations.

The style of the Apology is exceedingly simple. It is curiously misdescribed by Jerome, who never can have seen it, as "Apologeticum pro Christianis contextum philosophorum sententiis." Its merits are its recognition of the helplessness of the old heathenism to satisfy human aspiration after the divine, and the impressive simplicity with which it presents the unfailing argument of the lives of Christians.

The student may consult *The Apology of Aristides*, Syriac text and translation (J. R. HARRIS), with an appendix containing the Greek texts, *Texts and Studies*, i. 1 (1891), and a critical discussion by R. SEEBERG in Zahn's *Forschungen*, v. 2 (1893); also, brief discussions by HARNACK, *Altchristl. Litteratur*, i. 96 ff., *Chronologie*, i. 271 ff., where references to other writers may be found.

(J. A. R.)

Arithmetic. See NUMBER.

Arizona.—A territory of the United States, lying on the south-western border, between 37° and from 32°·8 to 33°·5 N. lat., and 109° and from 114°·8 to 114° W. long.; and bounded on the N. by Utah, on the E. by New Mexico, on the S. by Mexico, and on the W. by California and Nevada. It is traversed from the north-west to the south-east, a distance of about 450 miles, by mountain ranges of the Great Basin system, which form the main axis of elevation. On the north-east side, the great Colorado Plateau, with an average elevation of from 6000 to 8000 feet, stretches away into Utah and New Mexico. The southern margin of this plateau, marked by a line of cliffs, divides the head waters of the Colorado Chiquito from those of the Gila. The plateau is dominated in its middle southern portion,

north of Williams and Flagstaff, by a series of extinct volcanic cones, reaching in San Francisco Mountain an altitude of nearly 13,000 feet, from which in late Tertiary time great floods of lava flowed, chiefly to the southward and westward, forming a protecting covering to the foundation of nearly horizontal sedimentary rocks through which, on the north side, the Colorado carved the Great Cañon. Southward and westward from the central mass of mountains the surface slopes away to the Gulf of California in a series of wide valleys, separated by isolated mountain ranges, preserving a general parallelism in a north-west and south-east direction. Of the approximate total area of 113,000 square miles, about 39,000 are below the altitude of 3000 feet; about 27,000 are from 3000 to 5000 feet, and 47,000 are over 5000 feet. The central mountain ranges are largely formed of granitic, porphyritic, and other plutonic rocks in great variety, including volcanic outflows and tufas. There are areas of Archæan gneiss and pre-Cambrian slates flanked by Palæozoic formations, especially by the Devonian and Carboniferous. Great beds of Palæozoic conglomerate and breccias give evidence of continental areas, shallow oceans, and beaches in the earlier ages, with currents of great volume and power. Well-marked horizons of the Devonian occur in the Santa Catalina and the Santa Ritas. Carboniferous limestones and sandstones are widely distributed in the southern isolated mountain ranges and are uplifted, flexed, and faulted. Beds of graphitic coal with much ash and of little or no value for fuel have been found, and show the far westward extension of the flora of the Coal Measures. Sandstones of the Permian underlie a part of the lava of San Francisco Mountain, and Mesozoic beds crop in many places towards the south and west. Fossil bones and teeth of both the mammoth and the mastodon, and of a giant species of *Bos*, show that some at least of the large extinct mammals roamed over the Pleistocene plains and valleys.

Shut in on all sides from the ocean by mountain ranges and wide areas of land, Arizona is without rain for the greater part of the year. The air is clear, and the rays of the unclouded sun have great power. At night the radiation is unobstructed and the temperature falls rapidly. Owing to the extreme dryness of the air the evaporation from all moist surfaces is rapid, and the high temperatures shown by the dry-bulb thermometer are less oppressive than much lower temperatures in a humid atmosphere. There is a short season of rain in the spring, and one in midsummer, and the accumulation of snow on the mountains in winter gives rise to springs, rivulets, and forest growth.

The native plants, especially upon the lower levels, are characteristic of arid and semi-desert regions. They are Sonoran rather than Californian in aspect and grouping. Altitude, with its increasing moisture conditions and lower temperature, is a greater factor in the geographic distribution than latitude. Thorny shrubs, cactaceæ, and yuccas abound on the plains, together with the mezquite and paloverde, wherever their deeply-extended roots can reach moisture or water. The *Larrea Mexicana*, the evergreen shrub with aromatic glossy leaves and bright yellow flowers, is rarely absent and thrives under the most adverse conditions. Of Cacti there are no less than seventy-five species. The giant columnar cactus (*Cereus giganteus*), sometimes 40 feet high, is a striking object. Along the streams the cottonwood, sycamore, ash, willow, and walnut give verdure and shade. At an elevation of about 4000 feet oak trees appear in cañons and on the foot hills, giving the country the aspect of an artificial park. In the Huachuca Mountains there are eleven

species of oak, most of them evergreen. At higher levels junipers, cedars, and cypress appear and give place in the region of snow to furs and pines which crown the summits of most of the mountain ranges, attaining their greatest development and commercial importance on the Colorado plateau. This is known as the Coconino Forest, and is one of the most extensive forest areas in the United States, a large part of which has been reserved by the Government. The trees are mostly the yellow pine (*Pinus ponderosa*), and its varietal forms, the most widely disseminated and most abundant tree of the interior forest area, and practically the only tree of commercial importance for lumber. It is estimated that the total quantity of pine lumber fit for sawing within the limits of Arizona is not less than 8,000,000,000 feet B.M. The principal lumber mills are at Flagstaff and Williams in Coconino county.

The manufactures are few and of comparatively small value, excepting lumber. A large flouring mill has been erected at Tucson, and there are also extensive railway repair shops, a foundry, and mining machinery plant. At Phoenix onyx marble is cut and polished by machinery and Indian labour. The Navajo and the Moqui Indians make woollen blankets and rugs, and the Pimas baskets.

There are four chief regions of valleys of great fertility especially adapted to agriculture: the Salt River Valley, the Upper Gila and its tributaries, the Lower Gila and the Colorado, and the Santa Cruz. The Salt River Valley has one of the largest known tracts of irrigable land in one body, estimated at 1,500,000 acres. Numerous irrigating canals have partly redeemed it from the desert-like condition to which it relapsed after the disappearance of the ancient Aztec population. It is a region of beautiful farms, gardens, and orchards. Alfalfa, the staple forage and hay crop, thrives luxuriantly, and as many as five cuttings a year are possible. In 1898 some 35,000 cattle, fattened on alfalfa, were shipped from this valley. Corn, wheat, and barley are grown, but the region is chiefly celebrated for its early crops of citrus fruits, grapes, figs, dates, pomegranates, and olives. The date-palm flourishes. The most desirable varieties have been introduced. Considerable promise attends the cultivation of the sugar-beet and the experiments upon canaigre as a source of tannin. Excluding farms of Indians, there were in 1900, 4040 farms, containing 1,891,985 acres (of which 12 per cent. were improved land), valued, with improvements, at \$13,088,550. Over 72 per cent. of the total farm acreage in the territory and nearly 20 per cent. of the value of farm property were credited to 71 farms of 1000 acres or more each. In 1899 there were 2052 farms devoted principally to producing hay and grain, and 2343 to live stock. The average value of all farms in the territory was \$5148, and of products in 1899 not fed to live stock, per farm, \$1064. In 1900 there were on farms and ranges 7,042,635 neat cattle, 125,063 horses, 4077 mules, 4625 asses, 861,761 sheep, 18,103 swine, and 98,403 goats. Of the neat cattle nearly 98 per cent. and of the sheep nearly 100 per cent. were pastured wholly or in part upon the public domain. The value of all live stock was \$15,458,717, or 15.7 per cent. of the total capital invested in agriculture. It has been estimated that Arizona is capable of maintaining 8,000,000 head of cattle, but in the past an overstocking of the ranges has caused much loss and suffering, and the almost total eradication of the fine native grasses over extended areas. The total value of all farm crops in 1899 was \$2,474,296, of which the hay and forage crops amounted to \$1,361,422. The total value of all farm products, including animals sold or slaughtered for food (\$3,204,758), was \$6,997,097. Of the total improved land (227,890

acres) outside of Indian reservations in 1899, 81 per cent. was irrigated land; the total increase of irrigated land from 1890 to 1900 was 119,575 acres. In 1899 there were 1492 miles of irrigation ditches, the construction cost of which was \$4,408,158. The raising of ostriches for their feathers is successful.

The production of copper increased from 17,398 tons in 1890 to 55,412 tons in 1898, and over 76,000 tons in 1899. The chief centres of production are Bisbee, Jerome, Clifton, and Globe. Several gold-mines are worked to a great depth. The production of gold and silver, chiefly gold, was approximately \$4,500,000 in value for 1899. Wolframite, an ore of tungsten, occurs in quantity and has been successfully worked. There are also valuable ores of molybdenum and vanadium. Quarries of onyx marble have been opened, and some fine gems of peridot, garnet, and turquoise have been found.

Two transcontinental systems of railways, the Southern Pacific and the Santa Fé Pacific, traverse the state from east to west, and are connected from north to south by several lines. There are in all 999.5 miles of railway, with an assessed valuation of \$4,189,075.20 on which taxes are paid, and 454 miles of road exempt from taxation for a term of years. A standard gauge railway has been laid from Williams to the Grand Cañon.

On 1st July 1899 the county and city funded indebtedness was \$1,634,027.57, and the bonded debt of the territory \$1,041,972.43. There are five national banks with an aggregate capital of \$400,000, deposits \$2,194,773; and seven territorial banks, capital \$219,700, deposits \$1,364,475.

According to the census of 1890 the population was 59,620. In 1900 it was 122,212, showing an increase for the decade of 62,592, or 104.9 per cent. The increase was due in part to the fact that there were 28,623 Indians or other persons on Indian reservations in 1890, but not included in the general population as shown by the census bulletins. The average number of persons per square mile was 1.0 in 1900, as compared with 0.5 in 1890. The three principal cities, Phoenix (the capital), Tucson, and Prescott, have respectively 5544, 7531, and 3559 inhabitants. The Indian population in 1890 was 58,540. In 1899 the number enrolled at the five Government agencies and under instruction was 39,744. Many friendly Papagoes in Papaguera are not included. Of the total, 20,500 are upon the Navajo reservations and 2641 at the Hopi Pueblo. The Territorial prison, located at Yuma, had in 1898, 214 male prisoners.

The public-school system was established in 1871, and is modelled after that of California. There are primary, grammar, and high schools, and two normal schools, one at Tempe in Maricopa county and one at Flagstaff. In 1900 there were 373 teachers, 251 women and 122 men, of whom 120 were graduates of normal schools; the total number of enrolled students was 15,898, and the average daily attendance 9396. The total expenditure for the school year ending 30th June 1899 was \$238,741. The Territorial University, including the School of Mines and the laboratories of the Agricultural Experiment Station, was established at Tucson in 1885 and was opened in October 1891. It has about 20 professors and instructors, and from 140 to 150 students. It is well equipped for instruction and investigation, and is sustained chiefly by the Morrill and Hatch funds amounting to about \$45,000 annually. A school for Indians at Phoenix, and one at San Carlos, are sustained by the United States. One at Tucson, with an average of 150 boys and girls, is supported by the Presbyterian Home Mission. There are 53 or more newspapers; 11 daily and 42 weekly, including 3 published in Spanish. There is an important and well-

selected reference library at the university. The Carnegie Library building, under construction, will receive the valuable Territorial Library collection of some thousands of volumes.

The Territorial Assembly meets biennially. A new Capitol of granite and white tufa has been erected at a cost of about \$150,000. There have been fourteen different governors between 1863 and 1900. There are four judicial districts, in which court is held twice a year. One chief justice and four associates are appointed by the president.

The early Spanish colonists of Mexico were incited to the exploration and settlement of the region by the reports of its wealth of precious metals and precious stones. In 1539 Padre Marco de Niza passed through the valley of the Santa Cruz, and was followed in 1540 by Coronado. A mission was established at Guevaiz, south of Tucson, in 1687, and thirty-three years later there were nine missions within the limits of the territory now known as Arizona. The converts were mostly from the Pima tribe, and after baptism were called Papago. New Mexico, which included all of Arizona north of the Gila river, was ceded to the United States in 1848. The strip of country south of the Gila, known as the Gadsden Purchase, was acquired in 1853. Arizona was set off from New Mexico and organized as a territory in 1863.

Arizona*. 1896. Agriculture and Horticulture: TOUMEX. *Report Gov. Arizona*. 1898.

(W. P. B.)

Arkansas, one of the Southern States of the American Union, situated between 36° 30' and 33° N. lat., and 89° 49' and 94° 30' W. long., and bounded on the W. by the Mississippi, on the S. by Louisiana, on the E. by Texas and Indian Territory, and on the N. by Missouri. Before 1875, because of the nature of its physical features—being swampy in the lowlands, everywhere covered with forests, and mountainous in the north-west—and because, too, of the political conditions after the Civil War, Arkansas attracted but little of the great stream of immigration that had peopled the flat lands to the north and the prairies to the south. The main development of the state dates from 1890. If a line be drawn from where the Black River cuts the northern boundary to where the Red cuts the western, east of it will lie the lowlands and forests, and to the west will lie the mountains. North of the Arkansas river, in the region of the Boston mountains and the Ozarks, the country is very broken. The general elevation of the land is between 800 and 1200 feet above sea-level; the mountains are scattered in broken ridges and spurs as if flung from a gigantic hand, and there are few peaks of imposing height, the loftiest being Boat Mountain and Lost Mountain, each 2200 feet above sea-level. South of the Arkansas, the mountains lie in long high ranges east and west, separated by low fertile valleys, and at times rising into fine and imposing peaks. Magazine Mountain, 2823 feet above sea-level and 2350 feet above the surrounding country, is the loftiest point between the Alleghanies and Rockies, and in beauty and grandeur surpasses the famous Lookout. Blue Mountain, 2800 feet, and Mt Mena (Rich Mountain), 2750 feet, each rises 2100 feet over its valley. The state is well watered, and there are 3000 miles of navigable rivers. Locks have been constructed on White River, a fine stream, navigable 300 miles of its length. In its passage through the mountains White River may be compared with the Hudson for beauty of scenery. Its name it takes from the clearness of its waters, which it remarkably preserves through the alluvial lands even to its mouth.

The mineral history of the state may be dated from 1887, when the larger operations in coal began. The coal area covers 9100 square miles in the western part of the state, and extends into the Indian Territory over 20,000 square miles. Its quality is semi-anthracite and semi-bituminous, and, being hard and smokeless, is valuable for domestic and steam uses. From an output of 129,000 short tons in 1887, the production had swollen to 1,173,804 tons in 1898. The development is very rapid: in 1901 the daily output was about 10,000 short tons, with an employment of 3920 miners. The production from the adjacent coal-fields of the Indian Territory about doubles that of Arkansas. In the northern part of the state 2199 square miles of lead and zinc fields have been opened, the zinc fields undoubtedly constituting one of the richest deposits in the world. Between 1888 and 1892 Prof. John C. Brauner made an exhaustive geological survey, the results of which have been published by the state; and his account of the location, extent, and economic value of mineral deposits has, in several instances, led to their practical development. His reports show that one of the "most valuable deposits of manganese in North America" lies in the north-east, that payable quantities of iron are found in the same section, that 4450 square miles of marble equal to the best Tennessee varieties are situated in the north, that limestone valuable for lime is to be had in inexhaustible quantities, that granites superior to any known exist near Little Rock, that the finest novaculites and whetstones yet found are in abundance in the southern mountains, that antimony and bauxites are found in abundance, that clays and kaolin fit for manufacture of the best grade of porcelain exist in great quantities in the south central portion, and that the greensand, gypsum, and chalk marls in the south, if properly utilized, "will be of more value to the state than all the gold dug within the bounds of California has been to that state." A large deposit of true chalk has been utilized by a company which produces Portland cement. Gold and silver are also to be found, but not in extensive or valuable quantities.

The alluvial bottoms are exceedingly productive, and the soil and climate of the higher regions are peculiarly adapted to fruit-growing. The chief staple is cotton. In 1899, 1,726,000 acres produced 770,000 bales, valued at \$30,800,000. In 1897, 922,000 were raised, and the crop of 1900, with an acreage of 1,899,000, was estimated at over 900,000 bales, valued at \$35,000,000. Other agricultural products, in order of value, are corn, oats, wheat, rye, hay, millet, fruits (particularly apples, berries, and peaches), potatoes, field peas, sugar-cane, sorghum, broom corn, and rice. It is estimated that in 1898 the fruit and vegetable shipments were as follows:—Apples, 2400 carloads; berries, 1000; peaches, 500; and potatoes, 1200 carloads. The fruit is of finest quality, especially the apples, to which the first prize has been awarded in every competition since 1885, including the World's Fair in 1893 at Chicago. Lumber has been extensively cut, and in 1898 the shipments amounted to over 50,000 carloads. The annual output of forest products is valued at over \$20,000,000. The forests cover over 25,000,000 acres.

There are 54 railways (including branches and leased lines worked under distinct names), with a total of 3052 miles, and an assessed value of \$24,051,139. The principal systems are the St Louis, Iron Mountain, and Southern, which with branches and leased lines has 1059 miles; the St Louis South-Western, 412; the Choctaw and Memphis, 282; the Kansas City, Fort Scott, and Memphis, 162; the Kansas City Southern, 153; and the St Louis and San Francisco, 108. The total assessed value of real estate in 1899 was \$127,062,908; of

personal property, \$62,936,142; total, \$189,999,050. The rate of taxation for state purposes was 2½ mills for general revenue, 2 mills for common schools, 1 mill for sinking fund, and ¼ of a mill for pensions; total, 5½ mills. The constitution limits taxation by the state to 10 mills, and by counties for county purposes to 5 mills. The statutes limit taxation for city purposes to 5 mills, and for schools to 5 mills. The annual general expenses of the state government average about \$500,000. The total revenue from all sources in 1897 was \$2,229,682.

The growth in population is shown by the following table:—

Year.	Whites.	Negroes.	Total. ¹
1870	362,115	122,169	484,471
1880	591,531	210,666	802,525
1890	818,752	309,117	1,128,179
1900	944,580	366,856	1,311,436

The increase for the last decade of the 19th century was 16.25 per cent. The total land surface is approximately 53,045 square miles, and the average number of persons to the square mile was, therefore, 24.73 in 1900, as compared with 21.27 ten years earlier. Of the cities or towns in the state nineteen had in 1900 a population in excess of 2000, and five in excess of 5000. These five were Little Rock with 38,307, Fort Smith with 11,587, Pine Bluff with 11,496, Hot Springs with 9973, and Helena with 5550. The blacks are confined to the eastern part of the state; slavery never penetrated the mountainous portion, and the conditions there more nearly resemble those of Missouri than of the Gulf States.

The common school system is well developed; the number of school-houses in 1898 was 4926; the value of school properties was \$2,294,396. The scholastic population in 1898 was 336,168 whites and 129,397 blacks; total, 465,565. The total enrolment in 1898 was 224,247 whites and 79,561 blacks; total, 303,808. The state supports an agricultural and industrial university at Fayetteville. A number of sectarian and private colleges and academies have been established. In 1898 there were in all eight institutions for higher education, all co-educational; the students, including those in the preparatory departments, numbered 1072 men and 564 women; the teachers, 78 men and 30 women. There were 22,708 volumes in the libraries. The state supports a lunatic asylum, a blind school, and a deaf mute institute at Little Rock.

In 1900 there were 7 national banks, with a capital of \$1,070,000; 104 state banks, with a capital and surplus of \$3,855,761; 6 private banks, with a capital and surplus of \$196,291; and 2 loan and trust companies, with capital and surplus of \$79,000.

There were 3791 church edifices, and the church property was valued at \$3,266,663. The communicants or members numbered 296,208, of whom 128,724 were Baptists, 123,316 Methodists, 18,022 Presbyterians, and 14,385 Disciples of Christ.

After the Reconstruction Act of 1867, all offices, state and county, fell into the hands of "carpet-baggers," who inaugurated a reign of force and corruption. The native whites, practically disfranchised, fell under a rule of strangers, based on a suffrage conferred on their former slaves. In political self-defence, they responded with force and with frauds against the ballot. Secret societies were formed, such as the Ku Klux Klan on the one side, and the Brothers of Freedom on the other. The reconstruction governor organized a militia and declared martial law in several counties, but this only aggravated the mischief. In 1873, the "regular" Republicans elected Elisha Baxter as governor over

Joseph Brooks, the nominee of the reform Republicans. The Democrats had no candidate, but supported Brooks. Governor Baxter, by an honest and just conduct of the administration, soon alienated the affections of the "regular" Republicans who had elected him. Deserting him, they joined Brooks in a legal contest for the office. The Republican Court, in which the contest was filed on 15th April 1874, entered judgment for Brooks in the absence of Baxter and without notice. Brooks in person, accompanied by a guard, went to the State House, ousted Baxter, and entrenched himself there. The Democrats, espousing Baxter's cause, flew to arms. The turmoil that followed is known as the Brooks-Baxter War. The matter was referred to the President, and the attorney-general delivered an opinion favourable to Baxter. On 15th May the President issued a proclamation declaring him entitled to the office, and ordering the Brooks forces to disperse. Since then, the state has been in the hands of the Democratic party. (E. E. B.)

Arkansas City, a city of Cowley county, Kansas, U.S.A., situated in 37° 04' N. lat. and 97° 03' W. long., near the southern boundary of the state, on the north bank of the Arkansas, at an altitude of 1073 feet. Its site is a level bottom land, and its streets are laid out according to a regular plan. It is a supply point for a rich agricultural region and is entered by four lines of railway, the Atchison, Topeka, and Santa Fé; the Missouri Pacific; the St Louis and San Francisco; and the Kansas South-Western railways. Population (1900), 6140.

Arkhangelsk, or ARCHANGEL, a government of N. Russia, on the Arctic Ocean. Area, 331,505 sq. miles. Population (1897), 347,589. The peninsula of Kola, as also the islands Kolguev, Vaigach, and Novaya Zemlya, belong to it. In 1899, 170,540 acres were under cereals. Forests cover nearly one-half of the total area, and provide hunting, as well as an opportunity for various important industries connected with wood (timber, pitch, and tar, etc.). Cattle-breeding is at a low stage; but there were in 1897, 42,600 horses, 105,760 cattle, and 125,000 sheep, and the race of Kholmogory cows is kept in high repute. The coasting trade between the town of Arkhangelsk and the Murman or Norman coast and St Petersburg has lately been on the increase, but the value of foreign exports has declined (£1,234,390 in 1874, and £833,823 in 1898; imports, £130,000). Archangel is divided into ten districts, of which the chief towns are—Arkhangelsk (population, 20,933 in 1897), now connected by a railway (525 miles) with Yaroslavl; Kem (1825); Kola (615); Kholmogory (1465); Mezeñ (2040); Onega, (2700); Ust Tzylma, in Pechora district; Pinega (1000); and Shenkursk (1308). A new military harbour has been established on the Murman coast at Alexandrovsk, in the unfreezing Ekaterininskaya Bay.

Arklow, a maritime town in the county of Wicklow, Ireland, 50 miles south of Dublin by rail. In 1882 an Act was passed providing for the improvement of the harbour and for the appointment of harbour commissioners. The town hall and the new Protestant church (1899) were both the gift of the Earl of Carysfort. Cordite works have recently been established. The number of vessels registered in the fishing district in 1898 was 170, employing 808 men and boys. Population, 4172.

Arlington, (1) a town of Middlesex county, in eastern Massachusetts, U.S.A., traversed by the Boston and Maine railway; known until 1867 as West Cambridge. Population (1900), 8603. (2) A soldiers' cemetery under the control of the U.S. Government, situated in northern Virginia, in Alexandria county, on the bluffs of the south bank of the Potomac, opposite the city of Washington. Sixteen thousand victims of the Civil War, among them numerous prominent officers, including General Sheridan, are buried here.

¹ Including Indians and Chinese.

The place was formerly the estate of the Lee family, and was confiscated by the Government, the family finally receiving payment for it. The grounds are beautifully laid out, and the old Lee mansion remains unchanged.

Armagh, an inland county of Ireland, province of Ulster, bounded on the N. by Lough Neagh, on the W. by Down, on the S. by Louth, and on the W. by Monaghan and Tyrone.

Population.—The area of the administrative county in 1899 was 312,659 acres, of which 132,269 were tillage, 141,455 pasture, 514 fallow, 3141 plantation, 6416 turf bog, 2493 marsh, 7473 barren mountain, and 18,898 water, roads, fences, &c. The new administrative county under the Local Government (Ireland) Act, 1898, does not include the portion of the town of Newry, formerly situated in Armagh. Population (1881), 163,177; (1891), 143,289; (1901), 125,238, of whom 59,687 were males and 65,551 females, divided as follows among the different religious sects:—Roman Catholics, 56,707; Protestant Episcopalians, 40,853; Presbyterians, 20,029; Methodists, 5066; and other denominations, 2583. The decrease of population between 1881 and 1891 was 12·19 per cent. and between 1891 and 1901 it was 9·2 per cent. Of the total population in 1891, 107,180 persons inhabited the rural districts, an average of 255 persons to each square mile under crops and pasture.

Education.—The following table gives the degree of education in 1891:—

	Males.	Females.	Total.	Percentage.		
				R.C.	Pr. Epis.	Presb.
Read and write . . .	41,979	42,881	84,860	55·9	68·1	82·6
Read only	8,078	12,324	20,402	17·8	16·6	11·3
Illiterate	10,864	13,120	23,984	26·8	15·8	6·1

In 1881 the percentage of illiterates among Roman Catholics was 32·6. In 1891 there were 19 superior schools with 428 pupils (133 Roman Catholics and 295 Protestants), and 290 primary schools with 20,655 pupils (8996 Roman Catholics and 11,659 Protestants). The number of pupils on the rolls of the national schools on 30th September 1899 was 24,332, of whom 10,795 were Roman Catholics and 13,537 Protestants.

The following table gives the number of births, deaths, and marriages in various years:—

Year.	Births.	Deaths.	Marriages.
1881	4874	3665	982
1891	3394	2926	694
1899	2842	2480	683

In 1899 the birth-rate per 1000 was 20·6, and the death-rate 18·0; the rate of illegitimacy was 3·5 per cent. of the total births. The total number of emigrants who left the county between 1st May 1851 and 31st December 1899 was 93,620, of whom 52,339 were males and 41,281 females. The following are the chief towns in the county, with their populations in 1901:—Armagh, 7569; Lurgan, 11,777; Portadown, 10,046. A portion of the borough of Newry was formerly in Armagh, but in 1898 it was added to Down.

Administration.—The county is divided into three parliamentary divisions, north, middle, and south, the number of registered electors in 1900 being respectively 10,114, 7363, and 7152. The rateable value in 1900 was £430,162. By the Local Government (Ireland) Act, 1898, the fiscal and administrative duties of the grand jury and (to a less extent) of other bodies were transferred to a county council, urban and rural district councils were established, and under that Act the county now comprises four urban and five rural sanitary districts.

Agriculture.—The following tables show the acreage under crops, including meadow and clover, and the amount of live stock in 1881, 1891, 1896, and 1899. The figures for 1899 are for the new administrative county:—

	Wheat.	Oats.	Barley, Beans, etc.	Potatoes.	Turnips.	Other green Crops.	Flax.	Meadow and Clover.	Total.
1881	7161	58,165	879	28,150	7739	2075	16,012	45,172	165,858
1891	2758	51,055	846	26,434	8049	2592	4,966	49,971	146,171
1896	1204	49,054	237	24,602	8198	1965	8,244	53,121	146,620
1899	1468	46,344	179	22,370	8227	1729	1,881	50,121	182,269

For 1899 the total value of the cereal and other crops was estimated by the Registrar-General at £866,848. The number of acres under pasture in 1881 was 112,655; in 1891, 126,130; and in 1899, 141,455.

	Horses and Mules.	Asses.	Cattle.	Sheep.	Pigs.	Goats.	Poultry.
1881	18,988	2124	77,009	8,970	21,888	9,250	896,256
1891	14,969	2450	88,524	25,216	31,442	10,586	470,673
1896	15,867	2892	86,387	18,674	27,957	9,216	540,099
1899	14,001	2894	88,748	21,093	26,960	8,589	616,914

The number of milch cows in 1891 was 31,311, and in 1899, 30,848. It is estimated that the total value of cattle, sheep, and pigs in 1899 was £1,158,077. In 1899 the number of holdings not exceeding 1 acre was 1690; between 1 and 5, 3785; between 5 and 15, 8355; between 15 and 30, 4334; between 30 and 50, 1401; between 50 and 100, 532; between 100 and 200, 95; between 200 and 500, 20; and above 500, only 1—total 20,163. The number of loans issued (the number of tenants being the same as the number of loans) under the Land Purchase Acts, 1885, 1891, and 1896, up to 31st March 1900, was 1360, amounting to £337,101. The number of loans sanctioned for agricultural improvements under sect. 31 of the Land Act, 1881, between 1882 and 1900 was 99, and the amount issued, £5203, the smallest amount issued in any Irish county. The total amount issued on loan for all classes of works under the Land Improvement Acts from the commencement of operations to 31st March 1900 was £22,363, also the smallest amount issued in any Irish county. (W. H. P.)

Armagh, a city in the above county, 64 miles N. of Dublin, and 30 S.W. of Belfast by rail. It ceased to be a parliamentary borough in 1885. The corporation was abolished in 1841, and the administration since 1898 has been in the hands of an urban district council. The Callan, which flows into the Blackwater, passes near the town, and the Ulster canal is within 4 miles. There are frequent markets and a fair once a month. Population (1881), 10,070; (1891), 7438; (1901), 7569.

Arnavir. Two places of this name must be mentioned. (1) The ruins of the old capital of Armenia, on the S.E. slope of the extinct volcano Ala-ghöz, built by Armais, a grandson of Haik, in 1980 B.C. and the capital of the Armenian kings till the 2nd century A.D. Now a small village, Tapadibi, occupies its seat. (2) A district town of Russia, Northern Caucasia, province of Kuban, on Kuban river, and on the main line of the Caucasian railway, 40 miles by rail west of Stavropol, built in 1848 for the settlement of Armenian mountaineers, and now a well-built, growing town with 8000 inhabitants, the merchants of which carry on a lively trade.

Armenia (old Persian *Armina*, Armenian *Hayasdan*, or *Haikh*) is the popular name of a district south of the Caucasus and Black Sea, which formed part of the old Armenian kingdom. The name, which first occurs in the cuneiform inscriptions of Darius Hystaspis, supplanted the earlier Urardhu, or Ararat, but its origin is unknown. In its widest extent Armenia stretched from 37° to 49° E. longitude, and from 37½° to 41½° N. latitude; but this area was never, or only for a brief period, united under one king. Armenia is now divided between Persia, Russia, and Turkey, and the three boundaries have a common point on Little Ararat.

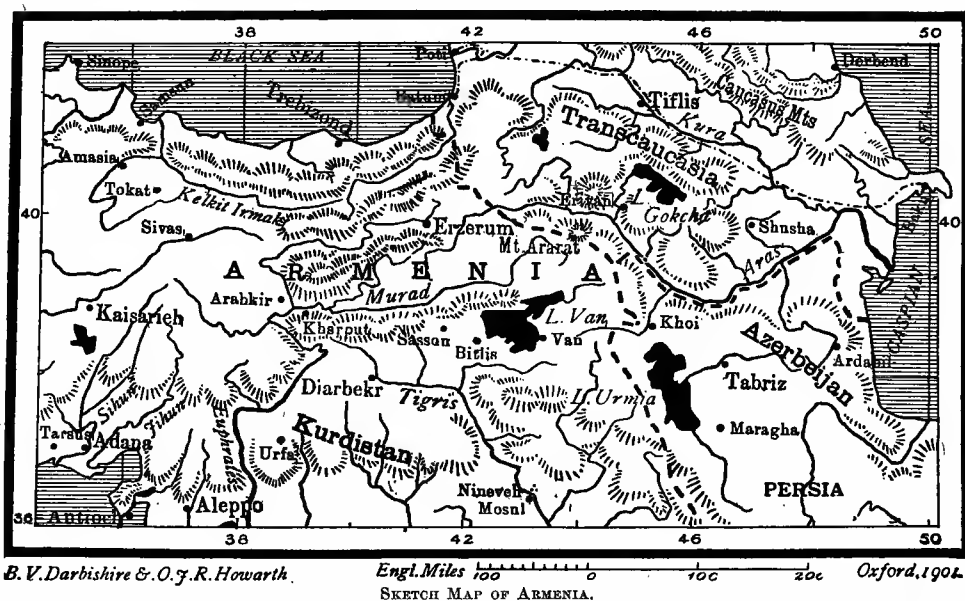

Geographically, Armenia is a continuation westward of the great Iranian plateau. On the north it descends abruptly to the Black Sea; on the south it breaks down in rugged terraces to the lowlands of Mesopotamia; and on the east and west it sinks more gradually to the lower plateaux of Persia and Asia Minor. Above the general level of the plateau, 6000 feet, rise bare ranges of mountains, which run from north-east to south-west at an altitude of 8000-12,000 feet, and culminate in Ararat, 17,100 feet. Between the ranges are broad elevated valleys, through which the rivers of the plateau flow before entering the rugged gorges that convey their waters to lower levels. Geologically, Armenia consists of archaic rocks upon which, towards the north, are superimposed Palæozoic

and towards the south later sedimentary rocks. The last have been pierced by volcanic outbursts that extend southward to Lake Van. Amongst the higher mountains are the two Ararats; Ala-geuz Dagh, north of the Aras; Bingeul Dagh, south of Erzerum; and the peaks near Lake Van. The rivers are the Euphrates, Tigris, Aras, Choruk Su, and Kelkit Irmak, all rising on the plateau. The more important lakes are Van, 5100 feet, about twice the size of the Lake of Geneva, and Urmia, 4000 feet, both salt; Gokcha or Sevan, 5870 feet, discharging into the Aras; and Chaldir, into the Kars Chai. The aspect of the plateau is dreary and monotonous. The valleys are wide expanses of arable land, and the hills are for the most part grass-covered and treeless. But the gorges of the Euphrates and Tigris, and their tributaries, cannot be surpassed in wildness and grandeur. The climate is varied. In the higher districts the winter is long and the cold severe; whilst the summer is short, dry, and hot. In Erzerum the temperature ranges from -22° to 84° F., and snow sometimes falls in June. In the valley of the Aras, and in the western and southern districts, the climate is more moderate. Most of the towns lie high, from 4000 to 6000 feet. The villages are usually built on gentle slopes, in which the houses are partially excavated as a protection against the severity of the weather. Many of the early towns were on or near the Araxes, and amongst their ruins are the remains of churches which throw light on the history of Christian architecture in the east. Armenia is rich in mineral wealth, and there are many hot and cold mineral springs. The vegetation varies according to the locality. Cereals and hardy fruits grow on the higher ground, whilst rice is cultivated in the hot, well-watered valley of the Araxes. The summer is so hot that the vine grows at much higher altitudes than it does in Western Europe, and the cotton tree and all southern fruit trees are cultivated in the deeper valleys. On the fine pasture lands which now support the flocks of the Kurds, the horses and mules, so celebrated in ancient times, were reared. Trout are found in the rivers, and a small herring in Lake Van.

Population.—Accurate statistics cannot be obtained; but it is estimated that in the nine vilayets, which include Turkish Armenia, there are 925,000 Gregorian, Roman Catholic, and Protestant Armenians, 645,000 other Christians, 100,000 Jews, Gypsies, &c., and 4,460,000 Moslems. The Armenians, taking the most favourable estimate, are in a majority in nine kazas or sub-districts only (seven near Van, and two near Músh) out of 159. In Russian Armenia there are 960,000 Armenians, and in Persian Armenia 130,000. According to an estimate made by General Zelenyi for the Caucasus Geographical Society (*Zapiski*, vol. xviii., Tiflis, 1896, with map), the population of the nine Turkish vilayets, Erzerum, Van, Bitlis, Kharpút, Diarbekr, Sivas, Aleppo, Adana, and Trebizond, was 6,000,000 (Armenians, 913,875, or 15 per cent.; other Christians, 632,875, or 11 per cent.; and

Moslems, 4,453,250, or 74 per cent.). In the first five vilayets, which contain most of the Armenians, the population was 2,642,000 (Armenians, 633,250, or 24 per cent.; other Christians, 179,875, or 7 per cent.; and Moslems, 1,828,875, or 69 per cent.); and in the seven Armenian kazas the population was 282,375 (Armenians, 184,875, or 65 per cent.; other Christians, 1000, or 0.3 per cent.; and Moslems, 96,500, or 34.7 per cent.). In 1897 there were 970,656 Armenians in Russia, of whom 827,634 were living in the provinces of Erivan, Elizabethpol, and Tiflis.

History.—The history of Armenia has been largely influenced by its physical features. The isolation of the valleys, especially in winter, encouraged a tendency to separation, which invariably showed itself when the central power was weak. The rugged mountains have always been the home of hardy mountaineers impatient of control, and the sanctuary to which the lowlanders fled for safety in times of invasion. The country stands as an open doorway between the east and the west. Through its long valleys run the roads that connect the Iranian

plateau with the fertile lands and protected harbours of Asia Minor, and for its possession nations have contended from the remotest past.

The early history of Armenia, more or less mythical, is partly based on traditions of the Biainian kings (see ARARAT), and is interwoven with the Bible narrative, of which a knowledge was possibly obtained from captive Jews settled in the country by Assyrian and Babylonian monarchs. The legendary kings are but faint echoes of the kings of Biainas; the story of Semiramis and Ara is but another form of the myth of Venus and Adonis; and tradition has clothed Tigranes, the reputed friend of Cyrus, with the transient glory of the opponent of Lucullus. The fall of the Biainian kingdom, perhaps overthrown by Cyaxares, was apparently soon followed by an immigration of Aryan (Medo-Persian) races, including the progenitors of the Armenians. But they spread slowly, for the "Ten Thousand," when crossing the plateau to Trebizond, 401-400 B.C., met no Armenians after leaving the villages four days' march beyond the Teleboas, now Kara Su. Under the Medes and Persians Armenia was a satrapy governed by a member of the reigning family; and after the battle of Arbela, 331 B.C., it was ruled by Persian governors appointed by Alexander and his successors.

Ardvates, 317-284 B.C., freed himself from Seleucid control;

Ancient history.

and after the defeat of Antiochus the Great by the Romans, 190 B.C., Artaxias (Ardashes), and Zadiades, the governors of Armenia Major and Armenia Minor, became independent kings, with the concurrence of Rome. Artaxias established his capital at Artaxata on the Araxes, and his most celebrated successor was Tigranes (Dikran), 94-56 B.C., the son-in-law of Mithradates. Tigranes founded a new capital, Tigranocerta, in Northern Mesopotamia, which he modelled on Nineveh and Babylon, and peopled with Greek and other captives. Here, and at Antioch, he played the part of "great-king" in Asia until his refusal to surrender his father-in-law involved him in war with Rome. Defeated, 69 B.C., by Lucullus beneath the walls of his capital, he surrendered his conquests to Pompey, 66 B.C., who had driven Mithradates across the Phasis, and was permitted to hold Armenia as a vassal state of Rome. The campaigns of Lucullus and Pompey brought Rome into delicate relations with Parthia. Armenia, although politically dependent upon Rome, was connected with Parthia by geographical position, a common language and faith, intermarriage, and similarity of arms and dress. It had never been Hellenized, as the provinces of Asia Minor had been; the Roman provincial system was never applied to it; and the policy of Rome towards it was never consistent. The country became the field upon which the East and the West contended for mastery, and the struggle ended for a time in the partition of Armenia, A.D. 387, between Rome and Persia. The Roman portion was soon added to the Diocesis Pontica. The Persian portion, Pers-Armenia, remained a vassal state under an Arsacid prince until 428. It was afterwards governed by Persian and Armenian noblemen selected by the "great-king," and entitled *marzbans*. Before the partition, Tiridates, converted by St Gregory, "the Illuminator," had established Christianity as the religion of the state, and set an example followed later by Constantine. After the partition, the invention of the Armenian alphabet, and the translation of the Bible into the vernacular, 410, drew the Armenians together, and the discontinuance of Greek in the Holy Offices relaxed the ecclesiastical dependence on Constantinople, which ceased entirely when the Patriarch, 491, refused to accept the decrees of the Council of Chalcedon. The rule of the *marzbans* was marked by relentless persecution of the Christians, forced conversions to Magism, frequent insurrections, and the rise to importance of the great families founded by men of Assyrian, Parthian, Persian, Syrian, and Jewish origin, and in some cases of royal blood, who had been governors of districts, or holders of fiefs under the Arsacids. Amongst the *marzbans* were Jewish Bagratids and Persian Mamegonians; and one of the latter family, Vartan, made himself independent (571-578), with Byzantine aid. In 632 the victories of Heraclius restored Armenia to the Byzantines; but the war that followed the Arab invasion, 636, left the country in the hands of the khalifs, who set over it Arab and Armenian governors (*ostikans*). One of the governors, the Bagratid Ashod I., was crowned king of Armenia by the khalif Mutamid, 885, and founded a dynasty which ended with Kagig II. in 1079. A little later the Ardzrunian Kagig, governor of Vaspuragan or Van, was crowned king of that province by the khalif Muktedir, 908, and his descendants ruled at Van and Sivas until 1080. Bagratids founded dynasties at Kars, 962-1080, and in Georgia, which they held until its absorption, 1801, by Russia. From 984 to 1085 the country from Diarbekr to Melasgerd was ruled, under the suzerainty first of Arabs, then of Byzantines and Seljüks, by the Mervanid dynasty of Kúrds, called princes of Abahuni (*Αβαχουνίς*). The Arab invasion drove many Armenian noblemen to Constantinople, where they inter-

married with the old Roman families or became soldiers of fortune. Artavasdes, an Arsacid, usurped the Byzantine throne for two years; Leo V., an Ardzrunian, and John Zimiskes, became emperors; whilst Manuel, the Mamegonian, and others were amongst the best generals of the empire. In 991, and again in 1021, Basil II. invaded Armenia, and in the latter year Senekherim, king of Vaspuragan, exchanged his kingdom for Sivas and its territory, where he settled down with many Armenian emigrants. Basil's policy was to make the great Armenian fortresses, garrisoned by imperial troops, the first line of defence on his eastern frontier; but it failed in the hands of his feeble successors, who thought more of converting heretical Armenia than of defending its frontier. The king of Ani, Kagig II., was compelled to exchange his kingdom for estates in Cappadocia. The country was raided by Seljüks and harried by Byzantine soldiers, and the miseries of the people were regarded as gain to the Orthodox church. After the defeat and capture of Romanus IV. by Alp Arslan, 1071, Armenia formed part of the Seljúk empire until it split up, 1157, into petty states, ruled by Arabs, Kúrds, and Seljüks, who were in turn swept away by the Mongol invasion, 1235. For more than three centuries after the appearance of the Seljüks, Armenia was traversed by a long succession of nomad tribes whose one aim was to secure good pasturage for their flocks on their way to the richer lands of Asia Minor. The cultivators were driven from the plains, agriculture was destroyed, and the country was seriously impoverished when its ruin was completed by the ravages and wholesale butcheries of Timúr. Many Armenians fled to the mountains where they embraced Islám, and intermarried with the Kúrds, or purchased security by paying blackmail to Kúrdish chiefs. Others migrated to Cappadocia or to Cilicia, where the Bagratid Rhuppen had founded, 1080, a small principality which, gradually extending its limits, became the kingdom of Lesser Armenia. This Christian kingdom in the midst of Moslem states, hostile to the Byzantines, giving valuable support to the leaders of the Crusades, and trading with the great commercial cities of Italy, had a stormy existence of about 300 years. Internal disorders, due to attempts by the later Lusignan kings, to make their subjects conform to the Roman Church, facilitated its conquest by Egypt, 1375. The memory of Kiligia (Cilicia) is enshrined in a popular song, and at Zeitún, in the recesses of Mount Taurus, a small Armenian community has hitherto maintained almost complete independence. After the death of Timúr, Armenia formed part of the territories of the Turkoman dynasties of Ak- and Kara-Koyunlu, and under their milder rule the seat of the Katholikos, which, during the Seljúk invasion, had been moved first to Sivas, and then to Lesser Armenia, was re-established, 1441, at Echmiadzin.

In 1514, the Persian campaign of Selim I. gave Armenia to the Osmanli Turks, and its reorganization was entrusted to Idris, the historian, who was a Kúrd of Bitlis. Idris found the rich arable lands almost deserted, and the mountains bristling with the castles of independent chieftains, of Kúrd, Arab, and Armenian descent, between whom there were long-standing feuds. He compelled the Kúrds to settle on the vacant lands, and divided the country into small sanjaks which in the plains were governed by Turkish officials, and in the mountains by local chiefs. This policy gave rest to the country, but favoured the growth of Kúrd influence and power, which by 1534 had spread westwards to Angora. Armenia was invaded by the Persians in 1575, and again in 1604, when Shah Abbas transplanted many thousand Armenians from Julfa to his new capital

Modern times.

Isfahan. In 1639, the province of Erivan, which included Echmiadzin, was assigned by treaty to Persia, and it remained in her hands until it passed to Russia, 1828, under the treaty of Turkman-chai. The Turko-Russian war of 1828-29, which advanced the Russian frontier to the Arpa Chai, was followed by a large emigration of Armenians from Turkish to Russian territory, and a smaller exodus took place after the war of 1877-78, which gave Batúm, Ardahan, and Kars to Russia. In 1834 the independent power of the Kúrds in Armenia was greatly curtailed; and risings under Bedr Khan Bey in 1843, and Sheikh Obeidullah in 1880, were firmly suppressed.

Gregorian Armenians.—After the capture of Constantinople, 1453, Muhammad II. organized his non-Moslem subjects in communities, or *millet*s, under ecclesiastical chiefs to whom he gave absolute authority in civil and religious matters, and in criminal offences that did not come under the Moslem religious law. Under this system the Armenian bishop of Brúsa, who was appointed patriarch of Constantinople by the Sultan, became the civil, and practically the ecclesiastical head of his community (*Ermeni millet*), and a recognized officer of the Imperial Government with the rank of vizier. He was assisted by a council of bishops and clergy, and was represented in each province by a bishop. This *imperium in imperio* secured to the Armenians a recognized position before the law, the free enjoyment of their religion, the possession of their churches and monasteries, and the right to educate their children and manage their municipal affairs. It also encouraged the growth of a community life, which eventually gave birth to an intense longing for national life. On the other hand it degraded the priesthood. The priests became political leaders rather than spiritual guides, and sought promotion by bribery and intrigue. Education was neglected and discouraged, servility and treachery were developed, and in less than a century the people had become depraved and degraded to an almost incredible extent. After the issue, 1839, of the Hatt-i-Sherif of Gül-khaneh, the tradesmen and artisans of the capital freed themselves from clerical control. Under regulations, approved by the Sultan in 1862, the patriarch remains the official representative of the community, but all real power has passed into the hands of clerical and lay councils elected by a representative assembly of 140 members. The "community," which excluded Roman Catholics and Protestants, was soon called the "nation," "domestic" became "national" affairs, and the "representative" the "national" assembly.

Roman Catholics.—The connexion of "Lesser Armenia" with the Western Powers led to the formation, 1335, of an Armenian fraternity, "the Unionists," which adopted the dogmas of the Roman church, and at the council of Florence, 1439, was entitled the "United Armenian Church." Under the millet system the unionists were frequently persecuted by the patriarchs, but this ended in 1830, when, at the intervention of France, they were made a community (*Katolik millet*), with their own ecclesiastical head. The Roman Catholics, through the works issued by the Mekhitarists at Venice, have greatly promoted the progress of education and the development of Armenian literature. They are most numerous at Constantinople, Angora, and Smyrna.

Protestants.—The Protestant movement, initiated, 1831, at Constantinople by American missionaries, was opposed by the patriarchs and Russia. In 1846 the patriarch anathematized all Armenians with Protestant sympathies, and this led to the formation of the "Evangelical Church of the Armenians," which was made, after much opposition from France and Russia, a community (*Protestant millet*), at the instance of the British ambassador.

The missionaries afterwards founded colleges on the Bosphorus, at Kharpút, Marsivan, and Aintab, to supply the needs of higher university education, and they opened good schools for both sexes at all their stations. Everywhere they supplied the people with pure, wholesome literature, and represented progress and religious liberty.

When Abdul Hamid came to the throne, 1876, the condition of the Armenians was better than it had ever been under the Osmanlis; but with the close of the war of 1877-78 came the "Armenian Question." By the Treaty of San Stefano, Turkey engaged to Russia to carry out reforms "in the provinces inhabited by the Armenians, and to guarantee their security against the Kúrds and Circassians." By the Treaty of Berlin, 13th July 1878, a like engagement to the six signatory Powers was substituted for that to Russia. By the Cyprus Convention, 4th June 1878, the Sultan promised Great Britain to introduce necessary reforms "for the protection of the Christians and other subjects of the Porte" in the Turkish territories in Asia. The Berlin Treaty encouraged the Armenians to look to the Powers, and not to Russia for protection; and the Convention, which did not mention the Armenians, was regarded as placing them under the special protection of Great Britain. This impression was strengthened by the action of England at Berlin in insisting that Russia should evacuate the occupied territory before reforms were introduced, and so removing the only security for their introduction. The presentation of identic and collective notes to the Porte by the Powers, in 1880, produced no result, and in 1882 it was apparent that Turkey would only yield to compulsion. In 1881 a circular note from the British Ministry to the five Powers was evasively answered, and in 1883 Prince Bismarck intimated to the British Government that Germany cared nothing about Armenian reforms and that the matter had better be allowed to drop. Russia had changed her policy towards the Armenians, and the other Powers were indifferent. The so-called "Concert of Europe" was at an end, but down to 1894 British ministries called the attention of the Sultan to his obligations under the Berlin Treaty.

Russia began to interest herself in the Armenians when she acquired Georgia in 1801; but it was not until 1828-29 that any appreciable number of them became her subjects. She found them necessary to the development of her new territories, and allowed them much freedom. They were permitted, within certain limits, to develop their national life; many became wealthy, and many rose to high positions in the military and civil service of the state. After the war of 1877-78 the Russian Consuls in Turkey encouraged the formation of patriotic committees in Armenia, and a project was formed to create a separate state, under the supremacy of Russia, which was to include Russian, Persian, and Turkish Armenia. The project was favoured by Loris Melikof, then all-powerful in Russia, but in 1881 Alexander II. was assassinated and shortly afterwards a strongly anti-Armenian policy was adopted. The schools were closed, the use of the Armenian language was discouraged, and attempts were made to Russify the Armenians and bring them within the pale of the Russian Church. All hope of practical self-government under Russian protection now ceased, and the Armenians of Tiflis turned their attention to Turkish Armenia. They had seen the success of the Slav committees in creating disturbances in the Balkans, and became the moving spirit in the attempts to produce similar troubles in Armenia. Russia made no real effort to check the action of her Armenian subjects, and since 1884 she has steadily opposed any active interference by Great Britain in favour of the Turkish Armenians. When

Recent events.

Russian policy.

Echmiadzin passed to Russia, in 1828, the Katholikos began to claim spiritual jurisdiction over the whole Armenian Church, and the submission of the patriarch of Constantinople was obtained by Russia when she helped Turkey in her war with Egypt. Recently Russia has secured the submission of the independent Katholikos of Sis, and has thus acquired a power of interference in Armenian affairs in all parts of the world. During 1900 Russia showed renewed interest in Turkish Armenia by securing the right to construct all railways in it, and in the Armenians by pressing the Porte to restore order and introduce reforms.

The Berlin Treaty was a disappointment to the Gregorian Armenians, who had hoped that Armenia and Cilicia would have been formed into an autonomous province administered by Christians. But the formation of such a province was impossible. The Gregorians were scattered over the empire, and, except in a few small districts, were nowhere in a majority. Nor were they bound together by any community of thought or sentiment. The Turkish-speaking Armenians of the south could scarcely converse with the Armenian-speaking people of the north; and the ignorant mountaineers of the east had nothing in common, except religion, with the

Revolutionary movement.

highly-educated townsmen of Constantinople and Smyrna. After the change in Russian policy and the failure of the Powers to secure reforms, the advanced party amongst the Armenians, some of whom had been educated in Europe and been deeply affected by the free thought and Nihilistic tendencies of the day, determined to secure their object by the production of disturbances such as those that had given birth to Bulgaria. Societies were formed at Tiflis and in several European capitals for the circulation of pamphlets and newspapers, and secret societies, such as the Huntchagist, were instituted for more revolutionary methods. An active propaganda was carried on in Turkish Armenia by emissaries, who tried to introduce arms and explosives, and represented the ordinary incidents of Turkish misrule to Europe as serious atrocities. The revolutionary movement was joined by some of the younger men, who formed local committees on the Nihilist plan, but it was strongly opposed by the Armenian clergy and the American missionaries, who saw the impossibility of success; and its irreligious tendency and the self-seeking ambition of its leaders made it unacceptable to the mass of the people. Exasperated at their failure, the emissaries organized attacks on individuals, wrote threatening letters, and at last posted revolutionary placards, 5th January 1893, at Yuzgat, and on the walls of the American College at Marsivan. In the last case the object of the Huntchagists was to compromise the missionaries, and in this they succeeded. The Americans were accused of issuing the placards; two Armenian professors were imprisoned; and the girls' school was burned down. Outbreaks, that were easily suppressed, followed at Kaisaríeh and other places.

One of the revolutionary dreams was to make the ancient Daron the centre of a new Armenia. But the movement met with no encouragement, either amongst the prosperous peasants on the rich plain of Músh or in the mountain villages of Sasún. In the summer of 1893, an emissary was captured near Músh, and the governor, hoping to secure others, ordered the Kúrdish Irregular Horse to raid the mountain district. The Armenians drove off the Kúrdish,¹ and, when attacked in the spring of

1894, again held their own. The Vali now called up regular troops from Erzingan; and the Sultan issued a firman calling upon all loyal subjects to aid in suppressing the revolt. A massacre of a most brutal character, in which Turkish soldiers took part, followed; and aroused deep indignation in Europe. In November 1894 a Turkish commission of inquiry was sent to Armenia, and was accompanied by the Consular delegates of Great Britain, France, and Russia, who elicited the fact that there had been no attempt at revolt to justify the action of the authorities. Throughout 1894 the state of the country bordered upon anarchy, and during the winter of 1894-95 the British Government, with lukewarm support from France and Russia, pressed for administrative reforms in the viláyets of Erzerúm, Van, Bitlis, Sivas, Memuret-el-Aziz (Kharpút), and Diarbekr. The Porte made counter-proposals, and officials concerned in the Sasún massacres were decorated and rewarded. On 11th May 1895 the three Powers presented to the Sultan a complicated scheme of reforms which was more calculated to increase than to lessen the difficulties connected with the government of Armenia; but it was the only one to which Russia would agree. The Sultan delayed his answer. Great Britain was in favour of coercion, but Russia when sounded, replied that she "would certainly not join in any coercive measures" and she was supported by France. At this moment, 21st June 1895, Lord Rosebery's Cabinet resigned, and when Lord Salisbury's Government resumed the negotiations in August, the Sultan appealed to France and Russia against England. During the negotiations the secret societies had not been inactive. Disturbances occurred at Tarsus; Armenians who did not espouse the "national" cause were murdered; the life of the patriarch was threatened; and a report was circulated that the British ambassador wished some Armenians killed to give him an excuse for bringing the fleet to Constantinople. On the 1st October 1895 a number of Armenians, some armed, went in procession with a petition to the Porte and were ordered by the police to disperse. Shots were fired, and a riot occurred in which many Armenian and some Moslem lives were lost. The British ambassador now pressed the scheme of reforms upon the Sultan, who accepted it on the 17th October. Meanwhile there had been a massacre at Trebizond (8th October), in which armed men from Constantinople took part, and it had become evident that no united action on the part of the Powers was to be feared. The Sultan refused to publish the scheme of reforms, and massacre followed massacre in Armenia in quick succession until 1st January 1896. Nothing was done. Russia refused to agree to any measure of coercion, and declared (19th December) that she would take no action except such as was needed for the protection of foreigners. Great Britain was not prepared to act alone. In the summer of 1896 (14th-22nd June) there were massacres at Van, Egin, and Niksar; and on the 26th August the Imperial Ottoman Bank at Constantinople was seized by revolutionists as a demonstration against the Christian Powers who had left the Armenians to their fate. The project was known to the Porte, and the rabble, previously armed and instructed, were at once turned loose in the streets. Two days' massacre followed, during which from 6000 to 7000 Gregorian Armenians perished. Soon afterwards the attention of the Turkish Government was fully occupied by the course of events in Crete.

The massacres were apparently organized and carried out in accordance with a well-considered plan. They

¹ The Armenians and Kúrdish have lived together from the earliest times. The adoption of Islám by the latter, and by many Armenians, divided the people sharply into Christian and Moslem, and placed the Christian in a position of inferiority. But the relations between the

two sects were not unfriendly previously to the Russian campaigns in Persia and Turkey. After 1829, the relations became less friendly; and later, when the Armenians attracted the sympathies of the European Powers after the war of 1877-78 they became bitterly hostile.

occurred, except in six places, in the viláyets to which the scheme of reforms was to apply. At Trebizond they took place just before the Sultan accepted that scheme, and after his acceptance of it they spread rapidly. They were confined to Gregorian and Protestant Armenians. The Roman Catholics were protected by France, the Greek Christians by Russia. The massacre of Syrians, Jacobites, and Chaldees at Urfa and elsewhere, formed no part of the original plan. Orders were given to protect foreigners, and in some cases guards were placed over their houses. The damage to the American buildings at Kharpút was due to direct disobedience of orders. The attacks on the bazárs were made without warning, during business hours, when the men were in their shops and the women in their houses. Explicit promises were given, in some instances, that there would be no danger to those who opened their shops, but they were deliberately broken. Nearly all those who, from their wealth, education, and influence, would have had a share in the government under the scheme of reforms, were killed and their families ruined by the destruction of their property. Where any attempt at defence was made the slaughter was greatest. The only successful resistance was at Zeitún, where the people received honourable terms after three months' fighting. In some towns the troops and police took an active part in the massacres. At Kharpút artillery was used. In some the slaughter commenced and ended by bugle-call, and in a few instances the Armenians were disarmed beforehand. Wherever a superior official or army officer intervened the massacre at once ceased, and wherever a governor stood firm there was no disturbance. The actual perpetrators of the massacres were the local Moslems, aided by Lazis, Kúrds, and Circassians. A large majority of the Moslems disapproved of the massacres, and many Armenians were saved by Moslem friends. But the lower orders were excited by reports that the Armenians, supported by the European Powers, were plotting the overthrow of the Sultan; and their cupidity was aroused by the prospect of wiping out their heavy debts to Armenian pedlars and merchants. No one was punished for the massacres, and many of those implicated in them were rewarded. In some districts, especially in the Kharpút viláyet, the cry of "Islám or death" was raised. Gregorian priests and Protestant pastors were tortured, but preferred death to apostasy. Men and women were killed in prison and in churches in cold blood. Churches, monasteries, schools, and houses were plundered and destroyed. In some places there was evidence of the previous activity of secret societies, in others none. The number of those who perished, excluding Constantinople, was 20,000 to 25,000.¹ Many were forced to embrace Islám, and numbers were reduced to poverty. The destruction of property was enormous, the hardest-working and best tax-paying element in the country was destroyed, or impoverished, and where the bread-winners were killed the women and children were left destitute. Efforts by Great Britain and the United States to alleviate the distress were opposed by the authorities, but met with some success. Since the massacres the number of students in the American schools and colleges has increased, and many Gregorian Armenians have become Roman Catholics in order to obtain the protection of France.

Ethnology.—The original inhabitants of Armenia are unknown, but, about the middle of the 9th century B.C., the mass of the people belonged to that great family of tribes which seems to have been spread over Western Asia and to have had a common non-Aryan language. Mixed

with these proto-Armenians, there was an important Semitic element of Assyrian and Hebrew origin. In the 7th century B.C., between 640 and 600, the country was conquered by an Aryan people, who imposed their language and possibly their name, upon the vanquished, and formed a military aristocracy that was constantly recruited from Persia and Parthia. Politically the two races soon amalgamated, but except in the towns, there was apparently little intermarriage, for the peasants in certain districts closely resemble the proto-Armenians, as depicted on their monuments. After the Arab and Seljúk invasions, there was a large emigration of Aryan and Semitic Armenians to Constantinople and Cilicia; and all that remained of the aristocracy was swept away by the Mongols and Tatars. This perhaps explains the diversity of type and characteristics amongst the modern Armenians. In the recesses of Mount Taurus the peasants are tall, handsome, though somewhat sharp-featured, agile, and brave. In Armenia and Asia Minor they are robust, thick-set, and coarse-featured, with straight black hair and large hooked noses. They are good cultivators of the soil, but are poor, superstitious, ignorant, and unambitious, and they live in semi-subterranean houses as their ancestors did 800 years B.C. The townsmen, especially in the large towns, have more regular features—often of the Persian type. They are skilled artisans, bankers, and merchants, and are remarkable for their industry, their quick intelligence, their aptitude for business, and for that enterprising spirit which led their ancestors, in Roman times, to trade with Scythia, China, and India. The upper classes are polished and well educated, and many have occupied high positions in the public service in Turkey, Russia, Persia, and Egypt. The Armenians are essentially an Oriental people, possessing, like the Jews, whom they resemble in their exclusiveness and widespread dispersion, a remarkable tenacity of race and faculty of adaptation to circumstances. They are frugal, sober, industrious, and intelligent, and their sturdiness of character has enabled them to preserve their nationality and religion under the sorest trials. They are strongly attached to old manners and customs, but have also a real desire for progress which is full of promise. On the other hand they are greedy of gain, quarrelsome in small matters, self-seeking, and wanting in stability; and they are gifted with a tendency to exaggeration and a love of intrigue which has had an unfortunate influence on their history. They are deeply separated by religious differences, and their mutual jealousies, their inordinate vanity, their versatility, and their cosmopolitan character must always be an obstacle to the realization of the dreams of the nationalists. The want of courage and self-reliance, the deficiency in truth and honesty sometimes noticed in connexion with them, are doubtless due to long servitude under an unsympathetic Government.

The total number of Armenians is estimated at 2,900,000 (in Turkey, 1,500,000; Russia, 1,000,000; Persia, 150,000; Europe, America, and East Indies, 250,000).

¹ According to some estimates the number killed was 50,000 or more.

Armentières, a town of France, department of Nord, arrondissement of Lille, 10 miles W.N.W. of that town, on the railway from Lille to Dunkirk. It has a communal college for boys and one for

girls, a national professional school, hospital, museum, and small library. It is an important centre of textile manufactures. Population (1896), 26,714; (1901), 29,401.

A R M I E S.

INTRODUCTORY.

THE last quarter of the 19th century saw a great development of military forces, but no organic changes. Armies have steadily grown in size, and the severe competition for predominance in numbers has led to reductions in the period of service with the colours. At the same time the principle of universal liability to service has been rigorously enforced by all the great powers of Europe. Relatively to that of France the population of Germany has been steadily increasing, and the former country, unless the period of service is still further curtailed, must soon find its army considerably inferior in numerical strength to that of the latter. Whether or not such further reduction is compatible with military efficiency appears to be doubtful. The tendency of modern war is to increase the demand for careful training of all ranks, and two years of continuous military life is barely sufficient to make the average man into a thoroughly competent infantry soldier, while the technical branches of an army cannot be adequately instructed in so short a time. Systems of national education, by developing the receptivity of the recruit and sharpening his faculties, have undoubtedly facilitated military training; but habits of discipline, the mutual reliance and mutual knowledge of officers and men, and the many qualities necessary to the making of effective military bodies, need time for their development. While, therefore, the standard of general intelligence of a population, other national characteristics being equal, may to some extent regulate the period of service necessary to ensure military efficiency, there is evidently a *minimum* in every case which cannot be passed without danger. The relatively low intelligence of the Russian population would probably render it impossible to transform the recruit into a trained soldier in two years, and in the Russian army, as in the British, the period is long, compared with that accepted in other great European forces. What the irreducible *minimum* is in any particular case cannot at present be stated. There have been signs that the short-service system does not confer the solidarity which existed in the older professional armies. The Franco-German war produced an almost unbroken series of successes for the German arms. The sense of military superiority conferred by the early victories on the frontier and maintained by subsequent experience was a moral factor of supreme importance. The system brought to perfection by the Germans cannot, however, be said to have been tested by defeat, and there were ugly symptoms of panic during the fighting around Metz, which, in less favourable circumstances, might have spread with disastrous results. Since this war, the period of service has been reduced in both Germany and France; and while in both countries careful consideration has been given to all that is implied in the term organization, and the military machine, as such, has therefore gained greatly in efficiency, the result, as effecting the solidarity of a great army in the field, remains to be shown. Where the constitution of two armies is practically the same, and where numbers and military skill are practically equal, the issue of a contest would turn upon the characteristics of the race or of the nation. On the other hand, it is possible that an army more

solidly constructed than those of modern Europe might be found to possess qualities of cohesion and of endurance which would, to a great extent, compensate for numerical deficiency. It can only be said with certainty that modern war makes increasing demands upon military training in every branch, enhances the value of individual military capacity, and imposes more and more strain upon the nerve and endurance of the soldier. At the same time, the race for numerical strength increases the difficulty of obtaining the necessary qualities without an inordinate growth of military expenditure and a consequent dislocation of the machinery of civil life entailed when masses of men are called up for periodical training. The problem of the future is to effect a satisfactory compromise between these conflicting conditions.

Military systems practically fall into two categories—the short-service, or German system, which is universal among great European powers, and which has now extended to Japan; and the militia system, which in England dates back to Saxon times, and which has reached its most complete development in Switzerland. The first system aims at sweeping the mass of the able-bodied manhood of a nation into the ranks for a short period of continuous training, followed by a long period of furlough and a further period of liability to service in a national reserve. During the period of furlough the soldier may be recalled from time to time to the colours for instruction. The militia system, on the other hand, imposes an initial training of six or eight weeks, followed by a general annual training of the whole force for a fixed period during several years, and by a further period in a national reserve. It is evident that, if the period of service with the colours in the first system is steadily reduced, there must come a point at which the second system may provide the best means of military training. This point may not have been yet reached; but some authorities, watching present tendencies, have been led to believe that the militia system may ultimately supersede that devised by Scharnhorst, with the powerful support of Stein, for the military regeneration of Prussia after the disasters of 1806.

The experience of recent years has gone far to modify the view, cherished in Great Britain, that universal service is destructive of the industrial vigour of a nation. Under a rigid system, relentlessly applied, Germany has presented the spectacle of an amazing commercial development. It has even been contended that the habits of order, of discipline, and of self-reliance inculcated by military training, wisely administered, have played a part in equipping the German people for the industrial competition upon which they have entered with the most marked success. In face of facts which cannot be disputed, it will be difficult in future to maintain that the burden of compulsory military service necessarily impedes the industrial progress of a nation and breaks up its civil organization. The management of public business in Germany and the handling of great questions of national defence stand in marked contrast to British methods. Military training, as enforced upon the best manhood of Germany, has not benumbed its intellectual vigour, and may have increased its capacity for the orderly transaction of business. Personal service is a higher test of patriotism than

pecuniary contributions, and it is not easy to determine which of the two imposes the greater drain upon national resources. The British nation must shortly decide between compulsion and greatly-increased expenditure; and while an army habitually required to serve abroad in peace time cannot be recruited by conscription in any form, there is a growing tendency to believe that the application of the ballot for recruiting a militia army may be justified. The past twenty-five years have witnessed the results of organic changes in the British army which began in 1870. It cannot be said that these changes have produced all that was claimed by their advocates or that the criticisms expended upon them were entirely without foundation. The British army has undergone a searching test in the South African war. Grave defects of many kinds have been plainly revealed, and a strong demand for radical reorganization has been the result.

The wars of the past quarter-century have not provided any specially striking military lessons, but all have presented points of interest and have emphasized the vital importance of organized preparation in time of peace. The Russo-Turkish war of 1877-78 illustrated the great defensive power of breech-loading small arms, and showed many tactical defects in the training of the Russian infantry. This war, like the war in South Africa of 1899 and 1900, was entered upon with a totally inadequate idea of the military requirements. In both cases certain disabilities on the part of the opposing forces—whether Turks or Boers—gave time which enabled the initial defeats to be redeemed. In the Servo-Bulgarian war of 1885, the militia army of Servia was opposed to a Bulgarian force organized on the German principles and supplemented by Rumelian militia. This conflict presented the remarkable feature that the whole of the superior officers of the Bulgarian army, being Russians, were suddenly withdrawn on the outbreak of hostilities. To the personal leadership of Prince Alexander, to the soldierly qualities of the Bulgarians, and to the remarkable marching power of the Rumelian militia, the victory over the Servians was directly due. A small-bore rifle in the modern sense was employed for the first time by the Servians, and the Bulgarian field artillery opposed time shrapnel to common shell with notable success. The China-Japan conflict of 1894 revealed in the most striking way the great fighting power of the newly-organized Japanese army and the marked ability with which it had been prepared for war. A new military nation may be said to have come into existence, which must play an important part in the affairs of the Far East. The brief Spanish-American war of 1898 plainly indicated the weakness of volunteer organizations and the heavy cost entailed by want of preparation. The small standing army of the United States was not organized for offensive war; but the excellent quality of the troops averted disaster at Santiago. The Spanish forces in Cuba showed little enterprise or capacity; but local conditions had tended to deteriorate their military qualities, and they did not fairly represent the army of Spain. The principal result of this war was to bring about the over-sea expansion of the United States. This has already entailed a considerable increase in their military forces. The Act of Congress of February 1901 authorizes the President to maintain a standing army of 100,000 men, and to raise local forces in the Philippine Islands. In the Greco-Turkish war, loose discipline, bad leading, and want of organization combined to cause the collapse of the Greek army. The conduct of the campaign by the Turks proved that progress had been attained under German instruction since the conflict with Russia; but certain disabilities, which appear to be inherent in Turkish armies, were again

manifested. Great Britain has been engaged in military operations of a varied character in many parts of the world, thus receiving lessons which were not in all cases turned to full account. A long series of minor campaigns, beginning at Alexandria in 1882, ended at Khartúm in 1898. Two considerable wars, in Afghanistan and on the north-west frontier, were carried on by the Government of India. The South African war severely strained British military resources and proved that the standard of preparations had not been adjusted to meet national requirements. No Power has, during the past twenty-five years, acquired experience of warlike operations comparable in extent and variety to that which the British army now has at its disposal. South America has been the scene of several conflicts, of which the Chilian civil war of 1891 was, perhaps, the most important. In this case a military force was organized *ad hoc* by a German expert and equipped with magazine rifles, which were used for the first time on a large scale.

The period, regarded as a whole, has been marked by a great expansion of military forces and by successive and costly re-armaments, both of artillery and infantry. Great attention has been generally devoted to organization and all that is implied in preparation for war. The armies of to-day are larger, better equipped, and more carefully trained than previously; and except in Italy, and possibly in Russia, there are no clear signs that the burdens of military service and of military expenditure are at present pressing with unbearable severity upon the population of Europe. (G. S. C.)

BRITISH ARMY.

The moment at which the following article was completed (November 1901) was necessarily an exceptional one in the history of the British army. The whole system of administration which was introduced after 1870 had undergone many modifications, and was about to undergo many more.

Recruiting and conditions of service.

In its general features, nevertheless, the recruiting system remained that which was introduced by Mr Cardwell in the years following 1870. It was adopted in the belief that a much larger number of recruits could be obtained if they had the option of leaving after a comparatively short period with the colours. It was assumed that after three years' service, at all events in the infantry, a man had learnt all that he was likely to learn, and that it was more economical for the country after that time to pay him for some years a small retaining fee, and call him up only for war. The necessity of sending troops to India and to distant British colonies did not admit of a strict application of this principle to the whole army. Whilst, therefore, the Guards, who do not serve during peace time in distant parts of the empire, and the Army Service Corps, which requires large expansion for war and is not required in India which has its own transport and supply department, have now for a long period been enlisted for three years with the colours and nine years in the Reserve,—the Line, the Artillery, and the Cavalry are mostly enlisted for seven years with the colours and five more in the Reserve. From time to time, however, enlistment for the line for three years has been allowed concurrently with the longer period.

The pay of the soldier has been slightly improved. First he was given in 1876 an allowance known as "deferred pay." A daily addition to his pay of 2d. a day was credited to him in his accounts; but he was not entitled to receive it till he took his discharge. There was a considerable conflict of evidence as to whether the money was valuable to the soldier in enabling him to start in civil life, or whether it was merely wasted. The

vast preponderance of the evidence of non-commissioned officers and men was in its favour. There was, however, a strong demand that the soldier should be given not only a free ration of meat and bread, as he had had for many years, but that all his food should be provided for him. The promise of a free ration was said to create the false impression that the men would have nothing to pay for their food, whereas a stoppage was made from their pay to provide groceries. In 1899, therefore, an allowance of 3d. was granted to provide what was absolutely necessary for the whole messing. At the same time the deferred pay ceased for those who accepted the messing allowance. Men serving when the change was made were allowed to choose whether they would prefer the free messing or the deferred pay. Some chose one, some the other. The actual conditions of service in these circumstances are as shown in Table C.

Another change has gradually been introduced. The canteens, which were formerly let out to tenants, and became, in fact, regulated public-houses and grocery shops within the barracks, have been placed under the management of a committee of officers, and are worked for the benefit of the men. Where they are well looked after very large profits accumulate. These are employed partly in adding to the comfort of the men's messes, partly in providing for emergencies, such as when the men are sent out on an early movement and require breakfast before they start, or on the sudden arrival from abroad or from out-stations of parties of men or of their families. In various other ways the money is used to provide for contingencies that can hardly be dealt with at the public expense, such as the provision of cricket and football implements.

Private benevolence has added greatly to the comfort of the soldier. Soldiers' "Homes" and "Institutes," set up by private subscription, give an opportunity for well-conducted entertainments and for quiet reading and writing such as would not be possible in the barrack-room. Some of the best of these are, in fact, excellent clubs, with good hot and cold water baths, billiard-rooms, and halls for concert and other performances.

The effect of the short-service system has been necessarily to throw annually upon civil life a very much larger number of men seeking employment than was the case formerly. It was some time before adequate agencies for assisting the men in this respect were brought into existence, but on the whole the machinery is now very complete. Partly through the colonels of brigade districts, partly through the officers of the recruiting department, partly through the organizations which have been established in most well-managed regiments, the men have much help from the army itself in obtaining situations. The "National Society for the Employment of Soldiers" and the "Soldiers' Help Society" have agencies which spread into every district of the country. Moreover, the earlier age at which soldiers now leave the army has this effect, that most of them have parents or other near relatives still alive, many of whom are in regular employment, or are able to assist the men in obtaining situations. The "Soldiers' and Sailors' Families Association," with an agency in every garrison, is most useful to the married soldier during peace time. During the strain of the South African war it was invaluable.

Altogether the "conditions of service" of the well-conducted soldier, though they still leave much to be desired, are beyond all comparison better than those of any army except that of the United States, in which the rates of pay are incomparably higher, although in other respects the physical comfort of the men is not so carefully provided for. In civil life a man has to pay for his own hair being cut and for repairs to his clothing, but he does this

at his own good pleasure. The orderly appearance of the soldier is a necessity of discipline, and undoubtedly the fact that these minor payments are not matters entirely of his own option gives colour to an idea that when he has to pay for them he has not had the whole of the cash he expected. It is not a question of a broken promise to him, but the system will probably be modified in its working.

The test of an army is not peace, but war. Gauged by that standard it is not too much to say that, relatively to the facility with which the British empire is able to provide men for war on a large scale, ^{Supply of officers.} the supply of officers has failed. The ordinary sources of the supply of officers to the army during peace time are, as they have been for many years, Sandhurst College for those of the Cavalry, Guards, and Infantry of the line; Woolwich for the Artillery and Engineers; and, as a further source of supply for all, the Militia. In addition, a certain number of commissions are given in all branches of the service to cadets of the Royal Military College at Kingston, Ontario, and to other colonies, while a few are given to men from the ranks. Commissions have during the war in South Africa been given freely through universities, public schools, and other institutions. During peace time, as will be seen when we speak of "the organization of the higher units for war," the staffs necessary for these and for the "lines of communication" in the field have not been maintained. The loss of officers in war is enormous. The consequence has been that everywhere, whether in the field or at home, the supply of officers has been wholly inadequate, and the battalions and regiments have been left deplorably short. At home, when it was necessary to create new units, the men could be obtained, but officers, especially experienced captains and subalterns, were wanting. A nominal "reserve of officers" existed in the sense that officers who had retired on their pensions were liable to be recalled to service; but changes in army training have proceeded with immense rapidity of late years, and when officers, who had left the army for some years, returned to it they found the conditions to which they had been accustomed greatly modified. Captains and majors who returned in those ranks were the contemporaries in age of men who occupied the higher ranks in the army.

The disproportion between the officers with the British army in this and in former times may be best shown thus:—In 1815, at Waterloo, Seton's famous battalion, about 1000 strong, had forty-two subalterns on parade; in the battle its front was never more than about 500 paces. In 1901 a garrison of 5800 men at Woolwich had for some months seventeen captains and subalterns, all told, of whom ten were second lieutenants too young to serve on a court-martial. At Driefontein (10th March 1900) the Buffs, including regimental staff, had one officer per company. Companies often covered more than 1000 yards.

A very large number (2700) of second lieutenants were commissioned during the Boer war. Many of these from the universities, from the Colonies, from various technical colleges, were men of an excellent stamp, but they have for the most part (except those from Kingston) had no previous military training. Some of them were twenty-six years of age. So far as their future prospects are concerned this is a serious matter, because, in order to keep the various ranks of officers young enough to be fit for their work, the rule now is that a

Captain (unless he is a brevet-major) must retire at 45 years of age.

Major-general	.	.	62
Lieutenant-general or General	.	.	67

As a rule this is a scale which corrects itself to some extent, since, if promotion has for a time been very slow, many men in the senior ranks have to retire, and more rapid promotion is given to the juniors. The effect of a war on so large a scale as that in South Africa is to upset this condition. Large numbers of officers in the senior ranks are relatively young. The accession of the immense number of subalterns of the same age as those much senior to them will force these junior officers out of the service in large numbers. The circumstances for some years, therefore, will be very exceptional.

As regards the general question of the supply of officers, it must be realized that one of the exceptional advantages of Great Britain as a military power is that it possesses a larger class of the type from which effective officers can be drawn than any other country. What restricts the supply for war is solely that, as a question of economy, the policy of Great Britain has always been during peace time to reduce to a minimum the number of officers actually employed. Many posts are occupied by officers who are borne on the strength of their regiments and counted as if they were effective. The result of not maintaining during peace time the staff appointments required for war, and of filling a considerable proportion of those that are maintained with officers who are thus counted twice, is obviously to leave a very small proportion of the men who might be utilized available for war. Very large numbers of officers are "specially employed" in all parts of the empire. These cannot be recalled for a war in a particular part of it. They are borne on the lists of certain regiments as subalterns or captains, and after a time they are "seconded," that is to say that, their names being placed in italics, their places are filled up by the promotion of other officers. They retain their position in the regimental list, and may or may not at some time or other be brought back into the regiment. The demands of the staff in such a campaign as that in South Africa are so enormous that the same process has necessarily been applied to fill it. The effect is that there are many regiments of which the nominal establishment is, say, twelve captains, which actually bear on their lists twenty-four, of whom twelve are thus "seconded." The whole subject is undoubtedly one that requires immediate attention.

Since 1870 enormous reductions have been made in the numbers of the higher ranks of the army. Thus, excluding the Indian army, which had its own list in 1870, and the Indian Staff Corps, which as to officers was the corresponding body in 1901—

The Generals have been reduced from	71	to	10.
The Lieutenant-generals	115	to	25.
Major-generals	188	to	74.

At the same time the pay of all the higher appointments in the army has been greatly reduced. In the first place, the colonel-commandantships (worth per annum £1800 for a general from the Household cavalry, £2000 for a general from the Foot Guards, £1000 for infantry, £994 for the Artillery, and £990 for the Engineers) have all been abolished. These formerly were held in addition to the pay of the higher appointments. The actual pay of the higher appointments—commander-in-chief, adjutant-general, quartermaster-general, governors of Woolwich and Sandhurst, &c.—have all been reduced by many hundreds a year each. It will be seen, therefore, that from the increase of the army contemporary with these reductions in the higher ranks, the transference of expenditure from the higher to the lower ranks has been large, and that, actuarially, from the great increase in the number of junior officers, the prospects held out to an

officer of reaching the higher ranks have been greatly reduced. A royal warrant, which came into operation on 1st January 1901, still further reduced the higher ranks. From that date no promotion from major-general to lieutenant-general was to take place except as a reward for distinguished service in the field or to fill an actual appointment. As the number of appointments held by lieutenant-generals had been much reduced, this further reduced the number of lieutenant-generals to fourteen.

It follows inevitably from the fact that officers, other than regimental officers, have not hitherto during peace time been employed in the positions which they will occupy in war, that they have not nearly all been trained in the specific duties of those positions. The staff is trained at the "Staff College" as far as that is possible without the discharge of the actual *Training of officers.* functions that have to be learnt. The number of officers that gain this functional training is very small. There is a great standing camp at Aldershot which normally in peace time has had the staff for one cavalry brigade, for three infantry brigades, and for one "brigade division" of horse with two of field artillery, besides the standing staff of the district. These numbers have been usually increased during the drill season, partly by bringing in from other stations regular troops, and partly by the addition of large bodies of militia and volunteers. All branches of the service go through a regular course of regimental training each year. This is specially designed to give each company-commander of an infantry battalion, each squadron-commander of a cavalry regiment, the opportunity of working up his unit before the whole are brought together for work under the lieutenant-colonel commanding the battalion or regiment. The several battalions, regiments, batteries, companies, and squadrons are inspected by their commanding officers and by the generals under whom they are serving. There is also a special technical inspection for the Cavalry and Army Service Corps by the inspector-general of Cavalry, and for the Artillery by the generals of Artillery at Aldershot, Woolwich, and Portsmouth. Musketry instruction has of late years been given under the general superintendence of musketry instructors and the supreme regulation of the head of the school at Hythe, but in detail by the captains of companies. This has been a great improvement in the training of the officers themselves. The competition between battalion and battalion and between company and company has been keen.

Between each rank, from subaltern to captain, from captain to major, up to the rank of lieutenant-colonel, an officer is required to pass an examination before a board of officers, who have to certify that he is fit for promotion. The examinations involve answers on paper and also the handling of troops on ground. As a rule, all the paper questions are only such as an officer might actually have to deal with when in command of troops. Thus the system of "training," apart from special arms, has consisted rather in ascertaining that officers have trained themselves than in any very systematized method for giving them that training. The "Staff College," the "Ordnance College," each train special classes of officers. Officers on the staff are detailed for "garrison instruction," but in the main the training has depended on battalion commanders, the effect being afterwards tested.

The training of men is mainly involved in and connected with that of the training of officers; but it is necessary to add that, in the recruit stage of late years, the most important change has been the large development of gymnastic instruction on a methodical system, devised for the development of the several parts of the body. The tendency has been

Training of men.

more and more to substitute this for what used to be known as "setting up" drill, which was too formal for modern requirements, and did not combine the suppleness with the smartness needed for military purposes nearly so well as the modern gymnastic course. Moreover, since one of the great objects of modern training, both for officers and men, is to carry organization in working down into the smallest fractions of an army, the training of comparatively small gymnastic squads in orderly movement by their own company officers affords important facilities for this purpose.

Shortly before the beginning of the Boer war, in the course of 1897, the cavalry underwent a new organization.

**Organiza-
tion and
special
training
of cavalry.**

Two cavalry regiments had been despatched to South Africa. There were then left in the United Kingdom eight regiments on a higher establishment and eight on a lower, which were each by this organization made up into three service squadrons and one reserve squadron. The higher establishment regiments had 670 men and 465 horses each, the lower 555 men and 343 horses. The 1st cavalry division was composed of five regiments on the higher establishment and a composite regiment of household cavalry. The 6th regiment of line cavalry was detailed as corps cavalry for the 1st army corps. Each squadron was 140 strong including officers. The object of this reorganization was to enable the regiments to start on a campaign without drawing on other regiments for non-commissioned officers and men. When the regiments went abroad the "reserve squadrons" left behind became in fact each regimental depots. There are always about 200 "non-grooming" men in a cavalry regiment required for various purposes, so that this proportion of horses to men was deliberately arranged. During the war a great strain was thrown on the "reserve squadrons." As recruits and remounts were poured into them they virtually came to be, in point of men and horses to be trained, equal in numbers to a cavalry regiment. The supply of officers and non-commissioned officers and the "office" were wholly inadequate for dealing with such numbers. There can be little doubt that considerable modification will necessarily be made in this provision for any future emergency.

The Boer war, in which the power of the new weapons made itself so conspicuous, has naturally led to much discussion as to the future rôle of cavalry. There is a disposition to assume that cavalry should abandon its old position of looking upon manœuvring facility and the *arme blanche* as its ruling *metier*, and should become, like the American cavalry of the civil war, a manœuvring mounted infantry. It is, however, premature to draw conclusions from the incidents of a very exceptional struggle, and until the question can be more fully discussed it should not be prejudged. On one point all the experience of the past may doubtless be trusted. It is necessary to decide definitely whether cavalry is to rely on a knowledge of ground, on horsemanship, skill in manœuvring, and the *arme blanche*, or whether it is to trust to dismounted fire. To train men both to charge home and to believe in victory in so doing, and at the same time to think that their only safety lies in dismounted fire, is a contradiction in terms. It would be wholly contrary to human nature if such training proved successful. That cavalry, if in the proper use of their arm they are to act effectively, must be supported and aided by mounted infantry, is not a new experience, though it has been much emphasized by the South African war. The immense numbers of mounted men ultimately employed were a necessary consequence of the peculiar nature of the contest, and not necessarily a certain element of future war under normal conditions.

The changes of late years both in the organization and training of artillery have been very numerous. In the first place the old "royal regiment" has been divided into two distinct branches, so that the *Artillery.* promotion of officers is no longer carried out in one long list. The officers for the field and horse artillery stand now on one seniority list for promotion, the garrison and mountain batteries on another. Within each branch important changes of organization have been also made. In the field branch of the regiment, both for "field" and "horse" artillery, the battery is no longer the one "unit" for all purposes. A lieutenant-colonel's command, which for the present bears the anomalous name of a "brigade division," has been created. It consists of a group in the horse artillery of two, in the field artillery of three batteries. As yet, the organization is not carried to its logical conclusion. The lieutenant-colonels belong to particular stations, the batteries move from station to station. Thus the elements composing the "brigade divisions" are continually changing. Moreover, the "staff" of the brigade division is only formed by taking officers from the batteries temporarily attached to the command. It is much to be hoped that this may soon be modified, and a beginning has been made by the appointment of warrant officers as sergeants-major of the brigade division. For the training of the horse and field artillery a large area of ground on the wild open country of Dartmoor, near Okehampton, has for some years been utilized. A similar school has been started at Glen Imaal in Ireland. There it is possible, to a large extent, to combine the actual firing with service ammunition, the bursting of shells and the practice at dummies representing artillery, cavalry, and infantry, with training in rapid changes of formation and field movements. For these purposes the brigade divisions move together and are trained together. An elaborate system of "fire discipline" has been worked out in order to bring the whole fire of a battery completely under the control of the officer commanding the battery, so that the officer commanding the brigade division may be able to use his unit for such purposes as may be required by the general's combinations. During the winter and early months of the year the batteries are trained in elementary work at their own stations. During the summer the brigade divisions give practical effect to the training either by preference at Okehampton, or if there be not time for all to go there, then some have hitherto been sent to Shoeburyness. A new training ground has been opened on the area recently purchased at Salisbury. There also actual firing with service ammunition is combined with field movements. This promises to become the most valuable field artillery school the army possesses. Similarly, with the garrison artillery, a much more perfect system has been devised for the regulation and practice of the fire of a fortress. The whole *personnel* of the artillery within coast fortresses is now organized so that the fire can be brought to bear upon the positions likely to be taken up by a hostile fleet. The invention and adoption of instruments known as "position finders" and "depression range finders" enables the fire to be directed with great precision upon given spots likely to be passed by ships. To a large extent the actual organization of the defence depends on the special nature of the fortress. The organization of the defence of a fortress like Gibraltar or Malta must obviously differ from that of a tortuous channel such as gives approach to the harbour of Harwich. In general terms the manning of the sea-board guns of the British islands depends upon militia and volunteer artillery, with only a small stiffening of regular garrison artillery and a proportion of officers of the royal garrison artillery. The

militia and volunteer artillery are periodically trained in the different works to which they are assigned. A practice school for the garrison artillery has been established at Lydd, but the various coast fortresses themselves carry out regular practice with service ammunition.

It is one of the peculiar characteristics of the service of the British army that, from the extent and dispersion of the empire over the world, it is almost

Infantry. always at war on a greater or less scale. If the temple of Janus were, as an indication of peace, closed for one year, it would have the next to be opened at four doors for four different wars. Thus in 1900, independently of Indian frontier expeditions, of which there were more than one in the year, Great Britain had war in the Egyptian Sudan, war on the West Coast of Africa, two expeditions in East Africa, and war in China, whilst the war in South Africa was going on. The practical training of the British infantry more than that of any other army is necessarily affected by this fact. Not only are the experiences through which officers and men pass in these wars very important in their effect on the preparation which they give for future war, but they have a great influence on the permanent training of the army, and especially of the infantry, during peace time. Now even in this one year, 1900, no two of the wars were alike in their circumstances; and, unless the comparison be made between some two Indian frontier expeditions, hardly in the thirty wars of the thirty years 1870-1901 would it be possible to find two of which the tactical conditions were identical. In these circumstances the actual views which dominate British schools of training are apt to be modified considerably by the most recent experience. This modification finds expression to some extent in the successive drill books which are issued. It is in reality much more important in its influence through the decisions given by umpires and the comments on field days. The influence of the experience of the great war between France and Germany in 1870 showed itself in the training of the British army for some years in a much more open order of fighting, in the continual study of ground with a view to cover, and in carefully-arranged turning movements. The influence of wars in which Zulus and Mahdists showed the power of determined attacks pushed home regardless of loss, had its effect on our training in a tendency to encourage frontal attacks provided that a certain numerical superiority was attained at a given point. The actual training imparted at any given period in the camps at Aldershot or Salisbury has oscillated much between these extremes. The training of the other arms being largely dependent on the principles adopted for infantry in defence and attack, it is safe to say that there is this necessary contrast between the adequate training of the British army and that of any other European Power, that with the British army the officers at least, and to some extent the men, require to be prepared for many varied circumstances and conditions, whereas in the training of other European armies the conditions under which they will enter upon war are fixed and well known beforehand. The extent to which a British army is prepared by training for a given war must depend on the extent to which all the conditions of that war have been studied beforehand. In one respect, however, so far as the infantry is concerned, all wars are alike. In every war the most important power of infantry depends on the efficiency of its training in the use of the rifle. In this respect several changes of importance have been made of late years in the British army. First, the actual detail training of the men has been put into the hands of the company officers, and they have been made responsible for it. Secondly, at Bisley and other places

a system of "field-firing" has been introduced. This consists in a most valuable combination between manœuvring to take up the right position from which to bring fire to bear, and the actual shooting at dummies placed to represent different bodies of troops arranged so that they can be made to appear unexpectedly in a position previously unknown. Further, the combination between drill manœuvres and shooting has been improved by requiring the actual orders for all firing to be given during the course of drill manœuvres in such a way as to determine the object to be fired at, the range, and the nature of the fire. Nevertheless, recent experience makes it almost certain that, under the present conditions of war, almost all firing will become individual and independent. The purchase of a large area of ground near Salisbury has given scope for manœuvres on a much larger scale than was possible formerly. As, independently of this, an Act has been passed to give facilities for the carrying out of manœuvres on varied ground to be chosen from time to time, it is to be hoped that when events at home resume their normal course, annual manœuvres may be carried out in different parts of the country. The system of training at present consists during the winter in regularly graduated route-marches, accustoming the troops to carry their equipment and arms for long distances. At the same time indoor and barrack-yard instruction is given in elementary duties, in the principles of scouting and protection on the march, and in such other matters as may tend to interest the men in their work, such as the nature of their weapons, accounts of what the battalion has done in the field, and of other incidents of war. In the spring each company in succession is relieved of all other duties in order that it may go through a course of systematic instruction under its company officers. After the different companies have been inspected by the lieutenant-colonel and employed against one another in minor field days, the battalion is worked together as a whole. At Aldershot, the Curragh, and at special camps, the brigades of infantry are then worked together, after which the training ceases to be arm training and becomes that of the combined arms. In principle, and according to the instructions issued from headquarters, all training is conducted on the principle of giving great latitude to the company commanders, accustoming them to decide for themselves, and to train the subordinates under them to exercise similar responsibility. In practice it is to be feared that old habit and military conservatism have tended to keep all responsibility and power too closely in the hands of the lieutenant-colonel. Probably one of the most important effects of the South African war will be to bring before the eyes of the army the indispensable necessity of training all officers to exercise an increased responsibility. In any case training for war depends much more upon the spirit which in these respects animates an army than upon any formal regulations.

The special training of the Engineers is mainly given at Chatham, and embraces a very great variety of subjects, practically all the technical work of the *Engineers*. As an "arm of the service" it is a common delusion to speak of the engineers as essentially "defensive." The experience of the South African war has perhaps tended to modify this popular error. Strategically the offensive action of the army there, as always in modern wars, has depended on the rapid construction of railways, the restoration of destroyed bridges, and generally on those means of rapidly improved facilities for advance for which an army depends on the engineers. For that reason, even in Napoleon's time, engineers have always been present with the advanced parties of every column when moving forward with an army. Without the pontoon train, bridging

detachments, and the parties for removing obstacles, an army would be incessantly delayed, independently of the necessity for much larger operations on great rivers and on the general lines of railway. The changes that have taken place and are continually taking place in the detail of engineer organization and equipment simply consist in the adaptation to military purposes of the progressive advance of science. Otherwise there is little to note in any changes of organization in the corps. The development of hasty entrenchment in connexion with the movement of armies in action has become and promises to become still more one of the most marked features of the present phase of war. It is at least as important on the offensive as on the defensive side.

The Boer war has concentrated attention on the extreme importance of the rapid transfer of shooting power from point to point of a field of battle or of a campaign. The exceptional circumstances of the campaign have perhaps tended to leave an undue impression, both of the degree in which this is a novelty and of the extent to which it promises to dominate future warfare. Napoleon gained most of his exceptionally brilliant battles during the 1814 campaign, when with a handful of men he was keeping back the overwhelming masses of Allied Europe by this very means. He moved from side to side of the theatre of war the whole of his brigade of guards on country carts. It must be understood that the horses or cobs that are employed with the detachments of infantry, who have been trained at Aldershot and elsewhere, are only intended to supply the place of Napoleon's country carts. It may for various reasons be doubted whether under most conditions of warfare the cart is not the vehicle to be preferred. It is a question of circumstance. The Boers were a nation of trained riders and trained shots. In its Colonial troops and in some of the home yeomanry the British Empire possesses similar material. It is obviously desirable to utilize this material. The question is altogether apart from that change of the equipment, rôle, and training of the cavalry arm, which has been discussed under cavalry. At present there is no organized body of mounted infantry as such as a peace branch of the British army. For the purposes of the Boer war regularly formed brigades of mounted infantry have been created out of the various contingents of mounted infantry furnished by home battalions and the Colonial corps.

There can be no doubt that, especially in a country like England of numerous and excellent roads giving immediate access to favourable ground in which to delay and puzzle an invading enemy, the bicycle has established itself as a most valuable agent in war. It is certain that the tendency of time will be greatly to enhance its importance not merely for the purposes for which it has been frequently used, those of saving horses by its use for orderlies and for scouting, but for delivering more considerable bodies within the fighting area. There are such large numbers of men available who can both shoot and ride, or who can do one and would easily learn to do the other, that it is impossible that this valuable material should be long left to go to waste. Only practice and organization are needed to develop a most useful auxiliary in the defence of the country, and the volunteer companies that have been started promise to be the forerunners of a new arm for the British army.

The transport and supply departments have been formed into the Army Service Corps, organized by companies with senior officers locally appointed, very much as is done in the case of the royal artillery. The Army Service Corps is administered through these senior officers directly from the War Office, under the orders of the several general-

*Mounted
infantry.*

*Army
Service
Corps.*

officers commanding districts. The officers appointed to the Army Service Corps after a probation from regiments of the line, during peace time undertake the purchase of forage, and have under their immediate supervision such transport as is kept up during peace time. They have the privilege of being appointed to the staff for what are known as B duties, that is, virtually for the work of the quartermaster-general's department—food-supply and transport for man and beast. Contracts for these are made by them under the authority of general-officers. They superintend the bakery establishments and the abattoirs.

Hitherto in the matter of transport one large branch has been distributed to battalions under the title of "regimental transport." It was taken charge of and cared for by the battalions. It would seem probable, from the reports on the subject made by Lord Roberts, that this arrangement will be modified. Originally it was designed to enable regiments to have transport always available for their immediate needs on the march, and to bring up their supplies from the local depot. This was objected to in Africa, because it deprived the army at large of the services of that part of the transport which belonged to battalions not at the time on the move.

The Army Ordnance department was reconstituted on 31st March 1900. The Army Ordnance Corps is immediately under the director-general of ordnance, and consists, as to officers, of a principal ordnance officer ranking as major-general, of eight 1st-class ordnance officers ranking as colonels, of fifteen 2nd-class ordnance officers ranking as lieutenant-colonels, of twenty-five 3rd-class ranking as majors, of fifty-three 4th-class, of commissaries of ordnance, deputy commissaries of ordnance, assistant-commissaries of ordnance. It is charged with providing, receiving, holding, and issuing munitions of war, military stores, clothing for use in camps, and both clothing and necessaries for use in the field. The corps consists of eleven companies with a depot company. It is, so far as the personnel of these companies with their non-commissioned officers and men is concerned, administered from Woolwich by the ordnance officer, 2nd class, who is in command of the depot there. He acts for this purpose as staff-officer to the director-general of ordnance. It is, however, difficult to say whether the functions of this department are more important at home or in the field. Some estimate of the nature of its functions may be formed by the following list of articles sent out to South Africa *before the fall of Pretoria*. We have not the figures of a later date, but obviously the special strain was prior to that event. Afterwards it became simply a question of keeping up such further supplies as were asked for. We record the figures chiefly because we believe them for a despatch to a campaign 7000 miles off to be unique in the world's history.

Ammunition.

Over	105,000	rounds for the	12-pr. horse artillery gun
"	330,000	" "	15-pr. field gun
"	30,000	" "	5-in. howitzer
"	20,000	" "	5-in. gun
Nearly	21,000	" "	4.7 gun
"	380,000	" "	pom-pom (37 millimetres)

Clothing.

Drab suits	much over 200,000
Khaki suits	about 80,000
Boots (pairs)	over 370,000
Woollen drawers	" 400,000
Jerseys	" 200,000
Worsted socks	" 850,000
Cotton socks	" 170,000
Flannel belts	" 400,000
Flannel shirts	" 500,000

	<i>General Stores.</i>	
Circular tents		18,000 or thereabouts
Blankets		over 420,000
Waterproof sheets		300,000
Camp kettles		37,000
Horse rugs		about 100,000
Sets of ten or six spare mule harness, nearly		6,000

The medical department is administered from the War Office by a director-general and his staff. It is now formed into the Royal Army Medical Corps, to which officers are gazetted with commissions. The Army Medical Staff consists of ten surgeons-general. The Royal Army Medical Corps consists of colonels, lieutenant-colonels, majors, captains, and lieutenants. There are about 900 officers in all, besides 50 quartermasters. There are 36 warrant officers, 336 staff-sergeants and sergeants, and before the war rather more than 2000 rank and file. These were supplemented during the war by civil surgeons specially engaged for the war, both in South Africa and at home, and by the employment of volunteer medical orderlies. The chief general hospitals are at Netley, Woolwich, and Aldershot. There are also station hospitals, lunatic hospitals, and hospitals for women and children.

For service in the field, bearer companies, field hospitals, station hospitals, base hospitals, and general hospitals at various points on the lines of communication have been set up. Convalescent homes, both for officers and men, were found necessary in the South African campaign, and would probably be always used in any protracted operations. In the army corps organization one bearer company and one field hospital is attached to each brigade of cavalry or infantry, one field hospital to each of the divisions as such, and one field hospital to the corps troops. With the army corps there are six bearer companies, ten field hospitals. During a campaign a medical officer is attached to each unit and has especial charge of the regimental stretcher-bearers.

Each "general hospital" has a staff of women nurses, consisting of one superintendent, eight nursing sisters, two female servants.

An attempt has been made of late years to connect the militia and volunteers more closely with the regular forces by constituting every corps, whether of militia or volunteers, as a "battalion" in name at least of a particular regiment of which other regular battalions formed part. As the several battalions of regulars and militia or volunteers are never or only accidentally associated, the arrangement is little more than a paper one. Independently of this the volunteers have been nominally formed into brigades under "brigadiers." These officers have little or nothing to connect them with their brigades except on those few occasions when the brigade is, as a whole, brought out to a camp of exercise. Normally during peace time all the work of inspecting and carrying on the correspondence of volunteer battalions and batteries is done by the colonel of the "regimental district," who has under him the depot of the regular battalions and all the militia and volunteers of the territorial region to which the regiment is assigned. He in fact constitutes the link between the several auxiliary forces and the regular battalions. The adjutants of the volunteers, and the adjutants and quartermasters of the militia, and the non-commissioned officers forming the "permanent staff" of the militia, and the instructors of the volunteers, are detailed from the regular battalions of the regiment, but at that point the connexion has hitherto stopped. The numbers of militia on the 1st January 1901 were 92,741, and of volunteers, 277,900. During the year 1900, in consequence of the Boer war, the whole of the militia were embodied, that is to say, called up for home service and regularly brought

on pay. Thirty-five battalions, having volunteered for service abroad, were sent to South Africa, St Helena, or the Mediterranean. This has been the customary practice of war in relation to the militia, and constitutes them an exceedingly valuable force for setting free the active army in the field. Unfortunately during peace time their opportunities for rifle practice had been so limited that comparatively few if any of these men had been through any musketry training before they sailed for their foreign station.

In the case of the volunteers the patriotic zeal of the year 1899-1900 led to a new departure, and created a new link between them and the regular battalions of the "regiments" to which they both belonged. Seven thousand volunteers joined by companies the regular battalions, and were enlisted as regular soldiers for the year, while 2163 volunteers enlisted in the army reserve.

Seeing that the "British army" is the army as it is in war, it appears advisable to show in the following Table A, taken from the report of the inspector-general of recruiting, the different sources from which the number of regularly enlisted forces for home and colonial service had been increased from 290,914, at which it stood on 1st January 1900 after the general mobilization, to 406,443 by the 1st January 1901. This shows only non-commissioned officers and men, and allows for loss by death (10,153) and other causes, in all, including deaths, 37,269. It is put after the auxiliary forces because it will be seen how largely they contributed to swell the total. The regular forces on the Indian establishment of all arms and ranks are given in the army estimates at 63,023. These, the total establishment of officers, the militia (100,008), various colonial militia, the remainder of the army reserve after mobilization, the native Indian regiments (22,313), the yeomanry (8657), the volunteers (277,900), and the numbers on the general staff have to be added to those in Table A. Together they make up a total, exclusive of the local forces of the self-governing colonies, of about 840,000.

The term "mobilization" is one which is in fact due to the short-service system. It implies the calling up of the "reserve" created by relegating to civil life the trained soldiers who are held to serve when called upon. It implies the complete equipment and clothing of all that part of the army which is "mobilized" with equipment and clothing not necessary for peace service, but kept ready for war. It implies a

*Mobiliza-
tion.*

¹ Effective (1900) less than one year, 1664.

vast increase in the number of horses required by the army brought in from civil proprietors who have their names registered for the purpose. It implies the creation of a new "reserve" to keep up the numbers of the units in the field. This new reserve is formed in the following way:—When the "reserve" soldiers are called up to the colours those young soldiers who are not sufficiently trained to take their places in the ranks, or are not yet of a suitable age to be sent out, are relegated to depots left at home, their place being taken by the men from the reserve. There are also a large number of the "reserve" who are not required to fill up the vacancies in the battalion going out. These become what are known as "excess numbers." Naturally, the men left behind are at various stages of training. Some of them will in a month or so have completed their musketry training, and will then be quite fit to take their places in the ranks. Others have been laid up by some temporary accident or passing malady. It results from this that every month there are always coming on fresh men ready to take their places in the army at the front. The "excess numbers" of the reserve help largely to supply any deficiency. In this way, as a matter of fact, the numbers in units at the seat of war, as they have suffered from the attrition that wears them down in the field, have been kept during the South African campaign more regularly supplied with drafts than has been the case in any other in which the British army has ever been engaged, and much more perfectly than is recorded as the ordinary condition of most armies during a campaign. It is therefore a point not worth discussing whether the term "reserve" is or is not properly applied to the particular men who are called the reserve (because, as it is said, a "reserve" ought not to consist of men who are, many of them, at once put into the ranks in the field). That mistake, if it be a mistake, has been made by every nation in Europe; but in any case, the reserve behind the front, the reserve which fills up the losses of a campaign, has been provided more perfectly by this system than by any other that Great Britain has ever had. Moreover, for the purposes of keeping up a uniform strength at the front, it is one that continually and automatically renews itself, because, by the time that the "excess numbers" and the earlier lists of young soldiers who have been gradually sent out to the war in drafts have been exhausted, *this* reserve is supplied from fresh sources. Men wounded in the early stages of the campaign, or indisposed without being very seriously ill, begin to arrive at the depots after convalescence. The recruits enlisted since the war are, many of them, beginning to come to maturity. The interest and excitement of the war has drawn back into the ranks older trained soldiers who have offered themselves. In short, from various causes the drafts can be filled up month by month. This, of which we have given such an ideal sketch as presented itself to the minds of the framers of the scheme, is precisely what happened during the South African war. That was the value and importance of those 90,000 odd soldiers of whom we have heard as existing in England after the main army had been sent to South Africa, who, though they were not an army fit to take the field because they were only "details," were yet an invaluable element in keeping up the fighting strength of the army.

It is necessary further to observe that, whereas for Germany or France the time which mobilization ought to take depends on a competition in readiness with a neighbour across a frontier, for Great Britain that time depends on quite a different consideration. If the men are completely ready to embark as soon as the ships can be made ready for them, that represents the time and the only time at which there is any object in aiming for any other purpose than that of home defence.

The organization of an army for war is designed to make it a body as flexible and mobile as possible in the hands of its commander. The ideal army that Wellington had formed by the end of the Peninsular war was one that could, as he expressed it, "go anywhere and do anything." The organization of the British army during peace time has hitherto been essentially an organization by stations—a stationary organization. The units composing the several garrisons of the stations are in a continual state of flux and reflux. There has hitherto been no higher organization anywhere maintained as a whole complete in all its parts for more than a short time. In part this is an inevitable consequence of the different conditions of service between the army of a world-wide empire and that of countries like France and Germany, which have all their peace duties within a ring-fence of the borders of their fatherland. The corps which in Germany occupies a particular district is designed to move as a whole when it is required for war. The troops, which in England are stationed in a certain locality, have two entirely distinct functions. The several units are on a roster for foreign service, and will each in their due turn go to India or the Colonies, being replaced by other units from abroad. In the event of war they have hitherto been formed with other units into brigades, divisions, and army corps, but they have not been in these organizations prior to the preparation of the expeditionary army. The generals to command and the staffs to direct them have been appointed for the special purpose. To this there are two slight exceptions to be made. At Aldershot, in addition to the stationary headquarters staff of the general in command, there have been stationary brigadier-generals with their staffs. The units composing the brigades have been in the same condition of flux and reflux as the other parts of the British army. Aldershot was, up to the time of the acquisition of the ground at Salisbury, the one great training-place of the British army in England, just as the Curragh is in Ireland. It is still the principal training school of the army. Therefore, in order that all parts of the army may share in this training, battalions and batteries have been only kept there for a short tour and then either gone out to stations abroad or taken their turn at other stations at home.

Thus the permanent peace organization of the higher parts of the British army has remained as described in the ninth edition of this Encyclopædia, one of district commands. The organization for war has been a paper organization, different in practice for each campaign, according to its nature, but having as a basis the tabular statement of units given in Table B, which is at present the paper organization of an army corps.

The other exception to the rule of perpetual flux and reflux has been the brigade of Guards. The three regiments of the Grenadier, the Coldstream, and the Fusilier Guards, to which was added in 1900 the regiment of Irish Guards, are not liable to ordinary or colonial service. Therefore, their organization at home remains constant, and they are available as a whole for active service in the same organization in which they are trained in peace. The close connexion by short steam journey with Gibraltar caused that fortress to be treated for a short time as a home station, and garrisoned by the Guards in order to reduce the number of line battalions abroad in proportion to those at home. That arrangement was soon given up, and it may therefore be treated as a temporary episode, but it did not very materially affect the broad distinction between the permanency of the Guards' organization and the perpetual change of all other units. The new scheme laid before the House of Commons by Mr Brodrick in 1901 was an attempt

Organization of higher units for war.

to meet the difficulty which has hitherto prevented the training at home of bodies such as are at once required for action in the field. It is pointed out in the ninth edition of this work that "as the battle-field is the ultimate object of all preparation, administrative considerations must give way to tactical ones where they clash, and all organization must conform to the tactical requirements of the day." Unfortunately, the administrative difficulties which attend a vast empire, a free constitution, and voluntary service, and the indispensable condition of presenting an economical budget, have hitherto prevented the practical application of this sound principle. In order to create the reserve for filling up the ranks for war, and to provide for the colonial reliefs, it was arranged that there should be a battalion at home which should supply the battalion of the same regiment abroad with the annual draft required. This consideration became so paramount, that the importance for the purpose of training staffs for their work in war, and, therefore, of having constituted staffs to train, fell into the background at a time when the nation only calculated upon having to prepare for minor operations. There can be no doubt that the South African campaign plainly showed that trained staffs, accustomed to work together, and each to know its own particular share of the work, are indispensable to the smooth working of a large organization. The plea that it is frequently necessary to send out forces no larger than a division, and, therefore, that an army corps is not wanted, is not a strong one, because a division, or a force of similar strength, will not be the less effective because it is taken out of a larger body habitually associated with it, and out of which it can be supplemented by other troops with which it has regularly worked.

We give in Table B the ordinary composition of a British army corps, because it is well that the term should be understood; but, ever since this form of organization for armies was created, army corps have been of an infinite variety of form. All that the term implies is that it is a little army complete in itself, formed of every branch of the service, and being made up with all that is necessary to enable it to take its place in the field: that in itself it stands ready for war as soon as it has been mobilized. An army made up of army corps consists of several associated small armies, each capable of independent action in all respects. The "divisions," though called "infantry divisions," in fact consist of all arms, and frequently the several arms have been distributed throughout the divisions to form what are called "mixed divisions." In the German army there is a double organization by which, while the several arms are associated together, unit by unit, larger bodies of each arm are for the purpose of working in larger bodies of the arm associated together.

The great difficulty which encounters any attempt to associate large bodies of troops in England without flux or reflux, lies in the necessity of making provision for the constant interchange and relief between the units at home and abroad. The "cry of the exiles" is too strong to permit of their being left abroad for more than a reasonable number of years, and experience has shown that there are grave disadvantages in allowing two separate systems to grow up in different parts of the empire. On the whole, it has proved better for the training of drafts that they should not be sent direct from depots to India, but that, after a few months with the depot, they should be passed to battalions which will, in turn, later in the year, send on a draft to the sister battalion in India. In order that this may not injure the home battalion it is necessary that the draft should bear only a limited proportion to the strength

of the nucleus of the battalion, and that the draft supplied early in the year to the home battalion from the depot should considerably exceed the draft to be sent out later to India; but, if provision be made to that effect, the system appears to work best for both battalions. A similar allowance is necessary for the cavalry, and even more for the artillery, because in the case of batteries it becomes a question, if the draft is too severe, of the loss of specially trained men. Independently of the movement of drafts, the change in units will involve special provision if the value of the permanent organization by army corps is not to be lost.

The War Office, as at present constituted under the supreme and absolute authority of the Secretary of State for war, is regulated, so far as its military personnel is concerned, by an Order in Council of the 7th March 1899. That Order, altering in certain respects the Order in Council of 21st November 1895, which is cancelled by it, provides for the distribution of the military branch into five great departments—those of the commander-in-chief, of the adjutant-general, of the quartermaster-general, of the inspector-general of fortifications, and of the director-general of ordnance. Each of these officers "advises the Secretary of State" directly on all questions connected with the duties of his department.

The several officers are assigned duties which may be summarized thus:—

Commander-in-Chief.—"Principal adviser" and "general superintendent" of military departments. He is charged with the issue of army orders, inspections, the distribution of and "mobilization" of the land forces, with schemes of offensive and defensive warfare and military

The War Office and general administration of army.

Supply of troops for India and the Colonies.

information, with recommending for commissions and proposing officers for promotion, honours, appointments, and rewards.

Adjutant-General.—Discipline, military education and training, patterns of clothing and necessaries, returns and statistics of personnel, enlistment and discharge, and establishments. In the absence of commander-in-chief, acts for him.

Quartermaster-General.—Food, forage, fuel, light, quarters, land and water transport, remounts, movement, distribution of stores and equipment, the administration of the Army Service Corps and Pay Department, sanitation.

Inspector-General of Fortifications.—Fortifications, barracks, and store-buildings, inspection of ordnance factory buildings, military railways and telegraphs, War Office lands and unoccupied buildings, submarine mining stores. Estimates for Engineer services, appointment and removal of officers Royal Engineers, technical instruction of Royal Engineers.

Director-General of Ordnance.—Warlike stores, equipment, clothing, the direction of the ordnance committee and manufacturing departments. Armament patterns, inventions and designs, inspection of all stores. The administration of the Army Ordnance Department and Army Ordnance Corps; annual estimates for these services.

The most important part of the War Office is, however, not mentioned in the Order in Council. The "sinews of war" have at all times been money, without which neither could the army exist nor any military operation in peace or war be undertaken. It is true that, as a kind of appendix to the Order in Council, the statement is made that "the financial secretary is charged with the whole finance of the army in gross and detail"; but it is not mentioned that the "War Office" is a great permanent civil service, which has both independent offices, with its own heads, and also permeates the whole of the five departments. The Secretary of State has under him, in addition to the officers charged with the five departments and the financial secretary, a parliamentary under-secretary, who represents him in the House to which he himself does not belong, and a permanent under-secretary, who is the head of the permanent civil service of the War Office.

The enormous relative power of the civil service within the War Office, as compared with the military heads of departments, depends on the fact that these latter are appointed for five years at a time, and pass and re-pass through the War Office, while the War Office civil service is a permanent body which preserves all the traditions of decades, and can cite at will the records of opinion given at different epochs by soldiers who have temporarily occupied chairs in the office. Soldiers, like doctors, lawyers, and parsons, when called in to diagnose a case, do not always exhibit an absolute and instant agreement in the statement of their views. A Secretary of State holding all authority is necessarily much more likely to be impressed with the consistency and weight, and the method of a carefully collected catena of opinions, than with the comparatively casual dicta of men, very much overworked as compared with the officers of any other department of the kind in Europe, and relatively unfamiliar with the office aspect of a question. The practical result is, that the ordinary conviction of nearly every soldier employed within the office has been that he was helplessly in the hands of the permanent officials. This is altogether apart from the question of the supreme authority of the Secretary of State as the representative of the Cabinet.

The committee which in 1901 reported on the re-organization of the War Office appears to have taken this

view of the question, and to have considered that a better state of things would be produced if the authority of the War Office were largely devolved upon the army corps commanders to be created under Mr Brodrick's scheme. The practical possibility of this would appear ultimately to depend upon the extent to which Parliament will be content to accept reference to the army corps commanders as a final one as long as they are sustained in office. It is obvious that if the Secretary of State is to answer in Parliament for every incident that takes place in every army corps no practical independence can be left to any of them. Everything must be reported to the War Office in order to satisfy the demands of the House. It is a large question which can only be judged in its practical outcome.

In accordance with the recommendations of the committee on War Office Reorganization presided over by Mr Clinton Dawkins in 1901, the Secretary of State directed that in future the "War Office Council" should be constituted as follows:—President—the Secretary of State for War. Members—the Commander-in-Chief; the Parliamentary Under-Secretary of State; the Permanent Under-Secretary of State; the Financial Secretary; the Quartermaster-General; the Inspector-General of Fortifications; the Director-General of Ordnance; the Adjutant-General; the Director-General of Mobilization and Military Intelligence; the Director-General, Army Medical Department (for medical and sanitary questions); the Secretary of the Council; and such other members of the staff of the War Office as may be specially summoned from time to time. In the absence of the Secretary of State, the Commander-in-Chief acts as president.

A Permanent Executive Committee of the War Office was also appointed, with the object of co-ordinating the business of the office and of ensuring that combined action might be taken in matters affecting more than one department. It consists of the following:—the Permanent Under-Secretary of State, or, in his absence, the Assistant Under-Secretary of State, chairman; the Deputy Adjutant-General, or, in his absence, an officer selected by the Adjutant-General; the Assistant Quartermaster-General, or officer selected by the Quartermaster-General; a Deputy Inspector-General of Fortifications, or an officer selected by the Inspector-General of Fortifications; the Deputy Director-General of Ordnance, or an officer selected by the Director-General of Ordnance; an officer of the Mobilization section of the department of the Director-General of Military Intelligence; an officer of the Intelligence section of the department of the Director-General of Military Intelligence; the Deputy Accountant-General, or an Assistant Accountant-General; the Deputy Director-General, Army Medical Department, or an officer selected by the Director-General; the Assistant Director of Contracts; the Secretary of the War Office Council, who will act as secretary of the executive committee.

In addition to the above, the "Army Board," which consists of the Commander-in-Chief, the Adjutant-General, the Quartermaster-General, the Inspector-General of Fortifications, the Director-General of Artillery, with usually the military secretary, as assessor, and the Director-General of the Army Medical Department now added, meets at such times as may be fixed by the Commander-in-Chief.

With an addition, in all corps, of 3d. a day messing allowance on obtaining a certificate of military efficiency from the commanding officer.

The actual working out of Mr Brodrick's new scheme for having six army corps organized in the United Kingdom had not been promulgated at the time when it was necessary for this article to go to press.

It was only known that Aldershot, Salisbury, and Dublin were to be the headquarters of the three active army corps, and Colchester, York, and Edinburgh of what may be called the three sedentary army corps. The scheme had involved much labour, but, even on paper, the detailed distribution of the several units of the army into their brigades, divisions, and army corps, and the definition of the territorial limits of the commanders' authority, did not appear to have reached its final stage. It has, we believe, been decided that there will be one marked difference between the new army corps and those which are known as such on the Continent. In Russia, France, Germany, and Austria the several ranks of senior officers have direct relation to the functions which they fulfil. Normally the army corps is commanded by a general, the division by a lieutenant-general, the brigade by a major-general, the regiment forming an intermediate link between the brigade and the battalion. In England this intermediate link does not exist as a part of the progressive expansion of the army from its smaller to its larger organism. The regiment forms the connecting link between the battalions at home and those abroad, and in some sort between the regular and auxiliary battalions. It is not intermediate between the battalion and the brigade. It appeared, from the indications furnished, to be intended to appoint colonels as brigadier-generals to

command the brigades, major-generals to command the divisions, while three full generals (Sir Redvers Buller, Sir Evelyn Wood, and the duke of Connaught) were appointed to the first command of the three active army corps, though, on Sir Redvers Buller's retirement in October 1901 his successor in the command of the 1st Army Corps, Sir John French, was a major-general with the local rank of lieutenant-general. If this be so, the rank of lieutenant-general would virtually disappear from the ordinary course of the military hierarchy during peace time. As experience has shown in South Africa, it becomes a very necessary link in any considerable war, and major-generals have been appointed with "local and temporary" rank as lieutenant-generals accordingly. This step as to the peace organization would have the further importance of greatly limiting the possibility of promoting major-generals during peace time. The royal warrant already referred to makes that promotion dependent upon there being a specific appointment to which the promotion is made. The filling up by major-generals of the specific appointments which in foreign armies are reserved for lieutenant-generals, obviously affects this question very materially, and practically would produce the result that nearly all officers who reached the rank would terminate their career as major-generals.

Two departments, each of which proved during the Boer war to be inadequate for the work assigned to it, have been the subjects of recent and special investigation, viz., the army medical department and the remount department. Experience has shown that the attractions offered by army medical service have not been adequate. Briefly, the new scheme is as follows:—The department is to be administered by an "Advisory Board" of nine members under the chairmanship of the Director-General. Two of these are to be officers of R.A.M.C., two civil physicians, two civil surgeons, one representative of the War Office, one representative of the India Office. It advises on all medical army matters, including promotion of officers, thus superseding the "promotion board," which hitherto has dealt with that subject. The scale of pay is to be—

Lieutenant "on probation" and Lieutenant, in all	£323	10	0	per annum.
Captain (after 3 years' total service)	379	15	2	"
" " 7 " " "	400	0	0	"
" " 10 " " "	477	15	2	"
Major " 12 " " "	537	12	10	"
Major (after 3 years as such)	632	12	10	"
Lieut.-Colonel (after 20 years' service)	713	15	4	"
" (selected to an establishment of 50)	804	15	4	"
Colonel	953	10	10	"
Surgeon-General	1500	0	0	"
Director-General	2000	0	0	"

Candidates must be British subjects of unmixed European blood, under 28 years of age, with good references and a registrable qualification to practise. Provision is made for examinations prior to appointment and promotion to each rank. Previous to each of these the candidate will have the opportunity of attending, partly at Netley, partly at selected civil hospitals, courses of instruction in the special subjects in which he is required to pass. Before promotion to captain and before promotion to major, he may, by passing exceptionally well, obtain an acceleration of promotion varying from 3 to 18 months. Brevet promotion may be given either for distinguished service in the field or other exceptional service not in the field. The creation of an instructional military hospital and military medical staff college is proposed. A retaining fee of £25 per annum is proposed for such medical officers as, after 3 years' service as lieutenants, go to a reserve of officers.

The nursing service is to be called "The Queen Alexandra's Imperial Military Nursing Service," and governed by a board under the Queen as president. The pay ranges from the matron-in-chief, from £250 to £300 per annum (by £10 annual increments), with lodging allowance, to nurses, £25 a year to £35 (by £2, 10s. annual increments). The ranks are principal matrons (from £110), matrons (from £70), sisters (from £37, 10s.), nurses, and female servants.

An almost equally elaborate scheme had been proposed for the reconstruction of the army remount department, but it would appear that financial considerations caused it to be abandoned. No department within the scope of its possibilities accomplished harder or more valuable work during the South African war. (J. F. M.*)

BRITISH COLONIAL FORCES.

The British colonial forces proper are those raised and maintained by the colonies at their own expense, either for local purposes or as a voluntary contribution towards imperial defence. The relative prominence of these two objects necessarily depends mainly on the position and population of individual colonies or groups. Canada must maintain a considerable land force for the defence of a long land frontier, while fortunately the chance of hostilities with the United States is sufficiently remote to enable the empire to count on Canadian troops under other conditions. Newfoundland, being little liable to attack and having small financial resources, has not hitherto kept up any military force beyond a few armed police; advantage has, however, now been taken of the exceptional advantages the colony offers as a source of supply of men for the royal navy in war. The Australian states, including New Zealand, derive security from their position against organized invasion so long as British naval supremacy is maintained in Far Eastern waters. Though in a maritime war their land forces would in part be required for protecting their ports against predatory raids, they would doubtless be largely available for offensive operations in aid of imperial strategy. In the West Indies the function of local troops, largely native, must be looked upon as entirely local defence; in Bermuda and Jamaica they are auxiliary to imperial garrisons; in the Leeward Islands, Barbados, Trinidad, British Guiana, and British Honduras, they secure internal tranquillity in peace and guard against any possible raiding attack from a cruiser in war. A small white corps in the Falkland Islands has been raised to serve the latter purpose. In West Africa considerable forces of armed natives are maintained to secure the peaceful administration of the more turbulent parts of Sierra Leone, the Gold Coast, Lagos, and Northern and Southern Nigeria. In St Helena, the eastern colonies of Ceylon, the Straits Settlements, and Hong Kong, colonial volunteers, mainly European or of European descent, form valuable auxiliaries to the regular garrisons of the imperial coaling stations in these colonies. There are also native armed police in the two last, and a Sikh force, maintained by the confederated Malay States, would in war furnish assistance to the Singapore garrison. Armed police in Labuan and Fiji, assisted by white volunteers in the latter colony, maintain order in peace and would resist predatory attack in war. An armed constabulary of Papuans secures the internal quiet of British New Guinea.

In the self-governing colonies the colonial forces are administered by a defence department, which in Canada, Victoria, and New Zealand, is under a minister of defence; in Natal, under the minister of lands and works, and in

the other colonies under the prime minister or the chief or colonial secretary. In Canada, West Australia, Queensland, and New Zealand, the forces are commanded by imperial officers lent to the colonial Governments; in South Australia, Victoria, and Tasmania, by officers of the local forces. In Cape Colony and Natal their command in war devolves on the generals commanding the imperial troops. This is also the case in crown colonies where there are imperial troops permanently stationed. In the Leeward Islands, Trinidad, and British Guiana, the militia or volunteer forces are commanded by an officer who has also the armed police of the colony under him, and the same arrangement was proposed for the volunteer force raised for Barbados to replace the imperial troops withdrawn from that island. A few imperial officers, in addition to the commandant, are employed on the headquarters staffs of several of the self-governing colonies, and the frontier forces of West Africa are almost entirely officered from the imperial regular or militia service.

The permanent troops of Canada, corresponding to the regular forces of the imperial army, consist of 2 squadrons of cavalry, 2 field batteries, and 2 garrison companies of artillery, and 4 companies of infantry. The North-West Mounted Police, though enrolled under civil law, are practically a fine military force. The only permanent forces of Cape Colony and Natal are the Cape Mounted Rifles and the Natal Police, who have proved themselves most efficient soldiers. There are armed police organized as a military force in Bechuanaland, Basutoland, and Rhodesia. In Australia and New Zealand the regular troops consist of forces of artillery and engineers, and a small staff of officers and non-commissioned officers for other branches. In the West Indies the permanent forces are armed native police, and in West Africa native constabulary organized on an entirely military basis. There are armed police at the Straits Settlements, Labuan, Hong Kong, Fiji, and British New Guinea, and the Malay States Guides in the Federated Malay States are permanent troops.

The establishments of permanent troops in the different groups of states are approximately as follows:—

North America	1,700
South Africa	3,200
Australasia	2,000
Mediterranean (Cyprus)	700
West Indies	2,800
West Africa	8,000
Eastern colonies	3,400
Total	21,800

These figures do not include the armed police of the Australian states and of New Zealand, of which certainly the mounted branch could be made available in war, and would be highly efficient as mounted infantry.

The pay of a private soldier in the permanent forces in Canada is 2s. 0½d. (½ dollar) a day. In South Africa it is 5s. or 6s., in New South Wales and Queensland, 2s. 3d., in Victoria, 3s. 6d., and in New Zealand, 5s. or 6s. The native armed police in the West Indies receive at the rate of 2s. to 3s. a day, the frontier forces of West Africa, 1s. or 1s. 3d., and the armed police and constabulary in the eastern colonies from 8d. to 1s.

In Canada, Natal, West Australia, and Queensland, men enlist in the permanent forces for three years, in Tasmania for five, in Cape Colony for five in the first instance, and afterwards for fresh periods of three years at the expiration of each former period, and in Victoria and New South Wales for five years, with the option of re-engagement for a further period of five years. The periods for which natives enlist in the armed police forces of the different West Indian colonies vary from one to six years. It has been proposed to make the term of enlistment in the West African frontier forces a uniform one of seven years, and to encourage re-engagement. Five years is the usual period in the East African colonies.

The colonial forces, apart from the permanent troops dealt with above, comprise the following units of cavalry, mounted infantry, infantry, artillery, and engineers, partially paid and unpaid.

Colony.	Cavalry (Squadrons).	Mounted Infantry (Coys.).	Infantry.		Field Artillery (Btns.).	Garrison Artillery (Coys.).	Engineers (Coys.).
			Btns.	Coys.

Fiji	5

There are also medical services, including officers and men, in Canada, Cape Colony, South Australia, New South Wales, Queensland, New Zealand, and Ceylon. One or two of the colonies have the nucleus of an Army Service Corps.

The establishments of partially paid and unpaid troops in the different groups of colonies are approximately as follows:—

North America	34,700
South Africa	9,800
Australasia	28,600
West Indies	3,000
West Africa	400
Eastern colonies	1,900
	<u>78,400</u>

These numbers, representing approximate peace establishments, are capable, especially in the first three groups, of large expansion in war by the accession of men who, from their ordinary conditions of life, possess considerable military aptitude.

Service in all the forces is at present entirely voluntary, in the sense that there is no man now serving who has been compelled to enrol, but the actual laws governing the forces in Canada, South Australia, Queensland, Tasmania, New Zealand, Jamaica, the Leeward Islands, and British Guiana provide for the ballot, if authorized establishments cannot otherwise be kept up, or in war. In Canada, Cape Colony, and New Zealand, all male inhabitants of fighting age can be called out for a *levée en masse*.

Apart from the permanent troops, the whole of the forces of Canada, Natal (though called volunteers), West Australia, South Australia, Jamaica, and British Guiana, are partially paid, *i.e.*, all ranks receive pay during peace according to the military duties they perform. Those of Cape Colony, Tasmania, New Zealand, the Leeward Islands, Trinidad, British Honduras, the Falkland Islands, St Helena, the Gold Coast, Ceylon, the Straits Settlements, Hong Kong, and Fiji are unpaid, except when called out for active service, though most of the corps receive capitation grants for efficient. In Victoria, New South Wales, and Queensland, though the bulk of the troops are partially paid, there are also unpaid corps. The forces in Jamaica, though termed militia, do not receive pay for the ordinary drills laid down by law. The general tendency of late years has been to substitute partially paid or militia for unpaid or purely volunteer troops, as with the former it is found possible, under the conditions which obtain in most of the colonies, to get greater efficiency than with the latter.

In Canada the daily rate of pay for a militiaman during training is 2s. 0½d. In Natal a volunteer, if mounted, 6s., and if dismounted, 5s. for each day's training. In South and West Australia a man receives 5s. for each of a certain number of paid drills. Militiamen in Victoria, New South Wales, and Queensland, can by attendance at specified parades, and by efficiency, earn £6: 5s., £6: 8s., and £7 per annum respectively. The daily rate of pay for a militiaman in Jamaica, during continuous training as distinct from ordinary drills, is 2s.

The period of service as laid down in Militia or Volunteer Acts of Canada, Natal, West Australia, Victoria, Queensland, Tasmania,

Jamaica, Trinidad, and British Guiana, is three years. In South Australia it is two years in the active force, and three in the reserve. For the Cape and New Zealand it is not less than one year. For New South Wales, and for the colonies not mentioned above, where the local forces are entirely volunteers, no period of service has been laid down, men being allowed to cease serving on giving notice varying from fourteen days to three months.

There is considerable variation in the amount of annual training undergone by the various colonial auxiliary forces. As far as it is provided for by legislative enactment, the average number of days' training in the year is about twelve. In Canada, Queensland, and Tasmania, eight days is laid down as the minimum and sixteen as the maximum period, but in Queensland the maximum does not include eight days' continuous training which may be ordered by the governor. In South Australia the maximum for the active force is twenty-four days, and the minimum twelve of five hours; for the reserve twelve days' training is required. In New Zealand 168 hours is the maximum. In all the Australasian states the partially paid troops frequently hold voluntary parades. The regulations for the unpaid volunteers in Cape Colony require for efficiency twenty-seven drills in the first year's service, and eighteen in subsequent years; those for the paid volunteers in Natal lay down ten days in camp or twenty-four drills. In Jamaica the Militia Act provides for twelve ordinary drills, in addition to target practice and inspection parades, and in British Guiana for twelve days' drill a year.

All the colonies have already, or are now acquiring, rifles of the same calibre as those used in the imperial army, and the greater number of these rifles are of Lee-Metford or Lee-Enfield pattern. In field artillery there is more diversity, but this is likely to be remedied in the future. With regard to fixed armaments, apart from those provided by the imperial Government at the imperial fortresses and coaling stations, the Governments of Natal, of the six Australian states, and of New Zealand, have mounted powerful guns at their principal ports. British Guiana has defended Georgetown, and Trinidad and Barbados are likely to follow suit when the state of their finances makes it possible for them to do this in addition to maintaining defence forces. Canada has contributed largely to the protection of Esquimaux; and Ceylon, the Straits Settlements, and Hong Kong, to the defended coaling stations in these colonies. For the supply of war material the colonies are still largely dependent on Great Britain, but Canada has a cartridge factory, and shell foundry, and there are private ammunition factories in Australia and New Zealand, capable of manufacturing ammunition for Government small arms.

Colonial naval forces are practically confined to South Australia, Victoria, New South Wales, and Queensland. South Australia owns a protected cruiser, Victoria an armoured turret-ship and five torpedo boats, New South Wales two torpedo boats, and Queensland two gun-vessels and two torpedo boats. To man these ships there are altogether some 200 permanent and 1400 partially paid or unpaid officers and men. In view of the fact that a considerable imperial squadron, to which the Australian states and New Zealand contribute £126,000 annually, is always maintained in Australasian waters, and that the states have also provided by fixed defences against the raiding attacks of cruisers on their ports, it is difficult to say what function is played by the local naval defences of Australia. There is undoubtedly a desire in Australia to make some contribution in *personnel* as well as in money to the naval forces of the empire, and the question as to how this can most effectively be done by men thoroughly trained at sea will require consideration. New Zealand, besides contributing to the imperial navy, keeps up naval volunteers, but these are really military forces trained in the duties of garrison artillery and submarine mining. The preventive service in Canada, which includes some 500 officers and men, cannot at present be looked upon as a fighting force. Arrangements are being made for utilizing the fishermen of Newfoundland for the royal naval reserve. Cape Colony makes an annual money contribution of £30,000 to the imperial navy, free of all conditions. Natal makes a contribution of 12,000 tons of coal. It has also naval volunteers; but these, though they have given proofs of their excellence in manning guns of position, have no sea training, and are more properly included in the military forces of the colony.

The following table shows the colonial military and naval expenditure as taken from the latest estimates and accounts:—

Group.	Colony.	Military and Naval Expenditure.	Population (estimated 31/12/97).	Military and Naval Expenditure per head of Population.	Remarks.
Mediterranean	Gibraltar	£	20,699	s. d.	
"	Malta	5,709	177,745	0 6	Contribution.

"	Fiji	2,283	121,798	3 4	Armed police and Volunteers.
"	British New Guinea	3,044	3,350,000	...	Armed police.

Besides Colonial forces proper there are what are officially known as Colonial corps, consisting of troops raised in the Colonies and India, and paid by the Imperial Government for garrison duty at the Imperial fortresses and coaling stations. The Colonial corps at the present time comprise the West India regiment (three battalions), West African regiment, British Central African regiment, Hong Kong regiment, and Chinese regiment; the Royal Malta artillery, the West Indian, West African, and East African companies of artillery, submarine miners, and fortress engineers; the Royal Malta militia, the Bermuda militia artillery; and the Bermuda volunteer rifle corps. These corps number altogether some 10,000 regular, 2500 militia, and 300 volunteer troops, and are under the direct control of the War Office. In addition to these Colonial corps under the War Office there are certain other troops of the Empire which also, not being properly Colonial forces, call only for brief mention. These are the military forces of the British Central Africa, British East Africa, Uganda and Somaliland Protectorates. They number altogether some 4500 regular native soldiers, under Imperial officers lent by the War Office, and are administered by the Foreign Office. (M. N.)

INDIA.

After the transfer of the Government of India to the Crown in 1858, the whole military organization was re-

cast. The local European army was abolished. The artillery became wholly British, with the exception of a few native mountain batteries. The Company's European artillery, engineers, cavalry, and infantry were amalgamated with the royal army. The total strength of the British troops, all of the royal army, was largely increased, while that of the native troops was largely diminished. Three distinct native armies—those of Bengal, Madras, and Bombay—were still maintained. The reduced Indian armies consisted of cavalry and infantry only, distributed as follows, with a few artillery:—

	Battalions, Infantry.	Regiments, Cavalry.
Bengal	49	19
Madras	40	4
Bombay	30	7
Punjab force	12	6
Total	131	36

There were also three sapper battalions, one to each army.

The Punjab force, which had 5 batteries of native

artillery attached to it, continued under the Punjab Government. In addition, the Hyderabad contingent of 4 cavalry, 6 infantry regiments, and 4 batteries native artillery, and a local force in Central India of 2 regiments cavalry and 6 infantry, were retained under the Government of India. After all the arrangements had been completed the army of India consisted of 62,000 British and 125,000 native troops.

The Company's military college at Addiscombe was closed in 1860, and the direct appointment of British officers to the Indian local forces ceased in 1861. In that year a staff corps was formed by Royal Warrant in each Presidency "to supply a body of officers for service in India, by whom various offices and appointments hitherto held by officers borne on the strength of the several corps in the Indian forces shall in future be held." Special rules of pay, pension, and promotion were laid down; the principle of the last being promotion by length of service in the various ranks from second lieutenant up to lieutenant-colonel. The corps was at first recruited partly from officers of the Company's service and partly from the royal army, holding staff appointments (the new regimental employment being considered as staff duty) and all kinds of political and civil posts; afterwards by young officers from the British service, and recently in addition by second lieutenants drafted direct from the Royal Military College, Sandhurst. The native artillery and sappers and miners were to be officered from the Royal Artillery and Royal Engineers. The only English warrant and non-commissioned officers now to be employed in the native army were to be those of the Royal Engineers with the sappers and miners. Officers of the old Indian army who did not accept service in the artillery, engineers, and new line regiments transferred to the British army on the amalgamation, remained in their former cadres for promotion. Now all have disappeared from the active list except a few generals.

A radical change in the regimental organization of all the native armies was effected in 1863. The Punjab Frontier Force was from the first organized on the irregular system, which was there seen at its best, as also were the new regiments raised during the Mutiny. This system was now applied to the whole army, each regiment and battalion having seven British officers attached to it for command and administrative duties, the immediate command of troops and companies being left to the native officers. Thus was the system reverted to which was initiated by Clive, in the early days, of a few British officers only being attached to each corps for the higher regimental duties of command and control. Time had shown that this was more effective than the regular system instituted in 1796 of British officers commanding troops and companies.

Selection for all regimental commands was now the order. A new spirit was breathed into the army. The supremacy of the commandant was the main principle. He was less hampered by the unbending regulations enjoined upon the old regular regiments, had greater powers of reward and punishment, was in a position to assume larger responsibility and greater freedom of action, and was supported in the full exercise of his authority. The system made the officers.

Up to 1881 the native army underwent little change, but in that year financial considerations prevailed and 18 regiments of infantry and 4 of cavalry were broken up, while the rank and file of the rest were increased. Almost the same number of men were maintained as before, but in fewer and stronger regiments and better organized for war. The only reduction made in the British troops was in the Royal Artillery, which was diminished by 11 batteries. The events of 1885, how-

ever, on the Russo-Afghan frontier led to an augmentation of the army. The 11 batteries Royal Artillery were brought back from England, each of the 9 British cavalry regiments in India received an addition of a fourth squadron; each of the British infantry battalions was increased by 100 men and 3 battalions were added. The native cavalry had a fourth squadron added to each regiment; three of the four regiments broken up in 1881 were re-raised, while the native infantry was increased in regimental strength, and 9 new battalions raised composed of Gurkhas, Sikhs, and Punjabis. The addition in all amounted to 10,600 British, and 21,200 native troops. In 1890 the strength of the army of India was 73,000 British, and, including irregulars, 147,500 native troops.

Many important changes have taken place since 1885, which have vastly improved the efficiency of the native army. Seven Madras infantry regiments were converted into regiments for local service in Burma, composed of Gurkhas and hardy races from Northern India; six Bengal and Bombay regiments were similarly converted into regiments of Punjabis, Pathans, and Gurkhas; the native mountain batteries have been increased to ten; the system of linked battalions has been introduced with the formation of regimental centres for mobilization; and reserves for infantry and mountain artillery have been formed. The number of British officers present with each regiment has been increased to nine, and the two wing commands in battalions have been converted into four double-company commands of 250 men each, under a British commander, who is responsible to the commandant for their training and efficiency, the command of the companies being left to the native officers. This system, which is analogous to the squadron command in the cavalry, admits of closer individual attention to training, and distributes among the senior British regimental officers effective responsibility of a personal kind.

An addition to the army of five native battalions at the expense of the imperial Government was made in 1900 as the result of India being called upon to furnish garrisons for Mauritius and other colonial stations over sea. These new battalions are raised from such warlike and hardy races as Sikhs, Punjabi Mahommedans, Jats, and hillmen in Northern India. Of these three are included in the Punjab army, and two in that of Bengal.

The unification of the triplicate army departments in the different Presidential armies was completed in 1891, all being brought directly under the supreme Government; and the three separate staff corps of Bengal, Madras, and Bombay were fused into one in 1891 as the Indian Staff Corps. These measures prepared the way for the new system of army organization, which, by authority of Parliament, abolished divided control and placed the whole army of India under the Governor-General and the Commander-in-Chief in India.

On the 1st April 1895 the army of India was divided into four great commands—Punjab, Bengal, Madras, Bombay. These commands are under lieutenant-generals, styled as commanding the forces therein, all under the direct command of the Commander-in-Chief, and the control of the Government of India. The Punjab command includes the whole of the Punjab province. The Bengal command includes the territories under the civil governments of Bengal, Assam, the North-West Provinces and Oude, and part of the Central Provinces. The Madras command includes the Madras Presidency, Burma, and the Belgaum district. The Bombay command includes the Bombay Presidency, Baluchistan, and parts of Rajputana, Central India, and the Central Provinces.

The two local cavalry regiments and six battalions in Central India are now included in the Bengal and Bombay commands. The Hyderabad contingent remains as a separate force under the direct orders of the Government of India. It is commanded by a

general officer and garrisons a district of the Hydrabad state, but is available for general service.

The unified army is now organized on the territorial principle. The old Madras and Bombay armies are included in the Madras and Bombay commands, and recruit with some exceptions within the territories of these commands. The Bengal army was divided into two parts. All that portion of it which recruits in the Punjab is included in the Punjab command, while that which recruits in North-West India and neighbourhood is included in the Bengal command. The Gurkha battalions, a foreign element, are divided between the Punjab and Bengal commands, with one battalion in Burma. All the troops, though they have a home connexion with their particular commands, are interchangeable and liable to serve anywhere in and outside India.

The composition of the several commands is as follows :—

Indian Army.

Native Troops.	Punjab.	Bengal.	Madras.	Bombay.	Hydrabad Contingent.	Total.
Cavalry regiments	15	11	3	7	4	40
Artillery batteries (10 mountain)	7	2	...	2	4	15
Sappers and miners	...	1	1	1	...	3
Infantry battalions	44	26	32	31	6	139
Strength, including officers	52,600	32,900	30,300	31,200	7,600	154,600

The Indian Staff Corps, consisting of a corps of British officers for regimental employment in the native army, for staff, departmental, and other duties, numbers at present 2600 effectives, with a tendency to increase. Of these 26 are general officers.

The Indian Medical Service numbers 700 officers of all ranks, with a subordinate establishment of 500 military assistant surgeons.

The present establishment of British troops in India numbers 73,600. They are periodically relieved from home, the tour of service varying from 9 years for cavalry up to 15 years for artillery and infantry; and are generally distributed in the several commands as follows :—

	Punjab.	Bengal.	Madras.	Bombay.	Total.
Cavalry regiments	3	3	2	1	9
Artillery horse batteries	4	2	2	2	11
„ field batteries	8	14	8	12	42
„ heavy batteries	2	1	1	...	4
„ mountain batteries	5	...	1	2	8
„ garrison batteries	3	8	3	9	23
Infantry battalions	15	17	8	11	51

Royal Engineers, Submarine Miners, etc., one company in the commands.

The regular troops, British and native together, number 228,100, the strength of the several arms being as follows :—

	British.	Native.	Total.
Cavalry	5,600	24,700	30,300
Infantry	52,600	122,000	174,600
Artillery	13,400	3,200	16,600
Guns	390	76	466

The Native Army Active Reserves, mainly infantry, are growing, and at present number about 21,000, nearly half of whom belong to the Punjab command. They consist of men who have served with the colours from five to twelve years, and are called out annually for one month's training at regimental centres. There is also a large garrison reserve of all arms, consisting of old soldiers who have served twenty-one years, and are on the pension establishment.

The auxiliary forces consist, in round numbers, of

Volunteers (British)	31,000
Imperial Service Troops (Native)	18,000
North-West Frontier Irregular Corps (Native)	5,000
Burma and Assam Military Police Battalions (Native)	15,000

The volunteers are drawn from the British element of the population; organized in corps in the different commands—rifles, mounted and foot, light horse, and artillery—under district general officers. Well armed and trained, they are of great defensive value.

The Imperial Service Troops came into existence in 1888, when the principal feudatory chiefs spontaneously offered men and money towards co-operation in imperial defence. Portions of their forces, under the instruction of a staff of British inspecting officers, have been raised to such a pitch of general efficiency as to

fit them to take a place in line with the army of India. At present they consist of 8000 cavalry, 8000 infantry, with pioneers, mountain artillery, camel and transport corps, and have done good service in the field at Gilgit, on the Punjab frontier, and in China. They are under the orders of the Government of India.

The North-West frontier Irregular Troops are organized in eight corps as rifles and militia, under two and three British officers to each corps, and form an efficient advanced frontier force for service in the tribal countries beyond the administrative border. They are under the political authorities of the frontier province, and are recruited from the Afridi and other mountain clans along the border.

The Burma and Assam Military Police are organized in battalions under British officers, seconded from their regiments for this duty. They are recruited from the best material in the Punjab and neighbourhood, and form a very efficient irregular force for service on the eastern frontiers. They are under the provincial civil governments.

The supreme military power in India is vested by law in the Governor-General in Council, subject to the control of the Secretary of State for India. The business of the army is conducted through the military branch of the Government secretariat, which is immediately under the military member of Council. The secretary of this branch, like all the others, holds a position somewhat above that of an under-secretary of state in England, as, apart from his responsibility to the military member, the duty rests with him of personally bringing to the knowledge of the Viceroy every matter of special importance. The executive head of the army is the Commander-in-Chief in India. He is responsible for its efficiency, is the adviser of Government in all military matters, and is an extraordinary member of Council with a voice in it, and precedence next after the Viceroy. Besides the great department of command and discipline of which he is the head, there are various army departments, for the most part spending—ordnance, works, accounts, commissariat-transport, Indian medical service, army remount, clothing. These, together with what comes up from the Commander-in-Chief, make up the whole business of the army, and are administered in the military department of the Government by the military member of Council. All orders are issued by the secretary of this department in the name of the Governor-General in Council.

The Commander-in-Chief nominates to all appointments in the combatant branches subject to regulations, the action of Government being limited to confirming his nominations, which in all important cases are the result of communications which obtain the Viceroy's approval beforehand. The military member nominates to all appointments in the departments under him. As a matter of fact, the disposal of questions of equipment, armament, and defence, is the result of deliberation between the two authorities previous to submission to the supreme authority. Communication between the Commander-in-Chief and the military department is carried on through the adjutant-general and quartermaster-general. The Commander-in-Chief has under him a personal office, of which his military secretary is head, dealing with appointments and promotion. Also under him is the adjutant-general's department, which includes the inspector-generals of royal artillery and cavalry, staff officers for musketry and royal engineers, &c., with the quartermaster-general's department, including mobilization, intelligence, army signalling, &c. Other heads at army headquarters are the surgeon-general, army and Indian medical staff, director military education, judge-advocate-general, principal veterinary officer.

The division of the army into four great commands with complete army and departmental staff, all under lieutenant-generals, vested with large responsibilities and powers, has relieved the Commander-in-Chief of much detail, and left him free to exercise general supervision over the army—to watch it in peace and direct it in war, and to consider the important military questions of the day. Comprised in the commands are thirty military districts. All the general officers and staff are selected according to a fixed proportion from both services, British and Indian.

The establishment of units of the British army in India is :—
Cavalry : 29 officers, 601 other ranks—total 630, in 4 squadrons.
Artillery, horse and field : 5 officers each, 157 other ranks—total, 162.
„ mountain : 5 officers, 106 other ranks—111.
„ heavy : 5 officers, 95 other ranks—100.

Artillery, garrison : 5 officers, 140 other ranks—145.
 Infantry battalion : 29 officers, 1003 other ranks—1032, in 8 companies.

The peace establishment of the Indian cavalry regiment is 11 British officers, 17 native officers, 608 other ranks—total 636, organized in 4 squadrons. Their armament is sword, lance, and Lee-Enfield carbine. Of the 40 cavalry regiments 25 are lancers. The British officers in each regiment fill the grades of commandant, squadron commanders (one of them second in command), adjutant, and squadron officers. Native officers are in command of half squadrons, and one of them is native adjutant as assistant to the British adjutant. That of the infantry battalion is 11 British officers, 16 native officers, other ranks 896—total 923, organized in 8 companies under native officers, and in 4 double companies under British officers. The British officers fill the grades of commandant, double-company commanders (one of them second in command), adjutant, quartermaster, and double-company officers. One of the native officers is native adjutant. The armament is the Lee-Enfield rifle. There are 9 battalions of pioneers, trained and armed as infantry, and instructed as pioneers, with a special equipment. The 3 corps of sappers and miners are organized in companies. They are armed as infantry and trained and equipped as engineers. They vary in strength; that of Bengal being 20 officers Royal Engineers, with 31 warrant and non-commissioned officers, 23 native officers, other ranks, 1414—total, 1488; that of Madras, 22 officers and 34 warrant and non-commissioned officers R.E., 24 native officers, 1490 other ranks—total, 1570; that of Bombay, 14 officers and 20 warrant and non-commissioned officers R.E., 15 native officers, 886 other ranks—total, 935. The R.E. officers fill the grades of commandant, superintendents, instruction, park and train, adjutant, company commanders, and company officers. The native mountain battery consists of 4 officers Royal Artillery, 3 native officers, 253 other ranks—total, 260. They are armed with 2.5" guns. All army accoutrements are of brown leather manufactured in India. The grades of the cavalry native officers are risaldar-major (one to each regiment), risaldars and ressaidars in command of troops, and under them jemadars; those in the infantry are subadar-major (one to each battalion), subadars in command of companies, and under them jemadars. Promotion is made by selection. Selected non-commissioned officers are promoted to the commissioned grades, and direct commissions are also given to native gentlemen of rank and position, who are required to serve a probationary period before confirmation. Many members of old military aristocratic families serve in the ranks in order to win a commission.

The full dress of the Indian army varies in colour—red, blue, dark green, and drab. The fighting and working dress of all is of "khaki" colour. Khaki uniform, which has now been adopted in the imperial army, was used first by the Punjab Frontier Force in 1849. It developed during the campaign in India in 1857, and became general during the Afghan war. The word is derived from the Persian "khak," meaning dust, ashes.

A medical officer of the Indian Medical Service is permanently attached to each corps. The establishment of British officers includes absentees on leave. All appointed to the staff or other duty for a term of years, are seconded in their regiments. Their army rank is regulated by substantive rank in the staff corps or by brevet. The temporary rank of lieutenant-colonel is given to a major selected for the appointment of commandant, and that of major to a captain for that of second in command. The principle which it is endeavoured to preserve is that none but approved British officers should be appointed to native regiments. They are first trained and tested in British regiments before appointment to the staff corps.

Annual field-training is carried out first by squadrons and double companies under their own commanders, followed by that of the regiment, and of larger bodies of the combined arms at every station where available. Camps of exercise are a great feature in India, where unrivalled facilities exist close at hand for training the troops in every kind of country, which are taken full advantage of. Musketry is a strong point in the training. The course is a very practical one, and the result is that the Indian soldier soon develops into a first-class shot.

Recruiting is conducted by British recruiting staff officers at various centres throughout the commands, and also at regimental headquarters where men offer themselves, particularly cavalry. Subject to certain restrictions as to active service, a man may claim his discharge after three years' service, but it is optional with him to serve on for pension, or to pass to the reserve after five years' service. The army draws its recruits as a rule from the peasant or yeoman class, men of good physique, hardy, enduring, and courageous. There is no lack of them. The service is very popular and well paid, and has a liberal system of pensions for long service and wounds, and also family pensions for widows or orphans in case of death on active or foreign service, an attractive feature which appeals to the homes. It would be difficult in any

country to find finer fighting material than that furnished by Gurkhas, Sikhs, Pathans, Rajputs, and Jats, men who have on many a field stood shoulder to shoulder with the best and bravest of the British force. There is hardly any practical limit to the number of excellent soldiers that in case of necessity can be raised at short notice from the martial races of India, who possess great aptitude for military training.

The Indian army is heterogeneous as a whole but homogeneous in its units. The variation in race of these units is great. About one-third of the regiments are composed of one class—tribe, caste, or religion—such as Gurkhas, Sikhs, Rajputs, Jats, Mahomedans, hillmen, &c., while the rest are composed of class squadrons and companies of the above and other races. Their languages differ, but there is one common to all which they soon acquire—the Oordoo or Hindustani—the language of the camp or *lingua franca* of India, which originated with the old-time Mahomedan invasions of India, and is a mixture of Persian, Arabic, and Hindi. It is obligatory upon all staff corps officers to pass in Hindustani, and upon the regimental officer to pass in the language peculiar to the men in his regiment.

In India the transport and supply services are termed the commissariat-transport department. It is under the control of a commissary general-in-chief (a major-general) who has directly under him a commissary-general for transport only. Each command has a commissary-general. Under them are assistant and deputy assistant commissary-generals. All these appointments are held by Indian staff corps officers. This department feeds and clothes the army in the field, and the British troops in quarters. All native troops in India during peace are independent of the commissariat for food and forage, making their own arrangements regimentally, as their pay includes the provision of these items. The transport consists of corps of mules and camels, trains of pony and bullock carts, with elephants for special work. Regiments and corps on the mobilization roster keep in charge a proportion of mule transport.

The ordnance department, under a director-general of ordnance (a major-general), is officered from the Royal Artillery. There is an inspector-general to each command. The military works services, under a director-general (a major-general), is officered from the Royal Engineers. There is a chief engineer in each command.

The organization for war is by brigades and divisions. Regiments and batteries on the mobilization roster are required to keep up a special equipment for field service, and on receipt of orders to mobilize know precisely what to do. Besides the divisions (four) which are always maintained in a state of readiness, there are other troops specially detailed for the lines of communication. When regiments move in course of relief to stations outside the mobilization area, their place in the list is taken by the relieving corps to which they make over their special equipment.

The number of the military forces of the many native states of India, great and small, is now returned at 90,000, mostly ill-armed and ill-trained, one-third of which are cavalry. This total does not include the 18,000 well armed and organized imperial service troops furnished by twenty-three of these states. Kashmir has a force of Dogra Rajput infantry, hardy, inured to hill marching, and valuable in protecting the far north corner of that state about Gilgit and Chitral. A considerable part of the Gwalior and Hyderabad forces is fairly well drilled, and possesses some equipped batteries of artillery. The Sikh states have good Sikh troops, well drilled and fairly officered. They are very loyal to their chiefs. Rajputana could supply a large force of cavalry, all members of a military class. There is much excellent material among these troops which, under the hands of British officers, could be made useful in escort duty and keeping open lines of communication. Among the states guns abound of all sorts, sizes, and conditions. They may be put down at 500, all smooth-bores of old pattern, half of them movable. Very little of their artillery is organized.

Nepal is not included in the native states of India. It pays no tribute. This mountainous state, the homeland of the Gurkhas, has maintained close and friendly relations with the Indian Government since the accession to power of the Jung Bahadur in 1846, especially after he had, to use his own expression, "stood on London Bridge." In 1857 he personally led a strong Gurkha force of infantry and artillery to co-operate with the British army at Lucknow. Nepal has an army of 48,000 infantry, capable of expansion, and about 600 guns of various kinds.

The maintenance of the 18,000 imperial service troops costs the states concerned about £420,000, the outlay of the Indian Government on them for inspection being £14,000.

The personal cost of the British garrison of India to Indian revenues is about £4,400,000 a year, while the net expenditure of the whole army of India is about 1½ millions. (J. J. H. G.)

THE UNITED STATES.

The regular army of the United States has always been small. During the Civil War the several States furnished

over 2,800,000 men, organized into volunteer regiments bearing State designations. The officers, except general and staff officers, were appointed by the Governors of the respective States. The maximum authorized strength of the regular army never, during the war, exceeded 40,000 men; and the number in the field, especially towards the close of the war, was very much less. The States, in order to obtain men to fill their quotas, offered liberal bounties to induce men to enlist, and it therefore became very difficult to obtain recruits for the regular army, for which no bounties were given. The regular regiments accordingly dwindled away to skeletons. The number of officers present was also much reduced, since many of them, while retaining their regular commissions, held higher rank in the volunteer army. After the close of the Civil War the volunteers were mustered out; and by the Act of Congress of 28th July 1866 the line of the army was made to consist of 10 regiments of cavalry of 12 troops each, 5 regiments of artillery of 12 batteries each, and 45 regiments of infantry of 10 companies each. The maximum enlisted strength was 51,605. The Act of 3rd March 1869 reduced the number of infantry regiments to 25 and the enlisted strength of the army to 35,036. This was still further reduced, without change in organization, to 32,788 in 1870 and to 25,000 in 1874. The latter number remained the maximum for twenty-four years. The number allotted to a regiment of cavalry, artillery, or infantry was published in orders, and was changed from time to time to meet the needs of the service.

In March 1898 the artillery was increased by 2 regiments, and in April 2 companies were added to each infantry regiment, giving it 3 battalions of 4 companies each. The strength of batteries, troops, and companies was increased, the maximum enlisted strength reached during 1898 being over 63,000. A volunteer army was also organized. Of this army, 3 regiments of engineer troops, 3 of cavalry, and 10 of infantry were United States volunteers, all the officers being commissioned by the President. The other organizations came from the States, the officers being appointed by the respective Governors. As fast as they were organized and filled up, they were mustered into the service of the United States. The total number furnished for the war with Spain was 10,017 officers and 213,218 enlisted men. All general and staff officers were appointed by the President. Three hundred and eighty-seven officers of the regular army received volunteer commissions. After the conclusion of hostilities with Spain, the mustering out of the volunteers was begun, and by June 1899 all the volunteers, except those in the Philippines, were out of the service. The latter, as well as those serving elsewhere, having enlisted only for the war, were brought home and mustered out as soon as practicable.

The Act of 2nd March 1899 added 2 batteries to each regiment of artillery. On 2nd February 1901 Congress passed a Bill providing that the regular army, including existing organizations, should consist of 15 regiments of cavalry, a corps of artillery, 30 regiments of infantry, 1 lieutenant-general, 6 major-generals, 15 brigadier-generals, an adjutant-general's department, an inspector-general's department, a judge-advocate-general's department, a quartermaster's department, a subsistence department, a medical department, a pay department, a corps of engineers, an ordnance department, a signal corps, the officers of the record and pension office, the chaplains, the officers and enlisted men of the army on the retired list, the professors, corps of cadets, the army detachments and band at the United States Military Academy, Indian scouts as now authorized by law, and such other officers and enlisted men as might be hereinafter provided for.

The head of the military establishment is the Secretary

of War, a member of the Cabinet. The supply, payment, and recruitment of the army, and the direction of the expenditure of the appropriations for its support, are by law entrusted to him. He exercises control through the bureaux of the War Department. The lieutenant-general commands the army, but all the supply departments are independent of him, and are directly under the Secretary. Promotion to the grade of brigadier-general is by selection, generally, but not necessarily, from the list of colonels. Promotion from brigadier to major-general, and from major-general to lieutenant-general, is also by selection, though the senior is usually selected. The officers of the various staff departments had previously been permanent. Each had as its head a brigadier-general, selected from the officers of the particular department or corps. Promotion to colonel was by seniority in the department or corps.

The Act of 2nd February 1901 provided that, so long as there should remain any officers holding permanent appointments in the adjutant-general's department, the inspector-general's department, the quartermaster's department, the subsistence department, the pay department, the ordnance department, and the signal corps, they should be promoted, according to seniority, in the several grades, and whenever a vacancy should thereafter occur, it should be filled by detail from the same grade in the line of the army, the length of the detail being four years. Any such officer, below the rank of lieutenant-colonel, who shall have served four years in the staff, is not again eligible for detail until he shall have served two years in the line. When a vacancy occurs in the position of chief of any staff corps or department, the President may appoint to such vacancy an officer of the army at large, not below the rank of lieutenant-colonel, and such officer, while holding said position, shall have the rank, pay, and allowances formerly provided for the chief of the corps or department. Appointments to the lowest grade in the judge-advocate's department are made from the army or from civil life; in the engineer corps, from the Military Academy at West Point, or by transfer of lieutenants of the line after examination; in the medical department, from civil life.

The *adjutant-general's department* is the bureau of orders and records of the army. Orders and instructions emanating from the War Department or army headquarters, and all general regulations, are communicated to troops and individuals in the military service through the adjutant-general. His office is the repository for the records of the War Department which relate to the personnel of the permanent military establishment and the militia in the service of the United States, to the military history of every commissioned officer and soldier thereof, and to the movements and operation of troops. The adjutant-general is charged, under the direction of the Secretary of War, with the management of the recruiting service, the collection and classification of military information in regard to the United States and foreign countries, the preparation of instructions to officers detailed to visit encampments of militia, and the digesting, arranging, and preserving of their reports. The sphere of inquiry of the *inspector-general's department* includes every branch of military affairs except when specially limited in regulations or orders. Inspectors-general and acting inspectors-general exercise a comprehensive and general observation within their respective districts over all that pertains to the efficiency of the army, the condition and state of supplies of all kinds of arms and equipments, the expenditure of public property and monies, the condition of accounts of all disbursing officers of every branch of the service, and the conduct, discipline, and efficiency of officers and troops; and they report with strict impartiality in regard to all irregularities that may be discovered. They make such suggestions as may appear to them practicable for the cure of any defect that may come under their observation. The *judge-advocate-general's department* is the bureau of military justice. The judge-advocate-general is the custodian of the records of all general courts-martial, courts of inquiry, and military commissions, and of all papers relating to the title of lands under the control of the War Department. The officers of this department render opinions upon legal questions when called upon by proper authority. They act as prosecutors in important military trials,

and sometimes represent the Government when cases affecting the army come up in civil courts. The *pay department* has charge of the supply and distribution of and accounting for funds for the payment of the army, and such other financial duties as may be specially assigned to it. The staff departments above enumerated have no enlisted personnel. The *quartermaster's department* is charged with the duty of providing means of transportation of every character, either under contract or in kind, which may be needed in the movement of troops and material of war. It furnishes all public animals employed in the service of the army, the forage consumed by them, waggons and all articles necessary for their use, except the equipment of cavalry and artillery. It furnishes clothing, camp and garrison equipage, fuel, barracks, storehouses, and other buildings; constructs and repairs roads, railways, bridges; builds and charters ships, boats, docks, and wharves needed for military purposes; and attends to all matters connected with military operations which are not expressly assigned to some other bureau of the War Department. Subsistence, ordnance, signal, medical, and hospital stores are procured and issued by other bureaus of the War Department, but the quartermaster's department transports them to the place of issue and provides storehouses for their preservation until consumed. The *subsistence department* has charge of the purchase, inspection, storage, and issue of food supplies for troops. It has one function which, especially at isolated posts, has been found very beneficial, and which is not common to other armies. It keeps for sale at cost to officers and men, in addition to the ration, a large list of other stores. The ration is abundant. Its composition is fixed by the President. In order to obtain variety and meet the necessities of varying climates, such parts of the ration as are not desired are, under direction of company commanders, sold back to the subsistence department at cost, and funds are thus provided for the purchase of articles of diet not included in the ration. The men's messes are improved through another agency, the post exchange. This has been in existence but a few years. It is practically a soldiers' club, under the supervision of officers, in which many articles desired by the men are sold. The profits are periodically distributed among the organizations serving at the post for the improvement of the messes. The enlisted personnel of the subsistence and quartermaster's departments consists of a number of sergeants appointed, after examination, from the line. Clerks, teamsters, labourers, &c., are furnished by temporary detail from the troops or by hire of civilians. The *medical department* is charged with the duties performed by the medical staff in all armies. It has charge of hospitals both at stations and in the field, of ambulances, and of hygiene. It has an enlisted personnel, as large as may be deemed necessary, in addition to the authorized strength of the army. This force is called the hospital corps, and performs all hospital service in garrison and in the field. Its non-commissioned officers, termed hospital stewards and acting hospital stewards, are appointed after examination. A knowledge of pharmacy is required. There is also a nurse corps (female) consisting of one superintendent and such number of nurses as may be needed. The surgeon-general is authorized to employ, under contract, dental surgeons, not to exceed thirty in number. The officers, in addition to their other duties, give instruction by lectures and practical demonstration on "First Aid to the Injured" to all lieutenants of the line and to such captains as may volunteer. Company officers in turn are required to give this instruction to their men four hours a month. There is thus always in every company a number of men able to supplement the work of the hospital corps in the field, or to give the first cares to the wounded in the absence of medical attendance. The *signal corps* is charged with the construction, repair, and operation of military telegraph lines, with the supervision of such instruction in military signalling and telegraphy as may be prescribed by the War Department, and with the procurement, preservation, and distribution of the necessary supplies. A line officer is appointed signal officer at each military post, and supervises instruction, which must be continued until there are in each company at least 1 officer and 4 enlisted men proficient in signalling by flag, torch, and heliograph. The signal corps has an enlisted personnel of 760, of which number 350 are non-commissioned officers. The duties of the *corps of engineers* comprise reconnoitring and surveying for military purposes, selection of sites and formation of plans and estimates for military defences, construction and repair of fortifications and their accessories, planning and superintending of defensive or offensive works of troops in the field, examination of routes of communications for supplies and for military movements, and construction of military roads and bridges, execution of river and harbour improvements assigned to it, and such other duties as the President may order. There are three battalions of engineer troops. They form a part of the line of the army, and are officered by officers of the engineer corps assigned temporarily. The principal engineer station is Willets Point, New York Harbour, where there is an engineer school of instruction. A field officer of engineers

commands the station and school. The captains, in addition to performing the routine duties of a military post, act as instructors. Lieutenants of engineers, after serving for about a year after graduating at West Point, are assigned to companies, and constitute the class. The course lasts two years, and comprises instruction supplementary to that given at West Point, where the same subjects are studied, in military and civil (including electrical) engineering, and in astronomical work. The *ordnance department* is charged with the duty of procuring, by purchase or manufacture, and distributing the necessary ordnance and ordnance supplies for the Government, and establishes and maintains arsenals and depots for their manufacture and safe-keeping. Infantry small-arms, carbines, swords, sabres, horse equipments, field-gun carriages, and most of the accoutrements, such as haversacks, knapsacks, canteens, &c., are manufactured at the various arsenals. Cannon of all calibres are constructed by the ordnance department, the rough forgings being furnished by private firms. Powder is purchased, but the cartridges are made at an arsenal. Revolvers are purchased. Most of the sea-coast gun-carriages and sea-coast mortars are made by private firms. The ordnance department has a proving ground at Sandy Hook, New York Harbour, where experiments are made and guns are tested. The *record and pension office* has but two officers. It has in charge the records of all volunteers, not only of those who served in the war with Spain, but in former wars. The *chaplains* are of various religious denominations. One is allowed to each regiment of infantry and cavalry, and twelve to the artillery corps.

An officer of engineers or ordnance, or of the adjutant-general's, inspector-general's, judge-advocate-general's, quartermaster's, or subsistence department, or of the signal corps, though eligible to command according to his rank, shall not assume command of troops unless put on duty under orders which specially so direct by authority of the President. An officer of the pay or medical department cannot exercise command except in his own department, but by virtue of his commission he may command all enlisted men like other commissioned officers.

When the United States adopted a policy of liberal appropriations for sea-coast defence, the need was felt of a single body of experts to decide upon what was needed and how the money should be spent. Congress accordingly passed a law creating a *board of ordnance and fortification* whose duty it was "to make all needful and proper purchases, experiments, and tests to ascertain, with a view to their utilization by the Government, the most effective guns, small-arms, cartridges, projectiles, fuses, explosives, torpedoes, armour-plates, and other implements and engines of war." The membership of this board comprises the lieutenant-general commanding the army (who is its president), one officer each from the corps of engineers and the ordnance department, two from the artillery, and one civilian. An officer of the army is detailed as recorder of the board.

By the Act of 2nd February 1901 each *regiment of cavalry* consists of 1 colonel, 1 lieutenant-colonel, 3 majors, 15 captains, 15 first lieutenants, and 15 second lieutenants; 2 veterinarians, 1 sergeant-major, 1 quartermaster-sergeant, 1 commissary-sergeant, 3 squadron sergeants-major, 2 colour-sergeants, 1 band, and 12 troops organized into 3 squadrons of 4 troops each. Each troop of cavalry consists of 1 captain, 1 first lieutenant, 1 second lieutenant, 1 first sergeant, 1 quartermaster-sergeant, 6 sergeants, 6 corporals, 2 cooks, 2 farriers and blacksmiths, 1 saddler, 1 wagoner, 2 trumpeters, and 43 privates. Each *regiment of infantry* consists of 1 colonel, 1 lieutenant-colonel, 3 majors, 15 captains, 15 first lieutenants, and 15 second lieutenants; 1 sergeant-major, 1 quartermaster-sergeant, 1 commissary-sergeant, 3 battalion sergeants-major, 2 colour-sergeants, 1 band, and 12 companies, organized into 3 battalions of 4 companies each. Each infantry company consists of 1 captain, 1 first lieutenant, 1 second lieutenant, 1 first sergeant, 1 quartermaster-sergeant, 4 sergeants, six corporals, 2 cooks, 2 musicians, 1 artificer, and 48 privates. The regimental organization of the artillery arm of the United States army is discontinued, and that arm is constituted and designated as the *artillery corps*. It comprises 2 branches, the coast artillery and the field artillery. The coast artillery is defined as that portion charged with the care and use of the fixed and movable elements of land and coast fortifications, including the submarine mine and torpedo defences; and the field artillery as that portion accompanying an army in the field, and including field and light artillery proper, horse artillery, siege artillery, mountain artillery, and also machine-gun batteries. All officers of artillery are on one list, in respect to promotion, according to seniority in their several grades, and are assigned to coast or to field artillery according to their special aptitude for the respective services. The artillery corps consists of a chief of artillery, selected and detailed by the President from the colonels of artillery, to serve on the staff of the general officer commanding the army, and his duties are prescribed by the Secretary of War; 14 colonels, 1 of whom shall be the chief of artillery; 13 lieutenant-colonels, 39 majors, 195 captains, 195 first lieutenants, 195 second lieutenants, 21

sergeants-major (senior grade), 27 sergeants-major (junior grade), 1 electrician sergeant to each coast artillery post having electrical appliances, 30 batteries of field artillery, 126 batteries of coast artillery, and 10 bands. The strength of batteries and companies is fixed by the Secretary of War, but the aggregate number of enlisted men for the artillery shall not exceed 18,920. Captains and lieutenants of cavalry, artillery, and infantry, not required for duty with troops, batteries, or companies, are available for regimental staff or other details.

The above organization provides for an enlisted strength of about 58,000 men. In case of emergency the President is authorized to enlarge it, so that the maximum shall not exceed 100,000 men. This increase is to be effected by augmenting the number of men in a company, troop, or battery, without adding to the number of organizations or of officers.

The cavalry is armed with the Krag-Jorgensen carbine, cal. 30, the revolver, cal. 38, and the sabre. The thimble waist-belt of woven web carries 100 carbine and 12 revolver cartridges. The infantry and coast artillery have the Krag-Jorgensen rifle, cal. 30. The woven waist-belt carries 100 cartridges. Horse and mountain batteries may be organized, but there are none at present in service. With the exception of one siege battery of 5-inch guns and one of 7-inch howitzers, all the field batteries have the 3.2 B.L. rifle. When mountain guns are needed, they are issued to regular field batteries, or batteries are temporarily formed by details from other organizations. Each man has a revolver, non-commissioned officers and trumpeters having also a sabre.

Promotion in the line of the army is exclusively by seniority in the arm, a vacancy among the majors of cavalry, for instance, being filled by the senior captain of cavalry. Examination for promotion obtains up to the grade of major. An officer found physically disqualified from causes incidental to the service is retired with the grade to which his promotion would have entitled him. Should he fail in the educational examination,¹ he is suspended from promotion for a year, when he is again examined. Should he again fail, he is dropped from the rolls of the army. Retirement of all officers is compulsory at the age of 64 years. Officers have the right to retire on their own application after forty years' service, and may do so, on their own application, in the discretion of the President, after thirty years'. An officer may be retired at any period of his service for physical disability should a board of officers so recommend. Officers going on the retired list in any of the ways mentioned receive three-fourths of the full pay of their grade. In time of war retired officers may be employed on active duty, other than in command of troops, and they then receive full pay and allowances.

The army is recruited entirely by voluntary enlistment. Recruiting officers are maintained in the principal cities and towns. In ordinary circumstances each regiment furnishes one officer for a two years' tour of recruiting duty, but during active service in the field this duty is largely performed by convalescent officers. These officers report direct to the adjutant-general. The principal requirements for enlistment are that the applicant for first enlistment must be between the ages of 18 and 35; must be of good character; must be able to read and write the English language; must be a citizen of the United States or have legally declared his intention to become such; and must pass a rigid physical examination. The records for a number of years show that over 80 per cent. of applicants for enlistment are rejected. The term of enlistment is three years. The pay of a soldier ranges from that of a private (13 dollars a month) up through the various grades to that of a chief musician (60 dollars a month). The third year a dollar a month is added, the fourth year (should the soldier re-enlist) two dollars a month, the fifth year three dollars a month, and the sixth year five dollars a month. Thereafter a dollar a month is added for each five years' service. After thirty years' service the soldier is entitled to go on the retired list with three-fourths of pay and allowances. The soldier has a liberal allowance of clothing, and his food is furnished, so that his pay is almost all spending money. Retired officers and men form a part of the army and are paid by army paymasters. Pensions, in regard to which the country is very liberal (they call for about 140,000,000 dollars annually) are paid to persons no longer in the service, and the money is not disbursed by the War Department.

The principal source from which officers are supplied to the army is the Military Academy at West Point. The President has thirty appointments of cadets at his disposal, which are generally given to sons of army and navy officers. Each senator and each representative and delegate in Congress has one. These appointments are not made annually, but as vacancies occur through graduation of cadets, or their discharge before graduation. The maximum number of cadets is 481. The commanding officer of the academy has the title of superintendent.

¹ That is, an examination in English grammar, mathematics, geography, history, constitutional and international law.

He is detailed from the army, and has the temporary rank of colonel. The corps of cadets is organized as a battalion, and is commanded by an officer detailed from the army, having the title of commandant of cadets. He has the temporary rank of lieutenant-colonel. An officer of engineers and of ordnance are detailed as instructors of practical military engineering and of ordnance and gunnery respectively. The heads of the other departments of instruction have the title of professors. They are selected generally from officers of the army, and their positions are permanent. The officers above mentioned, and the professors, constitute the academic board. The military staff and assistant instructors are officers of the army. The course of instruction covers four years, and is very thorough. Theoretical instruction comprises mathematics, French, Spanish, English, drawing, physics, astronomy, chemistry, ordnance and gunnery, art of war, civil and military engineering, law (international, constitutional, and military), history, and drill regulations of all arms. Practical instruction comprises the service drills in infantry, cavalry, and artillery, surveying, reconnaissances, field engineering, construction of temporary bridges, simple astronomical observations, fencing, gymnastics, and swimming. Cadets are a part of the army, and rank between second lieutenants and the highest grade of non-commissioned officers. They receive from the Government a rate of pay sufficient to cover all necessary expenses at the academy. About 50 per cent. of those entering are able to complete the course. The graduating class each year numbers, on an average, about 60. A class, on graduating, is arranged in order according to merit, and its members are assigned as second lieutenants to corps and arm, according to the recommendation of the academic board. A few at the head of the class go into the corps of engineers; the next in order generally go into the artillery, and the rest of the class into the cavalry and infantry. The choice of graduates as to arm of service and regiments is consulted as far as practicable. Any enlisted man who has served honestly and faithfully not less than two years, who is between 21 and 30 years of age, unmarried, a citizen of the United States and of good moral character, may aspire to a commission. To obtain it he must pass an educational and physical examination before a board of five officers. This board must also inquire as to the character, capacity, and record of the candidate. Many well-educated young men, unable to obtain appointments to West Point, enlist in the army for the express purpose of obtaining a commission. Vacancies in the grade of second lieutenant remaining, after the graduates of the Military Academy and qualified enlisted men have been appointed, are filled from civil life. To be eligible for appointment a candidate must be a citizen of the United States, unmarried, between the ages of 21 and 27 years, and must be approved by an examining board of five officers as to habits, moral character, physical ability, education, and general fitness for the service. In time of peace very few appointments from civil life are made, but in time of war there is a large number.

There are, in addition to the Engineer School already mentioned, four service schools for officers. These are: the Artillery School at Fort Monroe, Virginia; the Infantry and Cavalry School at Fort Leavenworth, Kansas; the Cavalry and Light Artillery School at Fort Riley, Kansas; the Army Medical School at Washington. The commandants, staffs, and instructors at these schools are officers specially selected. The garrison at Fort Monroe is composed of several companies of coast artillery. The lieutenants constitute the class. They are relieved and replaced by others on 1st September of each year. The course of instruction comprises the following subjects: artillery, ballistics, engineering, steam and mechanics, electricity and mines, chemistry and explosives, military science, practical military exercises, photography, telegraphy, and cordage (the use of ropes, the making of various kinds of knots and lashings, rigging shears, &c., for the handling of heavy guns). July and August of each year are ordinarily devoted to artillery target practice. The course at the Infantry and Cavalry School is for two years. The class of student officers is made up of one lieutenant from each regiment of infantry and cavalry, and such others as may be detailed. They are assigned to the organizations comprising the garrison, normally a regiment of infantry, a squadron (four troops) of cavalry, and a battery of field artillery. The departments of instruction are: military art, engineering, law, infantry, cavalry, military hygiene. Much attention is paid to practical work in the minor operations of war, the troops of the garrison being utilized in connexion therewith. At the close of the final examinations of each class at Fort Monroe and Fort Leavenworth, those officers most distinguished for proficiency are reported to the adjutant-general of the army. Two from each class of the Artillery School, and not more than five (the number to be determined by the lieutenant-general commanding the army) from each class at the Infantry and Cavalry School, are thereafter, so long as they remain in the service, noted in the annual army register as "honour graduates." The work of the Cavalry and Light Artillery School at Fort Riley is mainly practical, and is carried on by the regular

garrison, which usually, in time of peace, consists of two squadrons of cavalry and three field batteries. The Government reservation at Fort Riley comprises about forty square miles of varied terrain, so that opportunities are afforded, and taken advantage of, for all kinds of field operations. The Army Medical School is established at Washington. The faculty consists of four or more professors selected from the senior officers of the medical department. The course of instruction covers a period of five months, beginning annually in November. The student officers are recently-appointed medical officers, and such other medical officers, available for detail, as may desire to take the course. Instruction is by lecture and practical work, special attention being given to the following subjects: duties of medical officers in peace and war; hospital administration; military medicine, surgery and hygiene; microscopy and bacteriology; hospital corps drill and first aid to the wounded.

The territory controlled by the United States, at home and abroad, is divided into territorial departments. These are established and their commanders assigned by direction of the President. In time of peace, army corps, divisions, or brigades are not formed except for purposes of instruction. The commander of a military department controls all the military forces of the Government within its limits, whether of the line or staff, which are not specially excepted. The exceptions include the Military Academy, the Artillery School, the schools at Forts Leavenworth and Riley in matters pertaining to the courses of instruction, the engineer establishment at Willets Point, arsenals, general depots of supply, general service recruiting stations, permanent fortifications in process of construction, and officers employed on special duty under the Secretary of War. But when an emergency demands it, all military men and material within the limits of their jurisdiction come under their control. A department commander is charged with the administration of all the military affairs of his department, and the execution of all orders from higher authority. He reports to the Commanding General of the Army all matters relating to the general welfare of his command, including such change of station of troops as he may deem desirable, but must obtain approval of the Commanding General of the Army before ordering the movement. If it be necessary to move troops to meet emergencies, such movements, and all the circumstances connected with them, must be reported at the earliest possible moment. The personal staff of a department commander consists of the authorized aids. The department staff is limited to the officers detailed by the Secretary of War from appropriate staff departments or corps, or of officers of the line detailed by the same authority to act in their stead, and their official designations are as follows: adjutant-general, chief quartermaster, chief commissary, chief surgeon, chief paymaster, judge advocate, and artillery inspector; also, when necessary, an engineer officer, an ordnance officer, and a signal officer, each detailed from his corps.

There are in the United States proper, including Alaska, about one hundred military posts. The garrisons of a majority of them, even when large forces are not needed out of the country, are necessarily small. The various staff positions at a post, such as adjutant, quartermaster, commissary, signal officer, and ordnance officer, are usually filled by lieutenants of the garrison temporarily detailed. At a post having the headquarters of a regiment, the first three positions above mentioned are filled by the regimental adjutant, quartermaster, and commissary respectively. The regimental adjutant, quartermaster, and commissary are selected from the captains, and the tour is limited to four years. As the great majority of officers of the line have, before obtaining their captaincies, filled one or more of the various staff positions, in addition to having taken the course at a service school, there is always available a large number of officers thoroughly qualified to fill any staff position.

The Act of 2nd March 1899 authorized the President to raise a volunteer force of 35,000 men for service in the Philippines, to continue in service not later than 30th June 1901, on which date the strength of the regular army, with the exception of the artillery, was to be reduced to the numbers in service prior to the outbreak of the war with Spain. On 5th July 1899 the President ordered the organization of ten regiments of volunteer infantry; on 18th July 1899, of two regiments of volunteer infantry and a regiment of volunteer cavalry (the three last-named regiments to be organized and recruited in the Philippine Islands); on 17th August 1899, of ten additional regiments of volunteer infantry; and on 9th September 1899, of two additional regiments of volunteer infantry (the enlisted men and company officers of the two last regiments to be coloured). Each regiment was organized at an army post. The men were recruited by regular army recruiting officers throughout the country, and were sent at once to the nearest regimental rendezvous. The time required, under each order, was about six weeks. All the colonels; nearly all the lieutenant-colonels and majors, and a few of the captains, were selected officers of the regular army. Most of the other officers and a large percentage of the men, had served, in the regulars or volunteers, in the war with Spain. The training of the men began at once on arrival at rendezvous, special attention being given to instruction in duties of guards and outposts, to fighting in extended order, and to target practice. The physical examinations were rigid, and the character of the accepted personnel was excellent. The result was the best volunteer force ever raised in the United States. The first regiment sailed for Manila, 8th September, 1899, and the last, 21st December. They were at once ready to take the field on arrival, and did most excellent service. One instance is the remarkable and energetic pursuit of the insurgents by volunteer troops, through the mountainous, heavily-wooded, entirely unknown country of northern Luzon, where transportation of supplies was at all times difficult and in many cases impracticable.

The Act of 2nd February 1901 repealed so much of the Act of 2nd March 1899 as provided for a reduction of force, 30th June 1901, and put the regular army on a permanent basis. It authorized the raising of 12,000 (provided the maximum of 100,000 for the entire army was not exceeded) Philippine native troops, organized into companies and battalions; the majors and captains being selected from the next lower grades in the line of the army. It also provided for a three-battalion native Porto Rican regiment, the field officers and captains to be selected as for the Philippine native troops.

The United States has never had a satisfactory system of increasing its armed strength for war. The subject has received a great deal of attention, and much legislation has been proposed, but the form of government makes the question very difficult of solution. The militia, numbering about 115,000 officers and men, is distributed through the various States, constitutes State troops, and is independent of the general government. Disorders within the limits of a State are to be dealt with by the State authorities, and the Constitution expressly prohibits the use of United States troops in such cases, except upon the formal application of the State authorities. The several States are very jealous of their prerogatives and never call for federal troops except as a last resort. The method adopted for raising the twenty-five regiments of volunteers for Philippine service proved very satisfactory, but might not be feasible for the sudden creation of a large army. It would require much time, and there would not be a large enough number of regular officers available. The practice both in the Civil War and in the war with Spain was for

the President to decide upon the number of men required, and then call upon Governors of States to furnish each their quota, according to population. Regiments were then organized in the several States, either by filling up organizations of the militia already existing, or by creating entirely new ones. The officers were appointed by the respective Governors. The troops thus organized did not come under federal control until formally mustered into the service of the United States; and this means of rapidly raising a large army has been found by experience to be inefficient and expensive. (W. A. S.)

GERMANY.

The liability to service in the German army is universal, and lasts from the 17th to the 45th year. Liability to active service begins on the 1st January of the year in which the man completes his 20th year, and is divided into service in the standing army, its reserve, and the landwehr of the 1st and 2nd bans. Liability to serve in the standing army lasts for three years from the date of joining (usually in October), for men posted to the cavalry and horse artillery, and for two years for the other arms; but these latter may also be held to serve three years. Thereafter, men belong to the reserve for four years, and are passed to the 1st ban of the landwehr in the spring following the date on which they complete seven years' service. Service in the 1st ban lasts five years, and in the 2nd is prolonged to the 31st March of the year in which the man completes his 39th year, i.e., for the most part, six years. Men who serve three years with the colours only pass three years in the 1st ban of the landwehr. During their period of reserve service, men are liable to two trainings of eight weeks each, though the vast bulk only do one of fourteen days, and during their service in the 1st ban of the landwehr to two trainings of eight to fourteen days, the bulk being, however, only called out once for fourteen days. The men of the 2nd ban of the landwehr are liable neither to training nor to periodical control musters. To the landsturm belong all males liable to service, and not otherwise belonging to the army or navy, from their seventeenth to their forty-fifth year; its 1st ban comprising those of thirty-nine years and under, its 2nd the others. Its men are not trained in peace.

Volunteers are taken, from among men who have completed their seventeenth year, to serve for three years in the cavalry and horse artillery, and for two years in the other arms. These men may choose their own regiments; so that volunteering is preferred by men who either desire to make the army a profession, or, for private reasons, wish to complete their active service earlier, or have a fancy for a particular regiment. A special category is formed by the one-year volunteers, who must pass a high educational test or have gone through certain classes in the schools. These receive no pay, clothe and equip themselves, and in the mounted branches find their own horses, in consideration of which they only serve one year actively. They are supernumerary to the establishment, and their number is unlimited. Both categories of volunteers pass into the reserve, &c., with men of their own age recruited compulsorily.

Recruiting is managed by committees of officers and civil officials in each recruiting (landwehr) district. These draw up lists, decide on exemptions allowed by law, and conduct the medical examinations. All men passed as liable and fit draw lots for numbers, and the lowest numbers are taken up to the contingent required. No substitution is allowed.

Non-commissioned officers (corporals and above) are obtained from two classes—(a) from the two- or three-year volunteers mentioned above, or (b) from the non-commissioned officers' schools, which youths of seventeen to twenty years of age voluntarily join. Their course there lasts three (in exceptional cases, two)

years, and they are bound to serve four years in the army after leaving the school. Non-commissioned officers are encouraged to remain in the army by a promise of employment in the gendarmerie after nine, or in the civil service after twelve years; and on leaving the army they receive a gratuity which varies from 50s., after five, to £50 after twelve years' service. Pensions are given to invalids.

Officers are obtained from two sources—(a) cadets, and (b) two- or three-year volunteers. Cadets join a provincial cadet-house between ten and fifteen years of age, and afterwards pass two and a half years in the Central Institution, near Berlin. At about eighteen years of age, they are appointed ensigns (*Fähnrich*, an intermediate rank between officer and non-commissioned officer) direct. Those volunteers who desire to become officers must be approved of by their commanding officer, and pass an examination or produce equivalent school certificates. They are private soldiers, but are known as aspirants to commissions (*Fahnenjunker*); they may live at the officers' mess, and may wear when off duty uniforms of finer cloth. After five months' actual service, and being passed professionally, they may be promoted ensigns. All ensigns must pass through a "war school," at which the course (military subjects, both theoretical and practical instruction) lasts nine months; after which they pass their "officers' examination," and are nominated lieutenants as vacancies arise. They must, however, be first balloted for and accepted by the officers of the regiment they are to join.

Officers of the reserve come, for the most part, from former one-year volunteers, who, after their one year's service, do two trainings of eight weeks each, and pass an examination. The one-year volunteers who do not become reserve officers become non-commissioned officers of the reserve.

There are four separate armies—those of Prussia and of the minor states, Bavaria, Saxony, and Württemberg—each administered separately by its own War Ministry, but all bound to conform as regards organization, formation, training, pay, command, mobilization, and (to a great extent) clothing, to fixed regulations. The minor states have concluded military conventions with Prussia, and their contingents are administered by its War Ministry. By the law of 25th March 1899 the army was to be raised from the 1st October 1899 onwards to a strength of 495,500 lance-corporals and privates, which figure was to be attained in 1903, and at this strength it was to remain till 31st March 1904. It is divided into the following units, the figures in brackets showing those actually existing after the new formations of 1st October 1899 were completed:—Infantry, 625 (624) battalions; cavalry, including mounted rifles, 482 (472) squadrons; field artillery, 574 (541) batteries; foot artillery, 38 (37) battalions; pioneers, 26 (24) battalions; communications troops, 11 (10) battalions; train, 23 (22) battalions. The *infantry* consists of 175 regiments of 3 battalions, 41 regiments of 2 battalions, and 18 rifle battalions. Each battalion has 4 companies. A number of those on the frontiers have an establishment of 640 non-commissioned officers and men, the remainder have one of 570 only. The infantry is armed with magazine rifles of 8 millimetres' calibre, loaded by packets of 5 cartridges at a time, and bayonets. In marching order, each man carries 120 rounds of ammunition and his share of a portable tent equipment. The *cavalry* consists of 93 regiments of 5 squadrons each, of which 14 are heavy, 25 medium (lancers), and 54 light (dragoons and hussars). A regiment has 681 non-commissioned officers and men, and 687 horses, but those on the frontiers are slightly stronger. The armament of all cavalry consists of steel-shafted lances (for both ranks), carbines of the same construction as the infantry rifle, and swords. The *mounted rifles* consisted in 1900 of 7 squadrons, and 10 more were to be raised. Each has 133 non-commissioned officers and men, and 182 horses. They are armed with swords and revolvers, and are used as orderlies, scouts, &c., and attached to various staffs. The *field artillery*, consisting in 1900 of 85 regiments, was to attain its full strength of 94 regiments in 1901, each regiment having 6 batteries in two brigade divisions of 3 batteries each. In 6 regiments (one of these brigade divisions), and in 2 other regiments, one of the 6 batteries is of horse artillery. Eleven of the regiments have each an extra brigade division of 2 horse artillery batteries, which, on mobilization, would join the cavalry divisions. In each army corps (see below) one brigade division of one of the regiments consists of 3 field howitzer batteries. About one-third of the field batteries are on a higher establishment of 115 non-commissioned officers and men, 60 horses, and 6 guns (there are 12 batteries on a still higher establishment); the remainder having 102 men, 44 horses, and 4 guns horsed. The horse batteries for the cavalry divisions have 121 non-commissioned officers and men, 120 horses, 6 guns, and 2 waggons horsed; the others, 92 men, 76 horses, and 4 guns. The guns are of 1896 pattern, nickel-steel quick-loaders of 7.7 cm. calibre, and the howitzers of 1898 pattern of 10.5 cm. calibre. Both fire shrapnel shell and shell filled with high explosives. A battalion of *foot artillery* has 4 companies with 595 non-commissioned officers and men. Two (in 2 cases 3) battalions form a regiment. This arm is trained for siege and inland

fortress duties (except 3 battalions as coast artillery), and also mans the heavy position and howitzer batteries of the field army. The pioneers are organized in single battalions of 4 companies, with 611 non-commissioned officers and men, and are armed as infantry. They are trained in field and siege works and bridging. The communications troops consist of 3 railway regiments of 2 battalions each, and 1 independent battalion, 3 telegraph battalions, and a balloon company (to be expanded to a battalion of 2 companies). The train battalions correspond to the transport branch of the British Army Service Corps, and have each 3 companies, with 299 non-commissioned officers and men, and 190 horses. To 8 of them are attached sections of 59 men and 57 heavy draught horses for batteries of position.

The army is divided into 23 *army corps*. Twenty-two of these are assigned to certain territorial districts for recruiting, and the Prussian Guard Corps is recruited from the whole kingdom. Of these 22 (21) corps, 16 are furnished by Prussia, &c., 3 (2) by Bavaria, 2 by Saxony, and 1 by Württemberg. There are exceptions in many cases, but the usual composition of an army corps, when the artillery had reached its full strength, was to be: 2 divisions each of 2 (in 9 divisions, 3) brigades of infantry, each of 2 regiments, 1 brigade of cavalry of 2 regiments, and 1 brigade of field artillery of 2 regiments, besides which the corps would have 1 squadron of mounted rifles, 1 battalion of rifles, 1 foot artillery regiment, 1 pioneer battalion, and 1 train battalion. The 1st and 14th corps have each 3 divisions. In the various War Ministries mentioned above, the administration of the armies is conducted. Prussia and Bavaria have in addition a "Great General Staff," in which the preparation of the army for war and its employment in the field are studied. There is, further, in each State a "Military Cabinet," in which all questions of the promotion and appointment of officers are dealt with. The heads of these three departments are independent of each other, and are directly subordinate to the sovereign. Great independence is allowed to generals commanding army corps, who are directly responsible to the sovereign for the training and preparation for war of their troops.

The standing army would take the field as it stands in peace, except that the bulk of the cavalry would be formed into independent cavalry divisions, each of 6 regiments and 2 batteries of horse artillery, and that certain units of its artillery and engineers serve as *cadres* for 2nd line formations. An infantry battalion on the war footing has 26 officers and officials, 1031 other ranks, 46 horses, 15 carriages; a cavalry regiment of 4 squadrons (one of the squadrons being left behind as a depot), 31 officers, &c., 665 men, 741 horses, and 17 carriages; a horse battery, 5 officers, 166 men, 236 horses, 6 guns, 9 ammunition waggons, and 5 other carriages; and a field battery, 5 officers, 171 men, 150 horses, and carriages as in a horse battery. A normal army corps would have 25 to 29 battalions, 4 or 5 squadrons, 21 batteries, 3 pioneer companies, &c., or a total fighting strength of 25,000 to 29,000 infantry, 600 to 750 cavalry, 126 guns, and 750 pioneers, with a ration strength of 37,000 to 41,000 men and 12,000 horses. A cavalry division with 24 squadrons and 2 batteries would have a ration strength of about 4800 men and 5100 horses. It is not known to what extent reserve and landwehr troops would be formed, but it is generally assumed that a division of all arms of each category, 12,000 to 20,000 strong, would be formed in each army corps, which would give a 2nd line army equal in strength to the mobilized standing army, about half of which might easily be employed in 1st line. Roughly speaking, without calling on the landsturm, Germany could put 2,000,000 men in the field, and keep another 1,000,000 for home garrisons and depots.

The total budgetary strength of the German army for 1899 was:—23,730 officers, 79,873 non-commissioned officers, 491,826 men, 2155 surgeons, 2805 paymasters, veterinary surgeons, armourers, and saddlers, and 101,065 troop horses. The above figures are exclusive of the colonial troops, which are insignificant in number, there being in South-west Africa a force of about 750 Germans, in East Africa about 130 Germans and 1600 natives, in Togoland 3 Germans and 150 natives, and in Cameroon 15 Germans and 300 natives. Kiaochow is held by marines from the Imperial Navy. (J. M. GR.)

FRANCE.

Every Frenchman becomes liable to military service at the age of 20. This liability dates from the conscription law passed at Jourdan's instance on 5th September 1798. But the principle of universal service was soon impaired by the admission of substitutes, authorized by the decree of 7th March 1800, and at length abolished by the recruiting law of 27th July 1872. This was replaced on 15th July 1889 by a new law, which extended the total period of military service from 20 to 25 years, but reduced the term of service with the colours from 5 years to 3. This term was to be followed by 7 years in the reserve of the active army, 6 years in the territorial army, and 9 years in the reserve of the territorial army. Exemptions for family or educational reasons were withdrawn, and those who had hitherto been allowed the benefit of them were required to serve for one year with the colours. Those who are physically unfit to bear arms may be employed in the auxiliary services in time of war. To adjust the strength of the standing army to the annual budget, the minister of war is given power to release three-years' men when they have completed one year's service. The average annual contingent is about 200,000 able-bodied men, of whom about one-third are released at the end of the first year. There are also about 20,000 volunteers who serve for one year, and may prolong their service to five years. The law of 1889 was modified on 19th July 1892, the term of service in the reserve of the standing army being prolonged to 10 years, and that in the reserve of the territorial army reduced to 6 years. In the infantry and cavalry more than half the subaltern officers are from the ranks, the rest being from the military schools. In the artillery and engineers about three-fourths come from the schools. Promotion is partly by seniority, partly by selection. The latter method is applied to one-third of the promotions to the rank of captain, to one-half of those to the next grade (battalion, or squadron, commander), and to all above that rank.

The organization of the army is based upon the law of 24th July 1873, which fixed the territorial system, supplemented by the cadre law of 13th March 1875, which defined the number of units. But there have been several changes since. At present the units of the standing army are as follows:—

Infantry.—173 regiments, viz., 163 of the line, 4 of Zouaves, 4 of Algerian rifles, and 2 foreign. The regiments are nominally of 4 battalions, but some fourth battalions are wanting. The Zouave and foreign regiments have 5 battalions, and 3 of the Algerian rifles have 6. Each battalion consists of 4 companies, which, in line regiments, have a peace strength of 127 men, in the Zouave and foreign regiments of 151, and in the Algerian rifles of 164. There are 30 battalions of *chasseurs à pied*, each consisting of 6 companies. Twelve are mountain battalions, and have 150 men per company; the others have 133 men. There are 5 battalions of African light infantry, each having 6 companies of 250 men. There are 4 disciplinary companies of variable strength.

Cavalry.—Eighty-nine regiments, viz., 13 of cuirassiers, 31 of dragoons, and 45 of light cavalry (*chasseurs*, *hussars*, *chasseurs d'Afrique* and *spahis*). The regiments generally have 5 squadrons of 150 men; the 4 spahi regiments have 22 squadrons in all, of 178 men. There are also 8 remount companies.

Artillery.—Eighteen battalions of foot (or fortress) artillery, comprising 105 batteries, with a peace strength of 129 men each. Twenty brigades (40 regiments) of field and horse artillery, comprising 442 field and 52 horse batteries of 103 men, and 14 mountain batteries of 156 men. When serving in Algeria the batteries are of higher strength.

Engineers.—Seven regiments, including 1 railway regiment. Two are of 4 battalions, the others of 3 battalions. There are 4 companies to each battalion, the railway companies having a strength of 160, and the others of 108 men. Each regiment has also a company of "train." The engineer staff numbers 460 officers and 888 subordinates.

The infantry are armed with the "Lebel rifle" of 1886, 8 mm. (0.315 in.) in calibre. It is sighted to 2000 metres, and has a magazine for 8 cartridges in the stock. The batteries—field, horse, and mountain—are of 6 guns each. The field artillery gun is of 90 mm. (3.54 in.) calibre; the horse artillery gun is of 80 mm. (3.15 in.) calibre. A quick-firing gun of 75 mm. (3 in.) is being rapidly introduced. It is of nickel steel, and weighs with its carriage about 19 cwt., rather more than the horse artillery gun. It is said to have a range of 7000 metres, and to be capable of firing 20 rounds a minute. The weight of its shell is 15½ lb. A field howitzer of 120 mm. (4.7 in.) calibre has also been adopted. It weighs, with its carriage, 29 cwt., and has a range of 6000 metres. Besides shrapnel, it fires long shells weighing 45 lb, with a bursting charge of 13 lb of melinite.

Two regiments of infantry or cavalry form a brigade; 2 infantry brigades, with 6 field batteries, 1 company of engineers, &c., form an infantry division; and, as a rule, 2 infantry divisions, with a battalion of chasseurs, a brigade of cavalry, 8 batteries of field and horse artillery, &c., form an army corps. The foot artillery is allotted to those army corps which have fortresses within their regions. France is divided into 19 army corps regions, and Algeria forms an additional one. The principal elements of the field army corps, with the staff and the cadres of the territorial army, are, as a rule, quartered in the region assigned to it, though its recruits are not necessarily drawn from its region. Outside the army corps there are 7 independent cavalry divisions of 3 brigades and 3 horse batteries each. The Algerian army corps (numbered xix) has 3 divisions. It consists mainly of Zouave and African regiments, but draws its artillery and engineers from regiments in France. There is also a separate division in Tunis. The effective strength of the standing army in 1898 was 544,000 officers and men. On mobilization for war the strength of the companies of infantry of the line and chasseurs is raised to 250 men, of engineer companies to 262 men, of field batteries to 180, and horse batteries to 190 men. There is little change in the squadrons of cavalry. On a war footing a cavalry brigade numbers about 1200 men, an infantry brigade 6000, an army corps nearly 40,000 men. As a fighting force it may be reckoned at 25,000 infantry, 1200 cavalry, and 120 guns. Armies (the commanders of which are designated beforehand) would be formed by groups of three or more corps, and the cavalry divisions would be attached to them. The territorial army would be used chiefly for garrisons and on lines of communication. The strength of its units when mobilized is generally the same as that of similar units of the active army, but it is not at present organized in brigades. Each army corps region would furnish 8 regiments of infantry, 8 squadrons of cavalry, 1 regiment of artillery, and 1 battalion of engineers. The total war strength of the active army and its reserve would be nearly 2½ millions, and the territorial army with its reserve would raise this total to about 4½ millions of trained men when the present laws have had their full effect (viz., in 1915). This is more than 11 per cent. of the population. (E. M. L.)

ITALY.

The Italian military organization is governed by laws enacted in 1883, 1884, 1887, and 1888. The armed strength consists of (1) the active army, (2) the mobile militia, (3) the territorial militia. The annual contingent for service with the colours is determined by Parliament, and selected by lot from the men who reach the age of 20 in each year; the rest pass at once into the reserve; men exempted from service in the active army, but fit to bear arms, pass into the territorial militia. The liability to service lasts from the age of 20 to 39, and the 19 years may be spent as follows:—

ACTIVE ARMY.		MILITIA.	
With Colours.	Reserve.	Mobile.	Territorial.
Years.	Years.	Years.	Years.
3	5	4	7
...	8	4	7
...	19

Cavalry.—There are 24 regiments, each of 6 squadrons, and a depot. Twelve regiments are told off, one to each army corps; the rest would be formed into 3 cavalry divisions of 2 brigades of 2 regiments. All regiments have a territorial title as well as a number. The war strength is 43 officers and 845 men, of whom 740 are mounted.

Artillery.—There is 1 horse artillery regiment, consisting of 6 batteries of 6 guns. The battery at war strength contains 4 officers, 150 N.C.O.'s and men, and 166 horses. The regiment would form 3 brigades of 2 batteries to act with the 3 cavalry divisions. The field artillery comprises 24 regiments—12 divisional and 12 corps artillery. Each regiment contains 2 brigades of 4 batteries and a depot battery. A divisional regiment contains 47 officers, 904 men, and 428 horses; a corps regiment has 53 officers, 997 men, and 458 horses. The light battery is armed with a gun firing a 9½ lb shell. The total weight of the gun and limber is 30½ cwt. The heavy batteries are equipped with guns firing a 14.9 shell, and the weight behind the team is about 41½ cwt. A heavy brigade is attached to each infantry division, and a mixed brigade of 2 heavy and 2 light batteries is allotted to each army corps. The mountain artillery is organized in 1 regiment of 9 batteries of 6 guns and a depot. On a war footing each battery has 4 officers, 150 men, and 63 pack animals. The garrison artillery forms 3 regiments, each of 12 companies, and 1 depot, and 2 regiments of 16 companies and 1 depot. A company contains 3 officers and 100 men. The garrison artillery supplies the *personnel* for siege parks, for fortresses, or fortified positions, and for coast batteries.

Infantry.—The infantry of the line forms 2 regiments of grenadiers and 94 other regiments, organized in 48 brigades bearing local titles, and 24 divisions. A regiment has 3 battalions of 4 companies and a depot. The strength of a regiment and a battalion is:—

		Off.	N.C.O.'s and Men.
Regiment	{ Peace	61	1299
	{ War	76	2811
Battalion	{ Peace	15	400
	{ War	24	918

In addition to line infantry, there are 12 regiments of bersaglieri, which are not brigaded, and 7 regiments of Alpini, specially trained for mountain warfare. The regular infantry is armed with the Mannlicher magazine rifle, calibre 0.257 inch, weighing with bayonet 9 lb 2 oz.

Engineers.—These form 2 regiments, each of 16 sapper or field companies; 1 regiment of 7 sapper companies, 6 telegraph companies, 3 transport companies, and 1 specialist company; 1 regiment of 8 pontoon companies, 2 special lagoon companies for service at Venice, 4 railway companies, and 3 transport companies. Each of the 4 regiments has a depot. The sapper or field companies furnish 1 company and 1 pontoon section to each division in the field, 1 engineer park to each army corps, 1 brigade of 3 companies to each field army. They also supply detachments for sieges or for work in fortresses. The telegraph companies furnish a telegraph park to each army corps and to each army in the field. The pontoon companies furnish to an army one or more bridging trains, each carrying about 200 yards of bridge.

Higher Organization.—An infantry division is composed of 2 brigades of infantry of 12 battalions, 1 brigade of artillery of 4 battalions of 6 guns, 1 company of engineers, 1 pontoon section, 1 ammunition column. Its numbers at war strength 276 officers and 12,705 N.C.O.'s and men. A cavalry division comprises 2 brigades of 2 companies, and 2 horse artillery batteries numbering 213 officers and 3820 N.C.O.'s and men, together with an ammunition column and administration units. An army corps contains 2 divisions, with corps troops consisting of 1 regiment (3 battalions) of bersaglieri, 1 cavalry regiment of 6 squadrons, 2 artillery brigades (48 guns), the whole numbering 943 officers and 30,387 N.C.O.'s and men. There are also 1 corps ammunition column, 1 engineer

park, 1 telegraph park, and administration units. The active army can supply 12 army corps.

Mobile Militia.—The mobile militia is organized in 144 infantry battalions of 4 companies, 18 battalions of bersaglieri, and 22 companies of Alpini. In addition there are 12 brigades of field artillery, each of 4 batteries, 34 companies of garrison artillery, 9 of mountain artillery, 30 companies of engineers; 4 field batteries and 2 companies of garrison artillery for Sicily; together with 9 battalions of line infantry, 1 battalion of bersaglieri, 1 squadron of cavalry, 2 batteries of field, and 1 company of garrison artillery for Sardinia.

Territorial militia is organized in 320 battalions of infantry, 75 companies of Alpini, 100 companies of garrison artillery, and 30 companies of engineers.

Colonial Troops.—A special force exists for the garrisoning of Eritrea, composed of volunteers from the active army or reserve and of native troops.

The armed strength of Italy numbers about:—

	Officers.	N.C.O.'s and Men.
Active army and reserve	19,450	805,000
Mobile militia	3,600	295,500
Territorial militia	5,200	1,617,000
Total	28,250	2,717,500

(G. S. C.)

AUSTRIA-HUNGARY.

The military forces of Austria-Hungary consist of (1) the active army with its reserves, (2) the landwehr, (3) the landsturm. The active army is superintended by a single war ministry for the whole monarchy; but the landwehr and landsturm are under two separate ministries of national defence,—one for the troops of Hungary, Croatia, and Slavonia (the "Honved" troops), the other for the remaining states. Liability to military service was made universal in 1868. The law at present regulating it was passed in 1889. Except in "the occupied provinces," Bosnia and Herzegovina, which have special treatment in several respects, substitutes are not allowed. The liability begins at the age of 20, and the term of service is 12 years; but the nature of the service varies. Out of 180,000 able-bodied men annually available, over 100,000 are taken for the army, and after 3 years in its ranks, spend 7 years in the reserve and 2 years in the landwehr. About 23,000 serve their whole term in the landwehr. The remainder go to the ersatz (depot) reserve of the army or the landwehr as supernumeraries. The destination of the recruits is determined partly by lot, partly by their claims to consideration. Young men of good education are admitted as "one-year volunteers" at their own cost, or sometimes at the cost of the state. All men between the ages of 18 and 42 are further bound to serve in the landsturm, or general levy, if not otherwise enrolled; but the landsturm is not called out during peace, and in war only when the landwehr and ersatz-reserves are insufficient. Young men who are found unfit for service have to pay a military tax, according to their means, for the benefit of disabled soldiers, or of the widows and orphans of soldiers. The officers of the standing army are drawn from the military schools. Promotion is mainly by seniority, subject to tests of qualification, but selection is not excluded. The reserves are officered by retired officers and one-year volunteers. The units of the standing army (omitting depot cadres, &c.) are as follows:—

Infantry.—102 regiments of the line, 4 regiments of Tyrolese rifles, 4 Bosnian-Herzegovinian regiments, all of 4 battalions; also 26 independent rifle battalions; making a total of 466 battalions. There are four companies to each battalion, and their normal peace strength is 4 officers and 93 men.

Cavalry.—Forty-two regiments, viz., 15 dragoon, 16 hussar, and 11 uhlan. Each regiment has 6 squadrons and a pioneer section. The peace strength of a squadron is 5 officers and 166 men. The dragoons are recruited from the Austrian provinces, the hussars from Hungary, the uhlans mainly from Galicia. They are all armed alike with sabres and repeating carbines.

Artillery.—Fourteen brigades of field artillery, each consisting of 1 corps regiment and 3 divisional regiments. In each regiment there are 4 field batteries with a peace strength of 4 officers, 101 men, and 4 guns (to be raised to 8 guns in time of war). Attached to regiments of the corps artillery there are 8 divisions of horse artillery, making 16 horse batteries of 5 officers and 122 men each, and 11 batteries of mountain artillery of 2 officers and 60 men each. There are also 3 additional mountain batteries which form a separate division. Of fortress artillery there are 6 regiments and 3 independent battalions, making 18 battalions in all. In each battalion there are 4 field companies of 4 officers and 98 men.

Engineers, &c.—Fifteen pioneer battalions, each having 5 companies of 5 officers and 107 men. The 5th company is expanded into 3 fortress companies in war. The train includes bridge-equipment. There is a railway and telegraph regiment of 3 battalions, each having 4 companies of 50 officers and 118 men. The engineer staff comprises 146 officers.

The general staff of the army numbers 481 officers, of whom 276 belong to the staff corps, and the rest are attached. There are 29 infantry regiments (to be increased to 32) of Austrian landwehr, and 28 of Hungarian, making 195 battalions in all. Each battalion has 4 companies of about 55 men. The landwehr cavalry consists of 6 regiments of uhlans and 10 regiments of Hungarian hussars, of 6 squadrons each, and there are also 3 squadrons of Tyrolese and Dalmatian mounted infantry. The peace strength of the squadrons is from 43 to 65 men. There are no landwehr artillery or engineers. The infantry are armed with the Mannlicher magazine rifle of 8 mm. (0.315 inch) calibre, the latest pattern being of 1895. It is sighted to 3000 paces. The magazine holds 5 cartridges which are inserted simultaneously in a clip. The field and horse batteries are armed with steel-bronze guns of 9 cm. (3.42 inch) calibre, the field gun weighing 9½ cwt., and that of the horse artillery about 8 cwt. The pattern is of 1875, and no provision has yet been made for substituting quick-firing guns; but something has been done to check recoil and make the present guns more effective.

The higher units of the army are of variable strength. An infantry brigade consists of 6 to 9 battalions; a cavalry brigade of 2 or 3 regiments. Two brigades form a division. An infantry division comprises also 3 or 4 squadrons of cavalry, and a regiment (4 batteries) of field artillery. A cavalry division has 2 batteries of horse artillery and one or two battalions of rifles. A corps is ordinarily made up of 2 infantry divisions, a cavalry brigade, a regiment of corps artillery, and technical troops. The territory of Austria-Hungary (including Bosnia and Herzegovina) is divided into 15 corps districts and 1 divisional district (Zara in Dalmatia). There are 5 cavalry divisions, of which 2 are attached to the 11th corps (in East Galicia) and the other 3 to the 1st, 2nd, and 10th corps. The total peace strength of the regular army is about 283,000 men, and of the landwehr about 49,000, making 350,000 in all, officers included. The war strength of the various units is not published now, but the field troops available on mobilization would probably amount to 800,000 men, the landwehr to 320,000, the ersatz-reserves of army and landwehr to 480,000. It is reckoned that another million of trained men could be found in the landsturm. (E. M. L.)

RUSSIA.

Since the war of 1877-78 many changes have been introduced into the Russian army, which was not previously organized in higher units than the division.

Under the law of Jan. 13, 1874, modified by that of June 14, 1888, and Jan. 19, 1893, liability to service extends from the beginning of the 21st to the end of the 43rd year of age. The first 18 years are passed in the standing army, the rest in the militia. Service with the colours lasts for 5 (in practice 4) years, the remaining term being spent in the reserve, which entails two trainings of six weeks each for the entire period. The army mobilized for war is composed of (1) field troops, (2) reserve troops, (3) depot troops, (4) fortress troops, (5) local troops, (6) militia.

(1) The field troops are composed of the standing army made up to war strength by calling out the reserves. (2) The reserve troops are formed by the expansion of reserve cadres maintained in peace. (3) Depot troops are formed upon cadres detached at the outbreak of war from the standing army. Their function is to keep the field units up to strength. (4 and 5) Fortress and local troops are brought up to war strength in the same way as reserve troops, but are intended to be employed only on garrison duties. (6) The militia comprises all men physically fit for military purposes between the ages of 21 and 43 inclusive, and is divided into two bans. The 1st ban contains the men who have served with the colours, and those who have not been included in the annual contingents, but are wholly fit for active service. It may be used to complete the field army, or to form militia units for home defence. The 2nd ban includes men exempted on special grounds from service with the colours, and those regarded as not wholly fit for operations in the field. Military service in Finland was regulated by the law of Jan. 13, 1881, which prescribed 3 years with the colours and 2 with the reserve, the rest of the military period up to the end of the 43rd year of age being passed in the militia. The conditions have, however, been assimilated to those of the empire. Cossacks serve under special regulations for 20 years, beginning with the completion of the 18th year of age. The first 4 years are spent with the colours, the next 4 on leave. During the last 5 years they are only liable for service in case of war.

Infantry.—There are 209 regiments, each of 4 battalions, of 4 companies and a non-combatant company. These regiments comprise 12 of imperial guard, 16 grenadiers, 181 line infantry. Guard regiments have titles only, the rest (1 to 16 grenadiers and 1 to 180 line) have a geographical title as well as a number. The peace and war establishments of a regiment are as follows:—

	Peace.	War.
Officers	70	79
N.C.O.'s and men (combatants)	1816	3874
Horses	25	158
Carriages	77

Rifles are regarded as light troops, and are supplied with recruits of superior stamp. They consist in peace of 36 two-battalion regiments and 32 independent battalions, having on mobilization 4 four-battalion regiments, 32 two-battalion regiments, and 32 independent battalions. The magazine rifle, 1891 pattern, calibre 0.299 in., weighs with bayonet 9 lb 12 oz., has a muzzle velocity of 2000 f.s., and is sighted to 3000 paces. Every infantry regiment carries in the field 1280 light and 256 heavy spades, 320 light and 128 heavy axes. The Cossack infantry consists in war of 16 Kuban and 4 Transbaikal battalions. The reserve infantry cadres maintained in peace consist of 82 battalions in Europe, 26 battalions in the Caucasus, and 15 battalions in Asia, to be expanded on mobilization to 264, 74, and 51 battalions respectively. The fortress infantry is organized in peace in 1 regiment of 5 and 17 regiments of 2 battalions, each of 5 companies. On mobilization these expand into 31 regiments of 5 battalions. The regiment takes its title from its fortress. The militia is intended to be organized in 640 battalions in war, and to be brigaded in 2 categories, each of 320 battalions.

Cavalry.—The regular cavalry consists of 68 regiments of 4 or 6 squadrons, and 2 independent Asiatic divisions of 2 squadrons. The establishment of regiments is as follows:—

	Peace,		War.	
	4 squadrons.	6 squadrons.	4 squadrons.	6 squadrons.
Officers	32	38	30	36
N.C.O.'s and men (combatants)	706	1027	629	920
Horses	585	905	676	1016
Carriages	23	29

Each squadron carries 20 light spades and 20 light axes on the saddle. Pioneer detachments with a demolition equipment are provided in the case of regiments on the western frontier. The Cossack cavalry supplies 317 squadrons in peace and 905 in war. Each regular regiment has a depot cadre, which on mobilization forms 2 squadrons. The Cossack establishments supply in war 43 depot squadrons, to train men and horses for the active units. On general mobilization it is contemplated to form 80 squadrons of militia cavalry.

Artillery.—The field and mountain artillery consists of 52 brigades—3 guard, 4 grenadier, 45 line—attached to infantry divisions, together with 53 batteries, of which 7 form the Turkestan brigade, and 12 form 2 East Siberian brigades, the remainder being classed as "independent." An artillery "brigade" varies in strength from 9 batteries (guard, grenadier) to 4 batteries (2nd East Siberian). Batteries are classed according to their armament as heavy, light, mountain, and howitzer. Batteries of the first 3 classes have each 8 guns; howitzer batteries have 6. The following are the particulars of the equipments:—

	Heavy.	Light.	Mountain.	Howitzer.
Calibre (in.)	4.2	3.42	2.5	6
Shrapnel (lb)	28	15.4	8.9	59†
Muzzle velocity (f.s.)	1450	1700	1143	760
Projectiles carried	108	150	128	92
Load behind team (cwt.)	42½	37½	194*	41½

* Weight of gun, lb. † High explosive shell.

A field battery carries 32 spades, 24 axes, and 4 pickaxes for entrenching purposes. New equipments are being tried and will be gradually introduced. The howitzer artillery consists of 7 regiments, of which 1 to 5 have 4 batteries each, and the remainder 2 batteries. There are also 2 batteries forming part of the 1st East Siberian brigade. The regular horse artillery numbers 28 batteries (5 guard) and 3 independent horse mountain batteries. The horse batteries are organized in divisions of 2 batteries and attached to cavalry divisions. The Cossack horse artillery batteries number 20 in peace and 38 in war. The reserve field artillery in peace consists of 7 brigades, each of 2 divisions of 2 or 3 batteries, in all 41 batteries, expanding on mobilization to 164 batteries. The depot field artillery force is organized in peace cadres, forming 3 brigades of 3 batteries, 5 independent batteries, and 1 horse artillery battery, expanding in war to a total of 56 batteries. It is proposed, when the militia is called out, to form 80 militia batteries, organized in 40 regiments attached to the 40 divisions of infantry. The fortress artillery contains 56 battalions of 4 companies, 4 siege battalions of 4, 3, or 2 companies, 10 independent companies, and 5 sortie (field) batteries expanding into 16 batteries. The establishment of a fortress or siege battalion is:—

	Peace.	War.		
	Company.	Battalions of		
		2 Cos.	3 Cos.	4 Cos.
Officers	3	11	16	21
N.C.O.'s and men (combatants)	112	654	983	1310

The siege ordnance consists of 4.2-in., 6-in., 8-in. guns, and of 3.4-in., 8-in., and 9-in. (screw) mortars. The garrison and coast defence ordnance includes 14-in., 11-in., and 9-in. guns (1877), 11-in. (1886), 10-in. (1895), and 6-in. Q. F. (Canet) guns. A militia force of foot artillery, consisting of 10 battalions, each numbering 24 officers and 1308 N.C.O.'s and men, is to be formed in war.

Engineers.—The sapper and pontoon battalions and the

engineer parks are in peace time administered in 7 brigades. In war the units are distributed among the field and other troops. There are 25 sapper battalions in Europe and 4 in Asia, 8 pontoon battalions and 7 field parks. The sapper battalion has usually 3 sapper companies and 1 telegraph company. Its usual establishment strength is:—

	Peace.	War.
Officers	22	26
N.C.O.'s and men (combatants)	488	937
Horses	14	321
Carriages	119

A pontoon battalion carries from 340 to 400 yards of bridge equipment. There are 7 railway battalions, 4 in Europe and 3 in Asia. The latter are kept at war strength: 30 to 35 officers and 1300 to 1560 N.C.O.'s and men combatants. There is in peace an instructional balloon park, which would form detachments in war for armies in the field.

Higher Organization for War.—The active army in Europe and the Caucasus supplies 24 army corps composed of 51 infantry and 23 cavalry divisions and 2 rifle brigades. There are also 1 independent rifle division, 5 independent rifle brigades, and 2 independent cavalry brigades, together with a large body of active troops not included in the higher units. The empire is divided into 12 military districts and 1 province, subdivided into 23 local brigades.

The approximate total strength of the combatant forces on a war footing is as follows:—

	Battalions or Squadrons.	Guns.	Officers.	N.C.O.'s and Men.
I. Field Army—				
Infantry	985	...	19,454	952,708
Cavalry	730	...	3,728	109,916
Artillery	3782	4,484	164,096
Engineers	1,076	39,981
Total	3782	28,742	1,266,701
II. Field Reserves—				
Infantry	10,572	631,152
Cavalry	2,236	85,090
Artillery	1420	1,403	51,196
Engineers	137	6,001
Total	1420	14,348	773,439
III. Fortress Troops—				
All arms	128	4,357	235,861
IV. Local Troops—				
Cavalry and Infantry	(field)	379	29,690
V. Depot Troops—				
All arms	462	5,814	330,826
VI. Militia—				
All arms	640	10,752	673,686
Grand total	1715	6432	64,392	3,310,203

The conditions of the Russian empire render a rigid territorial system such as that of Germany impossible. Large Asiatic garrisons have to be provided, which, until the completion of the Siberian railway, must be mainly transported and supplied by sea. Native troops in considerable numbers are maintained, and have to be brought into the general system. Thus the military problems of Russia approximate more closely to those of Great Britain than to those of any other Power. (G. S. C.)

TURKEY.

The Turkish military forces are organized on a territorial system, the empire being divided into 6 districts (ordu), of which the headquarters are (1) Constantinople, (2) Adrianople, (3) Monastir, (4) Erzinjan, (5) Damascus, (6) Baghdad. The Yemen and Hejaz form a separate ordu, whose troops are recruited from (4) and (5). On account of the defective state of the internal communications and other circumstances, the territorial system is not rigidly adhered to, and even in peace time there is a considerable interchange of troops in the military districts.

All Mussulmans are liable to military service, but the nomad Arab tribes are not regularly recruited, and many of their men evade the conscription. Liability to service commences at the age of 20, and lasts 20 years. The armed strength is divided into 3 categories, in which the period of service is nominally as follows:—

I. Nizam (active army)	with colours	4 years.
	{ in reserves	2 "
II. Redif (landwehr)		8 "
III. Mustahfiz (landsturm)		6 "

The period of 4 years with the colours is sometimes varied, and the nizam reserve is liable to be recalled at any time. Between 130,000 and 140,000 men become liable to service in each year, and about 50,000 join the nizam force. Those not drawn are exempted from colour service, but receive some small training.

Cavalry.—The nizam cavalry forms 38 regiments of the line and 2 of the guard, each consisting of 4 squadrons and 1 depot squadron. Regiments 1 to 36 form 6 cavalry divisions, one for each of the 6 ordus. There is no redif cavalry, but a tribal militia force (Hamidieh), consisting of 48 regiments, is formed somewhat on the lines of Cossacks, the tribes supplying their own horses and equipment, and arms being provided by the Government. The war establishments of nizam cavalry are:—

	Officers.	N.C.O.'s and Men.
Squadrons	6	153
Regiments	39	647

Peace establishments are generally low and vary considerably, especially in Hamidieh regiments.

Artillery.—The Turkish artillery has been generally the most efficient of the three arms. Each of the ordus 1 to 5 has 1 battalion of horse artillery and 3 brigades of field and mountain artillery. A brigade consists of 2 regiments of 2 battalions of 3 batteries. The battery on a war footing has 6 guns. Thus each of these ordus should have—

	Batteries.	Guns.
Horse artillery	3	18
Field "	30	180
Mountain "	6	36
Total	39	234

To the 6th ordu 2 regiments of 2 battalions are allotted, each regiment having 12 field and 2 mountain batteries. For the Yemen and Hejaz divisions 2 field and 3 mountain batteries are provided. The total number of batteries is approximately:—Horse, 15; field, 169; mountain, 42.

A field battery on a war establishment is supposed to contain 4 officers, 133 N.C.O.'s and men, and 100 horses. Peace establishments vary considerably in the different ordus. Horse artillery is armed with 7.5-cm. guns, field artillery with 8.7-cm. guns, and mountain artillery with 6.9-cm. guns, all of Krupp manufacture. Fortress artillery is partly raised in the several ordus, and partly recruited specially for the ordnance department. The ordus are supposed to provide 64 companies, the ordnance department 20 battalions, comprising 74 companies. The fortress artillery is mainly concentrated at Constantinople, in the Bosphorus and Dardanelles defences, in the Bulair lines and at Erzeroum.

Infantry.—The nizam infantry consists of 69 regiments, 15 rifle battalions, and 1 battalion of mountain infantry. In all there are about 284 nizam battalions. There are 12 local battalions of militia in Tripoli. A brigade consists of 2 regiments of 4 battalions; a division consists of 2 brigades and 1 rifle battalion. Each ordu contains 8 line regiments and 2 rifle battalions. The nominal war establishments of line and rifles are:—

	Officers.	N.C.O.'s and Men.
Company	4	223
Battalion	24	898
Regiment	106	3658

The redif infantry is organized in 88 regiments and 352 battalions. Each of the ordus supplies 8 regiments of 4 battalions. Redif troops nominally belong to the 2nd line, but are frequently embodied in peace time, and employed outside their territorial districts. Small peace cadres are permanently maintained. The war establishment is intended to be the same as that of the nizams, but redif battalions may be 1200 strong. The nizam infantry is armed with the Mauser magazine rifle, calibre 0.302 inch, weighing with bayonet 10 lb 7½ oz. Other forces are not yet fully re-armed with recent weapons.

Engineers, like artillery, are partly organized in the ordus and partly recruited from the ordnance department. The ordus 1 to 4

provide each 1 battalion of 4 companies of pioneers, and 1 telegraph company; the remaining ordus have each 1 company only. The 2nd ordu has in addition a pontoon train under the ordnance department. There are two regiments of 3 battalions of 2 companies and 1 torpedo battalion. The establishment of an engineer company is about 200 men of all ranks, and of a telegraph company about 106.

Higher Organization.—Each ordu is supposed to form a nizam army corps of 2 divisions, and ordus 1 to 5 also supply 4 divisions of redifs. A nizam division would probably consist of 16 battalions of infantry, 1 battalion of rifles, and 1 regiment of field artillery. A cavalry division might consist of 6 regiments and 1 battalion of horse artillery—24 squadrons and 18 guns. A nizam army corps would comprise 2 infantry divisions and 1 cavalry division. The redif divisions would depend on the nizam army for their artillery, and there is not sufficient nizam cavalry to enable them to be formed into army corps. The army corps organization, however, has not been wholly naturalized in the Turkish empire, and is not well suited to its conditions. The combatant forces of Turkey number about 700,000 men, exclusive of a large number of mustahfiz, who cannot be said to be organized, but who would provide able-bodied men partly trained.

(g. s. c.)

SWITZERLAND.

The Swiss army is a purely militia force, receiving only periodical training, but based upon the principle of universal service. Liability begins at the age of 20 and lasts for 25 years. Cavalry men receive a recruit's course of 80 days' training on joining, and subsequently a repetition course of 10 days in each year, until the end of the 11th year. Artillery and infantry undergo recruits' courses of 55 and 45 days respectively, and a repetition course of 18 and 16 days in every alternate year till the end of the 12th year, when they pass into the landwehr, and receive 6 and 5 days' training every fourth year. The Confederation supplies certain units which are recruited throughout the country. The rest of the army is recruited in 8 territorial districts. The armed strength consists of (1) the active army; (2) the fortress garrison; (3) the landwehr; (4) the landsturm. The active army is organized in four army corps which draws only to a small extent upon the landwehr. The fortress garrisons are made up of active troops (*élite*) and landwehr. The rest of the landwehr is organized in regiments, squadrons, companies of position artillery and engineers, and administrative units. The landsturm includes all able-bodied men between 17 and 50 who are not included in the active army and landwehr, volunteers under 17 and over 50, and officers up to 55 years of age. It is divided into two classes, of which the first consists of all men under 20, who on mobilization join the active army as recruits. The 2nd class, consisting of men of 20 and upwards, is divided into the "armed landsturm" and the "auxiliary troops." The armed landsturm forms 96 fusilier battalions of 3, 4, or 5 companies, 23 carabinier companies, and 26 companies of position artillery. It is inspected and drilled on one day in each year. The "auxiliary troops" form 410 pioneer companies about 200 strong, and "special detachments" for administrative services.

Cavalry.—The cavalry of the active army consists of 24 squadrons of dragoons and 12 companies of guides, the former being organized in 8 regiments of 3 squadrons. The landwehr cavalry supplies the same number of units, but has no horses. A dragoon regiment has 17 officers and 358 N.C.O.'s and men. Of the 12 companies of guides, 8 are attached to divisions and have the same strength as a squadron of dragoons. Cavalry horses are kept for a year in the remount depots before being issued to recruits. After passing through the recruit's course, the cavalry man takes his horse to his home, paying half its cost as security. This sum is repaid by the state in "yearly instalments," and at the end of the 10 years' service the horse becomes the property of the man.

Dragoons are armed with sword and a magazine carbine, weighing 7·05 lb, calibre 0·295 in., muzzle velocity 1800 f.s. The Swiss cavalry, on account of its brief training, is intended to be employed almost wholly in reconnaissance and as mounted infantry.

Artillery.—The active artillery comprises 56 field and 4 mountain batteries, each of 6 guns; there is no horse artillery. For fortress work there are 8 companies, 3 observation companies, and 2 machine gun detachments. The landwehr provides parks, ammunition trains, and 15 position companies. The 56 field batteries form 12 regiments, 8 of which, each consisting of 2 brigade divisions of 2 batteries, are attached to the 8 divisions. The remaining 4 regiments each consist of 2 brigade divisions of 3 batteries, allotted as corps artillery to the 4 army corps. A regiment of 4 batteries contains 23 officers and 652 N.C.O.'s and men, with 340 horses and 24 guns. The field artillery is armed with a 3·31-in. Krupp gun, firing a 14·8-lb shrapnel, with a muzzle velocity of 1590 f.s. The mountain gun, calibre 2·95 in., fires a shrapnel of 10·14 lb, with a muzzle velocity of 1004 f.s. There are 5 brigade divisions of position artillery, each composed of 2 active companies and 3 of landwehr. A brigade division numbers 41 officers and 778 N.C.O.'s and men. Its armament consists of 16 12-cm. guns, 12 12-cm. mortars, and 12 6-cm. guns. Of the position artillery, 1½ brigade divisions are allotted to the St Gothard and St Maurice defences; the rest is available for employment with the field army. There are 3 brigade divisions of fortress artillery attached to the defences above mentioned. Artillery horses and those of the train are hired when required.

Infantry.—The active infantry consists of 96 fusilier and 8 carabinier battalions, each containing 25 officers and about 730 N.C.O.'s and men, or 720 combatants in all. A fusilier regiment consists of 3 battalions. The landwehr infantry consists of 66 fusilier and 8 carabinier battalions. Throughout the army there is only one establishment—that laid down for war. The active army and landwehr infantry are armed with the Schmidt magazine rifle, calibre 0·295 in., weight with bayonet 10·43 lb, muzzle velocity 1900 f.s. The landsturm infantry have the Vetterli rifle, calibre 0·410 in., weight with bayonet 11·46 lb, muzzle velocity 1411 f.s.

Engineers.—The engineers of the active army comprise 8 half-battalions of 2 companies of sappers, 4 bridging detachments of 2 pontoon companies, 4 telegraph companies, 1 railway battalion of 4 companies, 1 balloon company, and 3 fortress companies. The landwehr provides 16 sapper companies, 2 bridging detachments, 4 telegraph companies, and 4 railway companies.

Higher Organization.—The field army is organized in four army corps of 2 divisions, with corps troops. Each division contains 2 infantry brigades of 2 regiments of 2 battalions, together with 1 guide company, 2 brigade divisions of field artillery, a carabinier battalion, and half a battalion of engineers. The 8 divisions are recruited in 8 territorial districts. On mobilization the active army absorbs 230 officers and 5736 N.C.O.'s and men from the landwehr. The approximate total strength of establishments is as follows:—

	Officers.	N.C.O.'s and Men.	Total.
Active army	4522	97,169	101,691
Active landwehr	230	5,736	5,966
Fortress garrison	224	5,085	5,309
Fortress landwehr	314	8,462	8,776
Landwehr troops	1751	43,159	44,910
Total	7041	159,611	166,652

In addition, the "armed landsturm" numbers about 53,500 men of all ranks. The pioneer companies supply about 104,000 men, and the special detachments about 114,000 men. The former have received extremely little training, the latter consist of men told off as far as possible for miscellaneous duties to which they are accustomed.

The Swiss army is a highly organized force, which, regarded as a militia, has no equal. The amount of training imparted to it is necessarily limited, but is made as thorough as possible; and the results obtained, as shown by manœuvres, are surprising. Against the small amount of actual drill must be set the long service of 11 or 12 years passed in the same unit. The men thus acquire a solidarity which cannot be at once attained in bodies made up from reserves on mobilization. Composed of mature and hardy men inured to the conditions of a mountainous country, the army is unquestionably a powerful defensive force,

reflecting the sturdy national patriotism of the Swiss, and capable of offering a strong resistance to external aggression. The total annual military expenditure of Switzerland is under £1,000,000, which approximately represents the cost of the British volunteers.

(G. S. C.)

JAPAN.

Japanese military organization on Western lines may be held to date from 1873. Involving as it did the disappearance of the *samurai*, or feudal soldier *par excellence*, the altered state of things occasioned some trouble at first, but within three years the new model got into fair working order and has now been accepted with sober enthusiasm by the people. At the beginning an advisory board of British experts was set up. Then this gave way to the *mission militaire* of French officers and Italian artillerists in the arsenal at Osaka. These were in turn replaced by a staff of German specialists. Finally, since the period of the Chinese war, the Japanese have felt strong enough to dispense with all foreign assistance and to organize their army for and by themselves.

Conscription.—Every male of the age of twenty is liable to the conscription, provided he is passed by the doctor, is not (under safeguards) the sole breadwinner of his family, suffers from no permanent illness or disablement, is not a criminal, and is not undergoing a very specialized curriculum of education. The conscripts are chosen by lot. The minimum height for the infantry, cavalry, and army service corps is 5 feet 2 inches; for the artillery and engineers, 5 feet 4 inches. The number of eligibles is estimated at 427,000 a year, of whom 60,000 are actually taken for the colours, and 131,300 for the depot or supernumerary forces. There is an elaborate system of volunteering, devised to secure the thorough training of the exempted students and of natives who have been resident in foreign lands, who on their return to Japan at the age of thirty-two are drafted into the territorials.

Service.—There are four grades of service, namely—(a) with the colours for three years; (b) with the first reserves for 4½ years, who are called up twice during their full term for three or four weeks at a time; (c) with the second reserves for five years (the *Landwehr*), who are called up twice for two weeks at a spell during their full term; and (d) with the territorial troops (the *Landsturm*) up to the age of forty. Besides these grades there are two classes of supernumeraries (the depot), the first comprising men who, though physically qualified and otherwise liable to serve, have not been called up for service with the colours; the second, men who have not only escaped the lot for the colours, but also service with the first supernumeraries. The first depot serve for 7½ years, with 150 days' training during the full term, of which ninety days are usually required during the first year; the second depot serve for 1½ years, without any training, as a rule, during the period. Ultimately both classes pass into the territorial army. Their chief purpose is to fill such vacancies as occur in the ranks of the regulars.

Personnel.—The conscript private becomes first a second-class soldier, then first-class, then upper, promotion depending upon proficiency and good conduct. The non-commissioned steps are corporal, sergeant, sergeant-major, and special sergeant-major, with specified periods of service in each grade, promotion resting solely upon merit. Officers are recruited from graduates at the Officers' College—to which students go up either directly from one of the six local preparatory schools or the central preparatory school at Tokyo, after passing an examination in either case—but no commission is issued until the Staff Council are satisfied of the candidate's competence and progress. For the higher and specialized training and education of commissioned officers there are several schools, of which the most important is the Army College, in which instruction is given for the superior ranks and staff appointments. Others of these institutions are the Toyama School of Musketry and Strategy, the School of Artillery and Engineers, the Field Artillery School, the Garrison Artillery School, the Cavalry Practical School, the Army Service School, the Army Medical School, the Veterinary School, the Arsenal School, and the School of Military Music. The ranks of officers are, in their order, second-lieutenant, first-lieutenant, captain, major, lieutenant-colonel, colonel, major-general, lieutenant-general, general, and field-marshal. Up to and including the grade of captain, promotion is partly by seniority and partly by merit; but above that rank promotion takes place by merit alone. An officer who never rises beyond his captaincy is compulsorily retired at the age of forty-eight. The pay of a private runs from 1s. 10d. per mensem for a second-class to 3s. 0½d. for an upper soldier; of a non-commissioned officer from 9s. 2d. per mensem for a second-class corporal to

28s. 6d. for a first-class special sergeant-major, besides rations, uniform, and quarters. Officers are paid at rates varying from £34 per annum for a second-lieutenant to £71 for a captain, £115 for a major, £238 for a colonel, and £600 for a general.

Organization.—Taking the army as a whole, it is composed of twelve divisions, numbered 1 to 12, and one division of guards (the Imperial Guard). Each division is commanded by a lieutenant-general, is stationed permanently in an assigned district, comprises four regiments of infantry, one regiment of cavalry, one regiment of field artillery, one battalion of engineers, one battalion of army service, and is in itself a complete fighting unit. An infantry regiment is made up of four battalions of three companies each; a cavalry regiment of either three or four squadrons, with 100 sabres to each; and a field artillery regiment of six batteries of six guns each. A battalion of engineers is composed of three companies, or 600 men; a battalion of army service of 300 men. The normal strength of a division is thus made up, excepting the division of guards, which is somewhat smaller:—

Infantry	9,600
Cavalry	300
Engineers	600
Army Service	300

10,800 men and 36 guns.

Of mountain artillery there are six regiments, or 216 guns in all. The total force of field artillery amounts to seventeen regiments, or 612 guns; whilst the total strength of cavalry stands at about 5000 sabres. Over and above their normal strength, several of the divisions (the Imperial Guard, and the First, Fourth, Fifth, Sixth, Seventh, Tenth, and Twelfth) are furnished with extra corps, mostly of artillery, for the garrisoning of the forts at Tokyo, Yura, Kure, Geiyo, Saseho, Tsushima, Hakodate, Maizuru, and Shimonoseki; the additional complement of the guards consisting of a brigade (two regiments) of cavalry, a brigade (three regiments) of field artillery, and one battalion of railway engineers. The present peace footing may be taken at 100,000 men; but in 1905, when the whole scheme of readjustment will be completed, the *peace strength* will amount to 150,000 men of all ranks and 30,000 horses, the *war strength* to 500,000 men and 100,000 horses. The guards are recruited from every part of the empire; the divisions, from the districts to which they are attached. Formosa is garrisoned by a mixed brigade, supplied by the divisions in rotation, composed of two regiments of infantry, two squadrons of cavalry, three batteries of field artillery, half a battalion of engineers, and half a battalion of army service. Testimony is universal to the exceptional efficiency of the Medical Service Corps, which is distributed in the proportion of 100 surgeons to each division, with a complete equipment for field hospitals, bandaging stations, special hospitals, and the like. There is also a Red Cross Society, in addition to a great hospital at Tokyo, a large staff of trained nurses of both sexes, and two hospital ships designed and furnished for the transport of the wounded. The total cost of the whole army is a trifle over 37,000,000 yen, or £3,700,000 per annum.

Staff.—Supreme control is vested in the emperor, who is the commander-in-chief, but he is actively assisted by a general staff (with a field-marshal for chief and a general or lieutenant-general for vice-chief), the War Office, and a board of field-m Marshals. In addition to the transaction of general business, the general staff supervises the survey, trigonometry, cartography, and topography departments, and directs the Army College. The head of the War Office is a general on the active list, who has *ex officio* a seat in the Cabinet and is not affected by ministerial changes. There is a Tokyo Defence Office, under a lieutenant-general, specially charged with the defence of Tokyo Bay, and similar duties in regard to the other forts are entrusted to three major-generals, with headquarters respectively at Yokohama, Shimonoseki, and Yura. All questions concerning arms and ammunition are referred to expert committees of artillery and engineering, and there is besides a Remount Office. For military purposes the whole empire is divided into eastern, western, and central districts, each under the command of a general or lieutenant-general.

Arms.—Excepting in time of war, the Japanese are able to make all their munitions in the arsenals at Tokyo, Osaka, and Taipeh (Formosa). The infantry carry the repeating rifle designed by Colonel Arisaka, and the field and horse artillery are at present (new weapons, Arisaka pattern, are in hand) equipped with field guns (weight about 6 cwt.) and mountain guns (weight, 2 cwt.) of the same calibre (2·955 inches) and firing similar ammunition, of which the common shell weighs about 9½ lb.

For a full account of the military system under the *ancien régime* and further details about the existing organization, see under JAPAN.

ARMOUR.

I. BODY ARMOUR.

SINCE the publication of the article in the ninth edition of this work on "Arms and Armour," the subject has been closely studied by experts, and is better understood generally than was the case five-and-twenty years ago. The tendency at present is to appreciate beauty of design and excellence in workmanship rather than historic interest

or sentiment. This tendency, which especially exists among Continental collectors, may give place some day to a demand for pieces which speak more directly of the warrior fighting in the field than of the skill of the artificer in the workshop; but the entire value of such pieces depends on their genuine character, and this is more difficult to establish in plain than in elaborate workmanship. Suits of armour which embody both skill and sentiment can hardly

FIG. 1.—Gothic style of armour. Monument of Count Otto IV. von Henneberg.

FIG. 2.—Suit by Jacob Topf, nearly complete; the gorget does not belong to it. Below is the placcote.

fail to be sought after at all times. Of these, putting aside the question of armour known to have belonged to some celebrated man, the suits which are of by far the most value are those few which still remain of the 15th century, commonly called Gothic suits. These are appreciated not only on account of their rarity, but because of their singular beauty in design and excellence of manufacture. A few of these exist in the Tower of London, but the most beautiful suit in England is a mounted one in the Wallace collection. The monument of Count Otto IV. von Henneberg, executed after 1480, furnishes a very good example of 15th-century armour of the highest class. The

photograph from which Fig. 1 was reproduced is from the cast in the South Kensington Museum. The effigy of Earl Richard in Warwick chapel is another beautiful example. Of this Mr Starkey Gardner says that it looks like the work of nature rather than art. Most readers must be familiar with another example in Albert Dürer's print of "the Knight, Death, and the Devil." Armour culminated as to completeness, though it lost in beauty, at the end of the 15th century, when the so-called Maximilian type came in. In this the pointed toe gave place to one of extravagant width. Of this armour many fine examples exist, as the Tower of London includes several suits

which belonged to Henry VIII. Most high-class armour up to this time was made on the European Continent; that represented in the Warwick effigy is Italian, while the armour of Henry VIII. is chiefly German. Fig. 2, however, shows a beautiful suit or half-suit, still extant, which belonged to Sir Christopher Hatton, and was the work of a celebrated English armourer, Jacob Topf. The different classes of armour may be broadly distinguished as follows:—(1) *War harness* was seldom complete for the rider, and little was used on the horse in actual war. On foot, little armour could be worn below the knee—Sir Christopher Hatton's is an example of a very handsome suit for a mounted knight in war. (2) *Tournament armour*.—In the lists, not only would complete armour be used, but additional pieces of special weight. For jousting, the rider required to be quite rigid, in order to deliver the impetus of horse and man in a sharp blow through the end of the lance, so as to strike the adversary out of his saddle, or break the lance. Aim was generally taken at the helm (see a paper by Lord Dillon in the *Archæological Journal*). The rider sat against the cantle of the saddle with straight knees and stirrups home. Hence the helm in the 15th century was a rigid steel case resting on the shoulder. In the 16th this was superseded by extra pieces, chiefly one termed the grand guard or volant piece, protecting the chest and part of the face. (3) For *fighting in the lists on foot*, the armour was eventually carried inside the legs and arms, and under the seat, in plates fitting so closely that a penknife would scarcely find entrance. Of this an admirable example may be seen at the Tower in a suit made for Henry VIII.

The following examples of armour may be specially noted:—

The Tower of London.—The above-mentioned suits of Henry VIII, mounted and dismounted, especially that made by Conrad Seusenhofer; also Leicester's suit; a German tilting saddle in which the rider sat, or rather stood, with his legs in sockets; a few samples of jacks or brigantines, consisting of plates sewn to texture, one on an Elizabethan archer; also, two long bow staves recovered from the *Mary Rose* sunk at Spithead.

The Wallace Collection.—The Gothic suit above mentioned, and many suits possessing their original appearance in unusual measure, owing to careful preservation and gentle cleaning.

The Rotunda Museum, Woolwich.—Armour left behind in a guard-room at Rhodes by the knights on their evacuation in 1522, which constitutes the greatest recent "find." It consists chiefly of salades and 16th-century pieces. The Brocas tilting helm, unsurpassed by any, is also at Woolwich.

Windsor Castle.—Tilting pieces and armour about the close of the 15th century.

Warwick Castle.—Curious old closed chamfron.

Canterbury Cathedral.—Tilting helm, a short surcoat termed a jupon or cyclas, and gauntlets of the Black Prince; the last are perhaps the earliest extant.

Westminster Abbey.—Saddle and shield of Henry V. In the Chapter House is the only known sample of an old English arrow. Most of the armour placed over tombs and in churches is "mortuary," i.e., made specially for the purpose and generally good for nothing, but some beautiful pieces have been thus deposited.

Armour ceased to be used by combatants generally in the 17th century, but it has never been entirely given up, and has in exceptional cases been used up to the present day. The cuirasses worn by heavy cavalry are undoubtedly only used for display—the Life Guards left them behind when they went on active service to Egypt and South Africa; but helmets are retained for protection against sword cuts in hand-to-hand fighting, and it seems unlikely that anything can supersede them. The growing power of fire-arms, however, drove out armour. First, it was given up for the limbs, and thickened so as to be bullet-proof for the breast; when horsemen engaged hand to hand, with pistol and sword, bullet-proof armour must continually have saved life. Breastplates of the 17th century frequently have indentations made by bullets. Some of these are no doubt proof marks, but by no means

all. One pair of plates at Dover Castle has three bullet marks. In the siege of Athlone in 1691, complete armour was worn by a special body of men. Very heavy helmets and back plates were worn by sappers. A picture of the siege of Rome in 1848 shows a sapper in a special helmet worn for protection under fire. Hard steel breastplates were produced by Dowe, Maxim, and others in 1894. They stopped modern bullets, but weighed over ten pounds, which is too heavy for wear. Still, portable shields might be used in siege works, and steel shields are employed on gun-carriages and mountings. Against sword cuts, especially the sharp draw-cuts of an Eastern blade, mail is an efficient protection. Dervish warriors wore mail in the battle of Omdurman in 1898. Mail has been recently applied to the shoulders of the British cavalry, and one incident showing the value of mail may be recorded. In Egypt in 1885 an officer's wife purchased a patch of chain mail, which she insisted in sewing inside the breast of the uniform worn by her husband, a lieutenant of the 5th Bengal Cavalry. This regiment was engaged hand to hand shortly afterwards, and a spear-thrust aimed at his breast was stopped by the mail; he came out unharmed, with the spear-head broken off and hanging in it. Lastly, mail has been specially made of hard steel rings for gold-diggers, and the English detective department possesses such mail for wearing, if needed, inside a coat.

II. SHIPS AND FORTS.

The fact that armour for the defence of the soldier's body had failed to resist musket balls, and had gone out of use, probably tended to prevent its being proposed and tried on a larger scale for the protection of ships and forts. Nevertheless experiments were made with regard to both in the United States in 1812, 1841, and 1853, and in England in 1827 and 1840. In 1855 the French employed floating batteries at Kinburn; and before the end of the Prussian war both France and Great Britain had iron-plated batteries afloat. The British *Warrior* and French *Gloire* classes were ordered in 1858, and the United States coast vessels, termed monitors, were begun in 1861. The future use of armoured ships was indeed assured by the havoc wrought among unarmoured vessels by the Confederate ship *Merrimac*, protected by impromptu armour made of railway iron rails. The application of armour plates to vessels is dealt with under *SHIP CONSTRUCTION*, the object of the present article being to trace the development of the actual armour itself, whether intended for ships, coast defences, or inland forts.

For many years after the introduction of armour neither plate nor shot gave promise of the powers since attained. The shock of impact shattered or flattened the shot, and the harder plates were fractured to such an extent that wrought iron was adopted. For many years the only improvements made consisted in rolling plates of increased thickness and size, and in employing with them such bolts and backing as best enabled them to bear attack. Thus plates were applied in several thicknesses, sandwiched with thin layers of wood between them, and the so-called "Palliser English" bolt was introduced, ingeniously devised to avoid nipping and local strain, with a spherical head which accommodated itself to any slight displacement of the plate. This soft armour encouraged the development of hardness rather than toughness of shot; consequently, although steel projectiles held together better than those of cast iron, the latter, when made on Palliser's system with points and heads hardened by chilling, penetrated so well that they were largely adopted by all Powers, and no fundamental change either in shot or armour took place in naval armaments till 1876. In 1868, however, an entirely new form of armour for land defences had been devised,

which, although it has never attracted much attention in England, is used almost universally in European coast forts. It was proposed and made by Gruson of Magdeburg, and consists of massive shields of chilled cast iron, which are easily made of any required form. No backing or bolts are used, the shield being built up of heavy blocks, if possible cast on the spot, which are keyed together, and constitute the entire parapet (see Fig. 3). The metal can be made

Fig. 3.

of thickness varying according to the supposed needs of each part of face or roof, and the breech-loading ordnance, at that time existing on the Continent, but not in England, allowed the use of shields sloping down forward at the gun forts in curves well adapted to cause shot to glance off them.

In British coast forts vertical walls were adopted, covered with wrought-iron plates, either applied in a single thickness, or in successive layers sandwiched with wood or concrete (see Fig. 4). Thus British coast

Fig. 4.

armour differed fundamentally from that employed by other nations, and this difference is maintained to the present time. These two kinds of coast shields deserve attention as furnishing examples of the opposite extremes in character, and as justifying the classification of armour plates into "soft" and "hard" kinds, a distinction which must be kept in view in order to understand the power of artillery fire, and the behaviour of armour when attacked

by it. Soft armour plates, such as those of good wrought iron, do not break under the impact of shot, but yield by perforation. Thus a projectile with sufficient striking energy passes through soft armour, making a more or less clean hole, but leaving the plate practically as strong as before. A shot, however, that fails to perforate, effects nothing, lodging harmlessly in the shield. Hard armour, on the other hand, of which chilled iron furnishes the most extreme example, refuses to yield by perforation, and breaks up the shot on impact; but it gradually becomes disintegrated, the whole mass before long parting in fragments. Hard armour offers a complete defence against a few rounds from very heavy guns, men and ordnance covered by it being entirely protected until their shield is destroyed. On this account chilled iron shields have been used to protect coast artillery from the few rounds that the heavy guns of men-of-war may be expected to deliver during an attack of limited duration. Notable examples of Gruson's shields and forts are the St Marie battery near Antwerp (see Fig. 3), cupolas at the entrance of the Weser near Bremerhaven, and two turrets defending Spezia harbour, each mounting two 119-ton Krupp guns (see Fig. 5). The joints shown in this figure indicate that the

Fig. 5.

turret roof is built up of fifteen sector-shaped pieces and two centre plates of semicircular form. Before adoption a sector piece was subjected to three blows from projectiles fired from an Elswick 100-ton breech-loading gun. A fourth round indeed was afterwards delivered, as well as some rounds from 15-cm. (5.9 in.) guns. This shield was fractured in several directions, but the fragments remained *in situ*, and the defensive power of the shield was probably but little diminished, and would continue until some large fragments should become displaced. Soft armour, until recently best exemplified by wrought iron, but now by soft nickel steel, exhibits its capacity most fully in inland fortifications, where it may be called upon to resist the breaching attack of siege guns of such limited weight and power as not to be able to perforate it completely. First-class soft armour might bear such an attack for hours and days, or perhaps even for weeks. The continued breaching attack of inland forts by siege guns of limited weight, and the brief attack of coast shields by the very heavy guns of battleships, illustrate the conditions which bring out most completely the powers of soft and hard armour. Between these lie innumerable

cases; for example, the armoured belt of a cruiser and that of a battleship. The former is the thinner, and more liable to be overmatched by a shot, but a cruiser is not likely to be long exposed to attack. The thick belt of a battleship is less likely to be overmatched, but the vessel is more likely to be kept in continuous close action; consequently the belt of the cruiser might preferably be made harder than that of the battleship; and though such a distinction has never been recognized, and may be regarded as a refinement, it may have had influence, especially in retarding the adoption of nickel in medium armour, noticed hereafter. The power of guns to destroy hard and soft armour is greatly affected by the fact that the former requires to be shattered, the latter perforated. So far as the shot holds together on impact, shattering depends on its striking energy, while perforation depends directly on the energy, but nearly inversely on the calibre of the shot and consequent size of hole to be made. Thus for many years a new type 6-inch and an old type 10-inch gun were on board the *Nettle* at Portsmouth. The energy of the latter was about double that of the former, and its shattering power was probably proportionately greater, *i.e.*, about double; but its velocity was less, and the perforating power of the two projectiles was nearly the same. Thus against Gruson's shields the old heavy gun would deliver far the heavier blow, while the new type light gun would perforate any ship's side that was open to the attack of the 10-inch gun.

As noticed above, British coast armour is made of wrought iron, and is consequently liable to some evils from which Gruson's chilled iron is free; that is to say, it is conceivable that it might be perforated, though it is made thick enough to make this unlikely. Bolts might fly under a heavy blow, and injury might be done by these and other pieces of metal, or debris forming what is termed "longridge." On the other hand, the plate upon plate or sandwich system lends itself to future alterations and additions that are impossible with Gruson's armour, which has finality stamped on it, and might become a troublesome hindrance. Every preparation is, in fact, made for the addition of extra front plates to the armour on British coast forts, which can be removed, altered, or strengthened with the least conceivable labour. The best armour now made is intermediate between hard and soft, but generally yields by perforation more than fracture. Steel armour plates, although tried from time to time, long proved brittle, and gave little promise of success. In October 1876, however, was commenced at Spezia a series of trials which undoubtedly led to the immediate adoption of steel in one or another form by the principal Powers. In these trials targets representing the proposed belts of the Italian battleships *Duilio* and *Dandolo* (then under construction) were erected. All were made of the same thickness, *i.e.*, nearly 22 inches of metal, but differed in the fact that iron and steel were used by different makers. These shields were attacked first by 10-inch, and subsequently by 17.72 inch (100-ton) guns. The lighter projectiles lodged harmlessly in the soft iron, but produced serious cracks and fractures in the steel. On the other hand, the enormous 2000-lb projectiles of the 100-ton gun passed through the wrought-iron plates very easily, while the steel plates stopped them, though at the cost of their own complete destruction. The resisting power of steel was seen to be so disproportionate to that of iron that its adoption in some form was a mere question of time. In England the liability to fracture was thought so objectionable that great efforts were made to secure toughness in some form; and the Sheffield makers, Cammell and Brown, brought forward what are termed compound or hard-faced plates, each kind consisting of a hard steel face cemented to a

soft wrought-iron back or foundation. This armour possessed the advantage of a harder face than "all steel" plates of that date, combined with a tenacious back, and was adopted and largely made on the Continent; but long courses of competitive trials eventually proved that the "all steel" plates made by Schneider, and subsequently by other makers, were superior to the compound, mainly because the soft wrought-iron foundation gave insufficient support, though in one trial at Shoeburyness when fixed on granite a remarkable result was obtained.

In 1890 important competitive experiments in Russia and America brought out the value of two features of an entirely different character: first, a hard surface, and secondly, the ingredient nickel in steel. These are so important that they deserve to be dealt with separately.

The steel face of the compound plate was, as above noticed, harder than that of early "all steel," but this hardness was due to the employment of a front plate of harder steel throughout its mass than was deemed suitable for the foundation. Efforts were now made to impart excessive hardness to the actual surface or skin of a plate by the application of water-jets on a system proposed by Captain Tresidder, who found that water thus projected against hot metal came in actual contact with it, and produced a degree of hardness which was prevented in ordinary plunging by the formation of steam. About the same time Harvey in America perfected a process of carbonization applied to the front of armour plates. This could be extended to some inches in depth, and with it was associated an application of water to the face, but of a less perfect kind than on the Tresidder plan. It was found that a shot which would perforate a plate with an ordinary untreated face might be completely broken and defeated by a very hard skin. Successful resistance apparently depends on the fracture of the shot point or extreme tip on first contact. On the fracture of the tip, penetration becomes much more difficult, while the shot is still laterally unsupported, so that the latter may break outwards on the same principle as an arch may yield laterally under pressure applied to the centre. Palliser chilled shot indeed often broke on ordinary plates so completely that white radiating splashes were made by the minute particles flying across the plate face. At the date when Harvey and Tresidder plates came in steel projectiles had superseded those of chilled iron. These steel projectiles had tough bodies, with heads hardened by water or oil, and combined the penetration possessed by a hard point with considerable power to remain intact, so that steel shot would strike an ordinary steel plate at a fairly high velocity, penetrate to a considerable depth (perhaps more than a calibre), then bound back a long way towards the firing point, and yet suffer such inappreciable deformation or internal injury as to be capable of being repeatedly fired at armour, and of repeatedly behaving in the manner described.

On faces hardened by the Harvey and Tresidder processes, which soon became combined, excellent steel projectiles not only broke, but became so completely disintegrated at times that the white splash mentioned as characteristic of the defeat of chilled iron shot was seen; and a very curious device has been adopted to enable the shot to hold together, namely, a wrought-iron or steel cap applied to the shot point. It had been discovered accidentally at Shoeburyness in 1877 that a chilled shot which was defeated by a certain compound shield would perforate it when an additional plate of wrought-iron $2\frac{1}{2}$ inches thick was added in front of the shield, the explanation being that the additional resistance afforded by this soft plate by no means compensated for the fact that the shot point entered easily, and was well supported and saved from fracture before it encountered the steel. Colonel

(then Lieutenant) English suggested that a wrought-iron cap on the shot point might give the same result. This did not prove successful with compound plates, but when the experiment took place with very much harder, but necessarily thin, water-hardened skins in Russia in 1894, the same device of iron or steel caps was tried with success. Similar results have been obtained since in America and England, and it is probable that such caps may be used in actual war. Fig. 6 (see Plate) shows the back of a plate of Beardmore's recently attacked. A capped shot point nearly bored its way through, opening the metal in a star-shaped tear at 7. Uncapped shot were set up, and acted as punches, partially dislodging discs of plate, as seen at 2, 3, and 5. Harveyed armour was adopted in Great Britain in 1892.

Fig. 10.

In 1890 a Schneider 10½-inch steel plate, containing nickel, behaved well at Annapolis under the attack of 6-inch and 8-inch guns, exhibiting great toughness, and nickel was introduced soon afterwards in American armour. In England considerable delay took place, because nickel plate, till thoroughly understood, appeared to be capricious in its behaviour, and the supply of armour was then being pressed forward to meet the demands arising from the increase in the British Navy. Nickel was, however, adopted in 1896. As above mentioned, nickel used with judgment imparts toughness to armour without interfering with face hardening. Fig. 7 (see Plate) shows the front of a good specimen of unhardened 6-inch Krupp nickel plate after attack by 12, 15, and 17 cm. (4·7, 5·9, and 6·7 inch) guns. A fringed lip, characteristic of soft steel, rises up round each shot hole, but no cracking is visible; the projectiles have rebounded from their holes owing to the elasticity of plate and shot. This plate is the *beau idéal* of armour for inland forts. Krupp had manufactured armour for some little time, but first became known as the inventor of a special process at the World's Fair in Chicago in

1893, where he exhibited a plate which had borne very severe attack admirably. In 1895 a series of experiments took place with Krupp process armour, in which remarkable results were obtained, the most important being that shown in Fig. 8 (see Plate), which depicts the front of a plate 11·8 inches thick after attack by three 12-inch projectiles. These have broken, leaving their heads lodged in the plate without cracking it. The highest striking velocity was 1993 feet per second. The shot weighed 712·7 lb, and it would have perforated an iron plate 25·9 inches thick. The remarkable feature is the scale on which this success was achieved; for while a 12-inch plate may resist perforation by a 12-inch shot nearly as well as a 6-inch plate resists that of a 6-inch shot, the strain in the way of fracture greatly increases in the thicker plate, for the width of the thick plate is often not very much greater than that of the thin one. In these trials the 12-inch plate was about 6 feet wide, and the 6-inch nearly 5 feet, so that while the 6-inch shot head formed a wedge little more than one-tenth of the width of the plate attacked, the 12-inch plate was attacked with a wedge nearly one-sixth of its width. The figure indeed shows what enormous wedges are driven into the plate, and the excellence of metal bearing such a strain is apparent. At the end of 1896 the three great Sheffield armour-making firms, Brown, Cammell, and Vickers, purchased Krupp's process. Fig. 9 (see Plate) shows an admirable 6-inch plate submitted by Vickers for trial in March 1897. This entirely defeated the attack of six 6-inch projectiles striking with a velocity of about 1960 feet per second. All the armour at present made for the British Navy is practically on the Krupp process, although modifications may be introduced by each firm based on their own experience. Messrs Beardmore in Scotland have recently made armour by a process of their own, of about the same quality as Harveyed armour.

Excellent armour-piercing projectiles are made by Elswick on the American Wheeler Sterling patent, and Elswick and Firth have made large deliveries of shot on Firminy's patent. Many years ago Whitworth steel shot stood first in quality. Holtzer's subsequently became best known, and have been used so universally as to furnish a sort of standard of comparison. Krupp makes excellent projectiles, so does the firm of St Chamond. Carpenter shot in America are hardly inferior to those of Wheeler Sterling, or to a notable shot recently made by Johnson. The latter have probably obtained the greatest known penetration, but as they are generally made solid and fired with caps, comparison with others is difficult. In England Hadfields deserve special notice as having by special processes developed admirable projectiles, and especially as having made cast steel of a quality rivalling good forged steel. Lastly, the Royal Laboratory has also made excellent armour-piercing projectiles.

Before leaving the subject of the behaviour of armour under fire, one or two rough rules of thumb, which are based on calculation, may be given. The thickness of wrought iron which a projectile may perforate is about one calibre for each 1000 feet of striking velocity; that is to say, a 6-inch shot with 2000 feet velocity may perforate two calibres or 12 inches of iron, with 1500 feet it may perforate 9 inches, and so on. The equivalent thickness of the best steel plate now known is rather less than half that of wrought iron, so that a 6-inch shot will require something over 2000 feet velocity to perforate 6 inches of treated steel, while 1000 feet velocity will hardly carry it through 3 inches.

Attempts have been made to destroy armour by shells containing powder and high explosives, but hitherto it may be said that unless the projectile gets its head well

Fig. 6.

Fig. 7.

Fig. 8.

Fig. 9.

TESTS OF ARMOUR PLATES (see p. 672).

into the plate before explosion takes place, the effect is small. Consequently only those shells whose calibre considerably exceeds the thickness of the armour attacked can be used with good effect, and the preponderance should be greater with high explosives than with powder. In consequence of the destructive effect of shells charged with melinite and other high explosives on stone or earthworks, armoured structures have been adopted for inland defences on the Continent. These generally take the forms of cupolas and shielded mountings, which may be fixed, disappearing, or even portable. Fig. 10 shows a disappearing shielded mounting. The gun is protected by a steel armoured curved roof A, fixed on a central pillar Bd and DE, on which the whole system revolves. The gun is shown in action, the weight being held up by a counter-weight G at the end of a lever Fh. The gun can be run back inside the port, and the roof lowered to rest flush with the "glacis plate" or "vorpanser" CH. When thus taken out of action the gun is hardly open to attack of any kind.

With regard to manufacture, the newest and most interesting processes depend on delicate methods of treatment, which are carefully kept secret, so that information of a general character only can be given. Wrought iron is formed from scrap worked into slabs, and piled and rolled in so many successive processes that an 8-inch plate was said to have been rolled out of a column nearly 100 feet high. Specially soft fibrous iron was used. It was considered not only that great power of drawing out, but of doing so easily was necessary, because some metal, which might draw out well slowly, might tear in preference under a blow. Steel has been used of all descriptions, from something closely resembling wrought iron to really hard metal. Molecular displacement occurs round the

point of impact, and metal becomes heaped up and heated, and cracking may take place many minutes after impact. In Fig. 7 may be noticed round each point of impact a concentric circle of lighter shade than the rest of the plate, which extends gradually, and has been likened to the swelling of a black eye. Badly-made plates have been known to break spontaneously, and steel shot have done the same. Compound armour was made by running molten steel on to a white hot foundation plate of rolled wrought iron on Wilson's process, or by attaching a thin steel face plate to a wrought-iron foundation by running molten steel in between them on Ellis's process. In the Harvey process the face is carbonized by contact with carbon at a high temperature, kept up for several days, the face being finally water-hardened. There is some difficulty in bringing such plates to the exact curve required for the ship's side, because face hardening causes contortion. It is possible to flatten a plate slightly by compressing the hard face, but not to bend it further by stretching it. Until recently, armour under 5 inches thick could not be Harveved, because contortion could not be controlled. In the Krupp process carbonization may be produced by the action of gas, but not necessarily so. Some of the stages of manufacture require much experience, so that great expense and waste of material are apt to be involved in first adopting the process, especially with thick plates. It is said that in this process metal is at times used which would be expected to prove brittle, but which, after being subjected to treatment that would be likely to render it still worse, is eventually made very tough. Up to the present it has probably owed some of its qualities to the presence of nickel. It has been said that nickel would be dispensed with, but such reports have hitherto been contradicted. (c. o.-B.)

Armstrong, William George Armstrong, BARON (1810-1900), British inventor and founder of the Elswick manufacturing works, was born on 26th November 1810, at Newcastle-on-Tyne, and was educated at a school in Bishop Auckland. The profession which he adopted was that of a solicitor, and for a number of years he was engaged in active practice in Newcastle as a member of the firm of Donkin, Stable, & Armstrong. His sympathies, however, were always with mechanical and scientific pursuits, and several of his inventions date from a time anterior to his final abandonment of the law. In 1840 he published a paper on the electricity of effluent steam. This subject he was led to study by the experience of a colliery engineman, who noticed that he received a sharp shock on exposing one hand to a jet of steam issuing from a boiler with which his other hand was in contact, and the inquiry was followed by the invention of the "hydro-electric" machine, a powerful generator of electricity, which was thought worthy of careful investigation by Faraday. The question of the utilization of water-power had engaged his attention even earlier, and in 1838 he made his first contribution to hydraulic engineering by inventing a rotary water motor. Soon afterwards he designed a hydraulic crane, which contained the germ of all the hydraulic machinery for which he and Elswick were subsequently to become famous. This machine depended simply on the pressure of water acting directly in a cylinder on a piston, which was connected with suitable multiplying gear. In the first example, which was erected on the quay at Newcastle in 1846, the necessary pressure was obtained from the ordinary water mains of the town; but the merits and advan-

tages of the device soon became widely appreciated, and a demand arose for the erection of cranes in positions where the pressure afforded by the mains was insufficient. Of course pressure could always be obtained by the aid of special reservoirs, but to build these was not always desirable, or even practicable. The first way in which Armstrong attempted to meet the difficulty was by the use of an air vessel, but this did not prove very satisfactory in the few cases in which it was tried. Hence, when in 1850 a hydraulic installation was required for a new ferry station at New Holland, on the Humber estuary, the absence of water mains of any kind, coupled with the prohibitive cost of a special reservoir owing to the character of the soil, impelled him to invent a fresh piece of apparatus, the "accumulator," which consists of a large cylinder containing a piston that can be loaded to give any desired pressure, the water being pumped in below it by a steam-engine or other prime mover. This simple device may be looked upon as the crown of the hydraulic system, since by its various modifications the installation of hydraulic power became possible in almost any situation. In particular, it was rendered practicable on board ship, and its application to the manipulation of heavy naval guns and other purposes on warships was not the least important of Armstrong's achievements.

The Elswick works were originally founded for the manufacture of this hydraulic machinery, but it was not long before they became the birthplace of a revolution in gunmaking; indeed, could nothing more be placed to Armstrong's credit than their establishment, his name would still be worthy of remembrance, for they have contributed enormously to the progress of the world in the

mechanical arts, both of war and of peace. Modern artillery dates from about 1856, when Armstrong's first gun made its appearance. Of this weapon it may be affirmed that it embodied all the essential features which distinguish the ordnance of to-day from the cannon of the Middle Ages—it was built up of rings of metal shrunk upon an inner steel barrel; it was loaded at the breech; it was rifled; and it threw, not a round ball, but an elongated projectile with ogival head. Big guns, as Armstrong found them, were really nothing more than blocks of metal bored with a circular hole, their makers generally working on the assumption that their strength was proportionate to the thickness of the walls of the tube. But he saw that the greatest resistance to bursting was not to be obtained from a given weight of metal in this fashion, since the inner portions of the material composing a cylinder, which is subjected to high internal pressure, may be strained beyond the bursting-point before the outer ones have reached it. Hence he adopted the "shrinkage" principle of construction. Starting with a steel tube to form the barrel, he made a homogeneous cylindrical jacket by winding a bar of wrought-iron round a mandril slightly smaller than the barrel, and welding the turns together. This, when cold, was naturally too small to pass over the barrel; it could, however, be slipped on if expanded by heat, and, if it were then allowed to cool, its contraction brought about a condition of compression in the metal forming the inner layers of the gun, together with one of tension in those composing the outer ones, which theory indicated would offer the most advantageous disposition of metal as regards resistance to bursting. The guns which Armstrong constructed on this principle yielded such excellent results, both in range and accuracy, that they were adopted by the British Government in 1859, he himself being appointed Engineer of Rifled Ordnance and receiving the honour of knighthood. Great Britain thus originated a principle of gun construction which has since been universally followed, and obtained an armament superior to that possessed by any other country at that time. But while there was no doubt as to the shooting capacities of these guns, defects in the breech mechanism soon became equally patent, and in a few years caused a reversion to muzzle-loading. Armstrong resigned his position in 1863, and for seventeen years the Government's expert advisers remained faithful to the older method of loading, refusing to see the improvements which experiment and research at Elswick and elsewhere had during that period produced in the mechanism and performance of heavy guns. But at last Armstrong's results became too good to be ignored; and the official eye being no longer able to blink the fact that his long breech-loaders possessed advantages unobtainable with the obsolete type of muzzle-loaders, breech-loading guns were received back into the service in 1880. It should be mentioned that the use of steel wire for the construction of guns was also one of Armstrong's early ideas. He perceived that to coil many turns of thin wire round an inner barrel was a logical extension of the large hooped method already mentioned, and in conjunction with Brunel, the engineer, was preparing to put the plan to practical test when the discovery that it had already been patented caused him to abandon his intention for many years. This incident well illustrates the ground of his objection to the British system of patent law, which he looked upon as calculated to stifle invention and impede progress; the patentees in this case did not manage to make a practical success of their invention themselves, but the existence of prior patents was sufficient to turn him aside from a path which conducted him to valuable results, when afterwards, owing to the expiry of those patents, he was free to pursue it as he pleased.

Lord Armstrong, who was raised to the peerage in 1887, was the author of *A Visit to Egypt* (1873) and *Electric Movement in Air and Water* (1897), besides many professional papers. He died on 27th December 1900, at Rothbury, Northumberland. (H. M. R.)

Arnhem, the chief town of the province of Gelderland, Netherlands, 9 miles N. by E. of Nimeguen. Population, 31,626 in 1870, 56,812 in 1900. This increase is due to the beautiful situation of the town on the slope of the Veluwe Hills, its proximity to the fertile Betuwe district, the meeting of the Rhine and Ysel near the town, and its flourishing markets and shipping. A new Roman Catholic Church was founded in 1894; in 1880 a building to contain the archives was erected, and in 1893 an hospital. The large assembly hall (*Musis Sacrum*) was rebuilt in 1889, and the gasworks in 1892-3. A wharf for building and restoring iron steamers was constructed on the Rhine in 1889.

Arnim, Harry Karl Kurt Eduard von, COUNT (1824-1881), German diplomatist, was a member of one of the most numerous and most widely spread families of the Prussian nobility. He was born in Pomerania on the 3rd of October 1824, and brought up by his uncle Henry von Arnim, who was Prussian ambassador at Paris and foreign minister from March to June 1848, while Count Arnim of Boytzenburg, whose daughter Harry von Arnim afterwards married, was minister-president. It is noticeable that the uncle was brought before a court of justice and fined for publishing a pamphlet directed against the ministry of Manteuffel. After holding other posts in the diplomatic service Arnim was in 1864 appointed Prussian envoy, and in 1867 envoy of the North German Confederation at the Papal Court. In 1869 he proposed that the Governments should appoint representatives to be present at the Vatican Congress, a suggestion which was rejected by Bismarck, and foretold that the promulgation of papal infallibility would bring serious political difficulties. After the recall of the French troops from Rome he attempted unsuccessfully to mediate between the pope and the Italian Government. He was appointed in 1871 German commissioner to arrange the final treaty with France, a task which he carried out with such success that in 1871 he was appointed German envoy at Paris, and in 1872 received his definite appointment as ambassador, a post of the greatest difficulty and responsibility. Differences soon arose between him and Bismarck; he wished to support the Monarchical party which was trying to overthrow Thiers, while Bismarck ordered him to stand aloof from all French parties; he did not give that implicit obedience to his instructions which Bismarck required. Bismarck, however, was unable to recall him because of the great influence which he enjoyed at court and the confidence which the emperor placed in him. He was looked upon by the Conservative party, who were trying to overthrow Bismarck, as his successor, and it is said that he was closely connected with the court intrigues against the chancellor. In the beginning of 1874 he was recalled and appointed to the embassy at Constantinople, but this appointment was immediately revoked. A Vienna newspaper published some correspondence on the Vatican council, including confidential despatches of Arnim's, with the object of showing that he had shown greater foresight than Bismarck. It was then found that a considerable number of papers were missing from the Paris embassy, and on 4th October Arnim was arrested on the charge of embezzling state papers. This recourse to the criminal law against a man of his rank, who had held one of the most important diplomatic posts, caused great astonishment. His defence was that the

papers were not official, and he was acquitted on the charge of embezzlement but convicted of undue delay in restoring official papers and condemned to three months' imprisonment. On appeal the sentence was increased to nine months. Arnim avoided imprisonment by leaving the country, and in 1875 published anonymously a pamphlet entitled "Pro Nihilo," in which he attempted to show that the attack on him was caused by Bismarck's personal jealousy. For this he was accused of treason, insult to the emperor, and libelling Bismarck, and in his absence condemned to five years' penal servitude. From his exile in Austria he published two more pamphlets on the ecclesiastical policy of Prussia, "Der Nuntius Kommt" and "Quid faciamus nos?" He made repeated attempts, which were supported by his family, to be allowed to return to Germany in order to take his trial afresh on the charge of treason; his request had just been granted when he died on the 19th of May 1881.

In 1876 Bismarck carried an amendment to the criminal code making it an offence punishable with imprisonment or a fine up to £250 for an official of the Foreign Office to communicate to others official documents, or for an envoy to act contrary to his instructions. These clauses are commonly spoken of in Germany as the "Arnim paragraphs." (J. W. HE.)

Arnold, Sir Edwin (1832—), British poet, orientalist, and man of letters, was born on 10th June 1832 and educated at King's College, London, and University College, Oxford, where in 1852 he gained the Newdigate prize for a poem on Belshazzar's Feast. He spent some years in India as principal of the Government Sanscrit College, Poona, and upon his return in 1861 became connected with the *Daily Telegraph* newspaper, upon whose editorial staff he has ever since held an important position. He is nevertheless best known for his travels in India and Japan, and his endeavours to introduce Eastern thought to Europeans by a succession of works in prose and verse on Oriental subjects, both original and translated. The best known of these, *The Light of Asia*, an epical poem on the life and teaching of Buddha, entirely derived from native sources, has gone through more than sixty English and eighty American editions since its first publication in 1879. His other principal volumes of poetry are *With Sa'di in the Garden*, *The Light of the World*, *Potiphar's Wife*, *Adzuma*. In 1877, on the proclamation of Queen Victoria as Empress of India, the Companionship of the Star of India was conferred upon him; and in 1888 he was created K.C.I.E.

Arnold, Matthew (1822-1888), English poet, literary critic, and inspector of schools, was born at Laleham, near Staines, 24th December 1822. When it is said that he was the son of the famous Dr Arnold of Rugby, and that Winchester, Rugby, and Balliol College, Oxford, contributed their best towards his education, it seems superfluous to add that, in estimating Matthew Arnold and his work, training no less than original endowment has to be considered. A full academic training has its disadvantages as well as its gains. In the individual no less than in the species the history of man's development is the history of the struggle between the impulse to express original personal force and the impulse to make that force bow to the authority of custom. Where in any individual the first of these impulses is stronger than usual, a complete academic training is a gain; but where the second of these impulses is the dominant one, the effect of the academic habit upon the mind at its most sensitive and most plastic period is apt to be crippling. In regard to Matthew Arnold, it would be a bold critic of his life and his writings who should attempt to say what

his work would have been if his training had been different. In his judgments on Goethe, Wordsworth, Byron, Shelley, and Hugo, it may be seen how strong was his impulse to bow to authority. On the other hand, in Arnold's ingenious reasoning away the conception of Providence to "a stream of tendency not ourselves which makes for righteousness," we see how strong was his natural impulse for taking original views. The fact that the very air Arnold breathed during the whole of the impressionable period of his life was academic is therefore a very important fact to bear in mind.

In one of his own most charming critical essays he contrasts the poetry of Homer, which consists of "natural thoughts in natural words," with the poetry of Tennyson, which consists of "distilled thoughts in distilled words."

MATTHEW ARNOLD.

(From a photograph by Elliott and Fry, London.)

"Distilled" is one of the happiest words to be found in poetical criticism, and it may be used with equal aptitude in the criticism of life. To most people the waters of life come with all their natural qualities—sweet or bitter—undistilled. Only the ordinary conditions of civilization, common to all, flavoured the waters of life to Shakespeare, to Cervantes, to Burns, to Scott, to Dumas, and those other great creators whose minds were mirrors—broad and clear—for reflecting the rich drama of life around them. To Arnold the waters of life came distilled so carefully that the wonder is that he had any originality left. A member of the upper stratum of that "middle class" which he despised, or pretended to despise—the eldest son of one of the most accomplished as well as one of the most noble-tempered men of his time—Arnold from the moment of his birth drank the finest distilled waters that can be drunk even in these days. Perhaps, on the whole, the surprising thing is how little he suffered thereby. Indeed, those who had formed an idea of Arnold's personality from their knowledge of his "culture," and especially those who had been delighted by the fastidious and feminine delicacy of his prose style, used to be quite bewildered when for the first time they met him at a dinner-table or in a friend's smoking-room. His prose was so self-conscious that what people expected to find in the writer was the Arnold as he was conceived by certain "young lions" of journalism whom he satirized—a somewhat over-cultured *petit-maitre*—almost, indeed, a coxcomb of letters. On the other hand, those who had been

captured by his poetry expected to find a man whose sensitive organism responded nervously to every uttered word as an Æolian harp answers to the faintest breeze. What they found was a broad-shouldered, manly—almost burly—Englishman with a fine countenance, bronzed by the open air of England, wrinkled apparently by the sun, wind-worn as an English skipper's, open and frank as a fox-hunting squire's—and yet a countenance whose finely chiselled features were as high-bred and as commanding as Wellington's or Sir Charles Napier's. The voice they heard was deep-toned, fearless, rich, and frank, and yet modulated to express every nuance of thought, every movement of emotion and humour. In his prose essays the humour he showed was of a somewhat thin-lipped kind; in his more important poems he showed none at all. It was here, in this matter of humour, that Arnold's writings were specially misleading as to the personality of the man. Judged from his poems, it was not with a poet like the writer of "The Northern Farmer," or a poet like the writer of "Ned Bratts," that any student of poetry would have dreamed of classing him. Such a student would actually have been more likely to class him with two of his contemporaries between whom and himself there were but few points in common, the "humourless" William Morris and the "humourless" Rossetti. For, singularly enough, between him and them there was this one point of resemblance: while all three were richly endowed with humour, while all three were the very lights of the sets in which they moved, the moment they took pen in hand to write poetry they became sad. It would almost seem as if, like Rossetti, Arnold actually held that poetry was not the proper medium for humour. No wonder, then, if the absence of humour in his poetry did much to mislead the student of his work as to the real character of the man.

After a year at Winchester, Matthew Arnold entered Rugby School in 1837. He early began to write and print verses. His first publication was a Rugby prize poem, *Alaric at Rome*, in 1840. This was followed in 1843, after he had gone up to Oxford in 1840 as a scholar of Balliol, by his poem *Cromwell*, which won the Newdigate prize. In 1844 he graduated with second-class honours, and in 1845 was elected a fellow of Oriel College, where among his colleagues was A. H. Clough, his friendship with whom is commemorated in that exquisite elegy *Thyrsis*. From 1847 to 1851 he acted as private secretary to Lord Lansdowne; and in the latter year, after acting for a short time as assistant-master at Rugby, he was appointed to an Inspectorship of Schools, a post which he retained until two years before his death. He married, in June 1851, the daughter of Mr Justice Wightman. Meanwhile, in 1848, appeared *The Strayed Reveller, and other Poems, by A.*, a volume which gained a considerable esoteric reputation. In 1852 he published another volume under the same initial, *Empedocles on Etna*—as undramatic a poem, perhaps, as was ever written in dramatic form, but studded with lyrical beauties of a very high order. Other poems accompanied this. In 1853 Arnold published a volume under his own name. This consisted partially of poems selected from the two previous volumes. A second series of poems was published in 1855. So great was the impression made by these in academic circles that in 1857 Arnold was elected professor of poetry at Oxford, and he held the chair for ten years. In 1858 he published his classical tragedy, *Merope*. Nine years afterwards his *New Poems* were published. While he held the Oxford professorship he published several series of lectures, which gave him a high place as a scholar and critic. The essays *On Translating Homer*, published in 1861, and *On the Study of Celtic Literature*, published in 1867, were full of subtle and brilliant

if not of profound criticism. So were the two series of *Essays in Criticism*, the first of which appeared in 1865, and the second, edited by Lord Coleridge, in 1888. His poetic activity almost ceased after he left the chair of poetry at Oxford. He was several times sent by Government to make inquiries into the state of education in France, Germany, Holland, and other countries; and his reports, with their thorough-going and searching criticism of Continental methods, as contrasted with English methods, showed how conscientiously he had devoted some of his best energies to the work.¹ In 1883

¹ The following appreciation of Arnold's educational work is kindly contributed by Sir Joshua Fitch, one of his colleagues in the Education Office:—

The fame of Matthew Arnold as a poet and a literary critic has somewhat overshadowed the fact that he was during thirty-five years of his life—from 1851 to 1886—employed in the Education Department as one of H.M. Inspectors of Schools. His literary work was achieved in such intervals of leisure as could be spared from the public service. At the time of his appointment the Government, by arrangement with the religious bodies, entrusted the inspection of schools connected with the Church of England to clergymen, and agreed also to send Roman Catholic inspectors to schools managed by members of that communion. Other schools—those of the British and Foreign Society, the Wesleyans, and undenominational schools generally—were inspected by laymen, of whom Arnold was one. There were only three or four of these officers at first, and their districts were necessarily large. It is to the experience gained in intercourse with Nonconformist school managers that we may attribute the curiously intimate knowledge of religious sects which furnished the material for some of his keen though good-humoured sarcasms. The Education Act of 1870, which simplified the administrative system, abolished denominational inspection, and thus greatly reduced the area assigned to a single inspector. Arnold took charge of the district of Westminster, and remained in that office until his resignation, taking also an occasional share in the inspection of training colleges for teachers, and in conferences at the central office. His letters, *passim*, show that some of the routine which devolved upon him was distasteful, and that he was glad to entrust to a skilled assistant much of the duty of individual examination and the making up of schedules and returns. But the influence he exerted on schools, on the Department, and on the primary education of the whole country, was indirectly far greater than is generally supposed. His annual reports, of which more than twenty were collected into a volume by his friend and official chief, Sir Francis (afterwards Lord) Sandford, attracted, by reason of their freshness of style and thought, much more of public attention than is usually accorded to Blue-book literature; and his high aims, and his sympathetic appreciation of the efforts and difficulties of the teachers, had a remarkable effect in raising the tone of elementary education, and in indicating the way to improvement. In particular, he insisted on the formative elements of school education, on literature and the "humanities," as distinguished from the collection of scraps of information and "useful knowledge"; and he sought to impress all the young teachers with the necessity of broader mental cultivation than was absolutely required to obtain the Government certificate. In his reports also he dwelt often and forcibly on the place which the study of the Bible, not the distinctive formularies of the churches, ought to hold in English schools. He urged that besides the religious and moral purpose of Scriptural teaching, it had a literary value of its own, and was the best instrument in the hands even of the elementary teacher for uplifting the soul and refining and enlarging the thoughts of young children.

On three occasions Arnold was asked to assist the Government by making special inquiries into the state of education in foreign countries. These duties were especially welcome to him, serving as they did as a relief from the monotony of school inspection at home, and as opportunities for taking a wider survey of the whole subject of education, and for expressing his views on principles and national aims as well as administrative details. In 1859 he prepared for the Duke of Newcastle's Commission a report which was afterwards reprinted in a volume entitled *Popular Education in France, with Notes of that of Holland and Switzerland*. In 1895 he was again employed as assistant-commissioner by the Schools Inquiry Commission under Lord Taunton; and his report on this subject was subsequently reprinted under the title *Schools and Universities on the Continent*. Twenty years later he was sent by the Education Department to make special inquiries on certain specified points—e.g. free education, the status and training of teachers, and compulsory attendance at schools. The result of this investigation appeared as a parliamentary paper in 1886. He also contributed the chapter on "Schools" to the second volume of Mr Humphry Ward's *Reign of Queen Victoria*.

All these reports form substantial contributions to the history and literature of education in the Victorian age. They have been quoted

a pension of £250 was conferred on him in recognition of his literary merits. In the same year he went to the United States on a lecturing tour, and again in 1886, his subjects being "Emerson" and the "Principles and Value of Numbers." The success of these lectures, though they were admirable in matter and form, was marred by the lecturer's lack of experience in delivery. It is sufficient, further, to say that *Culture and Anarchy* appeared in 1869; *St Paul and Protestantism*, 1870; *Friendship's Garland*, 1871; *Literature and Dogma*, 1873; *God and the Bible*, 1875; *Last Essays on Church and Rebellion*, 1877; *Mixed Essays*, 1879; *Irish Essays*, 1882; and *Discourses on America*, 1885. Such essays as the first of these, embodying as they did Arnold's views of theological and polemical subjects, attracted much attention at the time of their publication, owing to the state of the intellectual atmosphere at the moment; but it is doubtful, perhaps, whether they will be greatly considered in the near future. Many severe things have been said, and will be said, concerning the inadequacy of poets like Coleridge and Wordsworth when confronting subjects of a theological or philosophical kind. Wordsworth's High Church Pantheism and Coleridge's disquisitions on the Logos seem farther removed from the speculations of to-day than do the dreams of Lucretius. But these two great writers lived before the days of modern science. Arnold, living only a few years later, came at a transition period when the winds of tyrannous knowledge had blown off the protecting roof that had covered the centuries before, but when time and much labour were needed to build another roof of new materials—a period when it was impossible for the poet to enjoy either the quietism of High Church Pantheism in which Wordsworth had basked, or the sheltering protection of German metaphysics under which Coleridge had preached—a period, nevertheless, when the wonderful revelations of science were still too raw, too cold and hard, to satisfy the yearnings of the poetic soul. Objectionable as Arnold's rationalizing criticism was to contemporary orthodoxy, and questionable as was his equipment in point of theological learning, his spirituality of outlook and ethical purpose were not to be denied. Yet it is not Arnold's views that have become current coin so much as his literary phrases—his craving for "culture" and "sweetness and light," his contempt for "the dissidence of Dissent and the Protestantism of the Protestant religion," his "stream of tendency not ourselves making for righteousness," his classification of "Philistines and barbarians"—and so forth. His death, at Liverpool, of heart failure, 15th April 1888, was sudden and quite unexpected.

Arnold was a prominent figure in that great galaxy of Victorian poets who were working simultaneously—Tennyson, Browning, Rossetti, William Morris and Mr Swinburne—poets between whom there was at least this connecting link, that the quest of all of them was the old-fashioned poetical quest of the beautiful. Beauty was their watchword, as it had been the watchword of their

immediate predecessors—Wordsworth, Coleridge, Keats, Shelley, and Byron. That this group of early 19th century poets might be divided into two—those whose primary quest was physical beauty, and those whose primary quest was moral beauty—is no doubt true. Still, in so far as beauty was their quest they were all akin. And so with the Victorian group to which Arnold belonged. As to the position which he takes among them opinions must necessarily vary. On the whole, our opinion is that his place in the group will be below all the others. The question as to whether he was primarily a poet or a *prosateur* has been often asked. If we were to try to answer that question here, we should have to examine his poetry in detail—we should have to inquire whether his primary impulse of expression was to seize upon the innate suggestive power of words; or whether his primary impulse was to rely upon the logical power of the sentence. In nobility of temper, in clearness of statement, and especially in descriptive power, he is beyond praise. But intellect, judgment, culture, and study of great poets may do much towards enabling a prose-writer to write what most needs be called good poetry. What they cannot enable him to do is to produce those magical effects which poets of the rarer kind can achieve by seizing that mysterious, suggestive power of words which is far beyond all mere statement. Notwithstanding the exquisite work that Arnold has left behind him, some critics have come to the conclusion that his primary impulse in expression was that of the poetically-minded *prosateur* rather than that of the born poet. And this has been said by some who nevertheless deeply admire poems like "The Scholar Gypsy," "Thyrsis," "The Forsaken Mermaid," "Dover Beach," "Heine's Grave," "Rugby Chapel," "The Grande Chartreuse," "Sohrab and Rustum," "The Sick King in Bokhara," "Tristram and Iseult," &c. We need not go nearly so far as that. But it would seem that a man may show all the endowments of a poet save one, and that one the most essential—the instinctive mastery over metrical effects.

In all literary expression there are two kinds of emphasis, the emphasis of sound and the emphasis of sense. Indeed the difference between those who have and those who have not the true rhythmic instinct is that, while the former have the innate faculty of making the emphasis of sound and the emphasis of sense meet and strengthen each other, the latter are without that faculty. But so imperfect is the human mind that it can rarely apprehend or grasp simultaneously these two kinds of emphasis. While to the born *prosateur* the emphasis of sense comes first, and refuses to be more than partially conditioned by the emphasis of sound, to the born poet the emphasis of sound comes first, and sometimes will, even as in the case of Shelley, revolt against the tyranny of the emphasis of sense. Perhaps the very origin of the old quantitative metres was the desire to make these two kinds of emphasis meet in the same syllable. In manipulating their quantitative metrical system the Greeks had facilities for bringing one kind of emphasis into harmony with the other such as are unknown to writers in accentuated metres. This accounts for the measureless superiority of Greek poetry in verbal melody as well as in general harmonic scheme to all the poetry of the modern world. In writers so diverse in many ways as Homer, Æschylus, Sophocles, Pindar, Sappho, the harmony between the emphasis of sound and the emphasis of sense is so complete that each of these kinds of emphasis seems always begetting, yet always born of the other. When in Europe the quantitative measures were superseded by the accentuated measures a reminiscence was naturally and inevitably left behind of the old system; and the result has been, in the English

often, and have exercised marked influence on subsequent changes and controversies. One great purpose underlies them all. It is to bring home to the English people a conviction that education ought to be a national concern, that it should not be left entirely to local, or private, or irresponsible initiative, that the watchful jealousy so long shown by Liberals, and especially by Nonconformists, in regard to State action was a grave practical mistake, and that in an enlightened democracy, animated by a progressive spirit and noble and generous ideals, it was the part of wisdom to invoke the collective power of the State to give effect to those ideals. To this theme he constantly recurred in his essays, articles, and official reports. "*Porro unum est necessarium*. One thing is needful; organize your secondary education." This is an object not yet fully attained; but the influence of his stimulating appeals to the intelligence and conscience of his countrymen, and the practical value of many of his detailed suggestions, are likely to be more and more fully recognized.

language at least, that no really great line can be written in which the emphasis of accent, the emphasis of quantity, and the emphasis of sense, do not meet on the same syllable. Whenever this junction does not take place the weaker line, or lines, are always introduced, not for make-shift purposes, but for variety, as in the finest lines of Milton and Wordsworth. Wordsworth no doubt seems to have had a theory that the accent of certain words, such as "without," "within," &c., could be disturbed in an iambic line; but in his best work he does not act upon his theory, and endeavours most successfully to make the emphasis of accent, of quantity, and of sense meet. It might not be well for a poem to contain an entire sequence of such perfect lines as

"I thought of Chatterton, the marvellous boy,"

or

"Thy soul was like a star and dwelt apart,"

for then the metricist's art would declare itself too loudly and weaken the imaginative strength of the picture. But such lines should no doubt form the basis of the poem, and weaker lines—lines in which there is no such combination of the three kinds of emphasis—should be sparingly used, and never used for make-shift purposes. Now, neither by instinct nor by critical study was Arnold ever able to apprehend this law of prosody. If he does write a line of the first order, metrically speaking, he seems to do so by accident. Such weak lines as these are constantly occurring—

"The poet, to whose mighty heart
Heaven doth a quicker pulse impart,
Subdues that energy to scan
Not his own course, but that of man."

Much has been said about what is called the "Greek temper" of Matthew Arnold's muse. A good deal depends upon what is meant by the Hellenic spirit. But if the Greek temper expresses itself, as is generally supposed, in the sweet acceptance and melodious utterance of the beauty of the world as it is, accepting that beauty without inquiring as to what it means and as to whither it goes, it is difficult to see where in Arnold's poetry this temper declares itself. Surely it is not in *Empedocles on Etna*, and surely it is not in *Merope*. If there is a poem of his in which one would expect to find the joyous acceptance of life apart from questionings about the civilization in which the poet finds himself environed (its hopes, its fears, its aspirations, and its failures)—such questionings, in short, as were for ever vexing Arnold's soul—it would be in "The Scholar Gypsy," a poem in which the poet tries to throw himself into the mood of a "Romany Rye." The great attraction of the gypsies to Englishmen of a certain temperament is that they alone seem to feel the joyous acceptance of life which is supposed to be specially Greek. Hence it would have been but reasonable to look, if anywhere, for the expression of Arnold's Greek temper in a poem which sets out to describe the feelings of the student who, according to Glanville's story, left Oxford to wander over England with the Romanies. But instead of this we get the old fretting about the unsatisfactoriness of modern civilization. Glanville's Oxford student, whose story is glanced at now and again in the poem, flits about in the scenery like a cloud-shadow on the grass; but the way in which Arnold contrives to avoid giving us the faintest idea either dramatic or pictorial of the student about whom he talks so much, and about the gypsies with whom the student lived, is one of the most singular feats in poetry. The reflections which come to a young Oxonian lying on the grass and longing to escape life's fitful fever without shuffling off this mortal coil are, no doubt, beautiful reflections beautifully expressed, but the temper they show is the very opposite of

the Greek. To say this is not in the least to disparage Arnold. "A man is more like the age in which he lives," says the Chinese aphorism, "than he is like his own father and mother," and Arnold's polemical writings alone are sufficient to show that the waters of life he drank were from fountains distilled, seven times distilled, at the topmost slope of 19th-century civilization. Mr George Meredith's "Old Chartist" exhibits far more of the temper of acceptance than does any poem by Matthew Arnold.

His most famous critical dictum is that poetry is a "criticism of life." What he seems to have meant is that poetry is the crowning fruit of a criticism of life; that just as the poet's metrical effects are and must be the result of a thousand semi-conscious generalizations upon the laws of cause and effect in metric art, so the beautiful things he says about life and the beautiful pictures he paints of life are the result of his generalizations upon life as he passes through it, and consequently that the value of his poetry consists in the beauty and the truth of his generalizations. But this is saying no more than is said in the line—

"Rien n'est beau que le vrai ; le vrai seul est aimable"—

or in the still more famous lines—

"Beauty is truth, truth beauty,"—that is all
Ye know on earth, and all ye need to know."

To suppose that Arnold confounded the poet with the writer of *pensées* would be absurd. Yet, having decided that poetry consists of generalizations on human life, in reading poetry he kept on the watch for those generalizations, and at last seemed to think that the less and not the more they are hidden behind the dramatic action, and the more unmistakably they are intruded as generalizations, the better. For instance, in one of his essays he quotes those lines from the "Chanson de Roland" of Turoldus, where Roland, mortally wounded, lays himself down under a pine-tree with his face turned towards Spain and the enemy, and begins to "call many things to remembrance; all the lands which his valour conquered, and pleasant France, and the men of his lineage, and Charlemagne, his liege lord, who nourished him"—

"De plusurs choses à remembrer li' prist,
De tantes terres cume li bers cunquist,
De dulce France, des humes de sun lignu,
De Carlemagne sun seignor ki l'nurrit."

"That," says Arnold, "is primitive work, I repeat, with an undeniable poetic quality of its own. It deserves much praise, and such praise is sufficient for it." Then he contrasts it with a famous passage in Homer—that same passage which has been quoted in the *Encyclopædia Britannica* (see Art. POETRY, vol. xix.) for the very opposite purpose to that of Arnold's—quoted indeed to show how the epic poet, leaving the dramatic action to act as chorus, weakens the *ἀπάρη* of the picture—the passage in the *Iliad* (iii. 243-4) where the poet, after Helen's pathetic mention of her brother's comments on the causes of their absence, "criticizes life" and generalizes upon the impotence of human intelligence, the impotence even of human love, to pierce the darkness in which the web of human fate is woven. He appends Dr Hawtrey's translation:—

Ὡς φάτο· τοὺς δ' ἤδη κάτεχεν φύσιζος αἶα
ἐν Λακεδαιμονίᾳ αἰθί, φίλῃ ἐν πατρίδι γαίῃ.

"So said she; they long since in Earth's soft arms were reposing
There, in their own dear land, their fatherland, Lacedæmon."

"We are here," says Arnold, "in another world, another order of poetry altogether; here is rightly due such supreme praise as that which M. Vitel gives to the *Chanson de Roland*. If our words are to have any

meaning, if our judgments are to have any solidity, we must not heap that supreme praise upon poetry of an order immeasurably inferior." He does not see that the two passages cannot properly be compared at all. In the one case the poet gives us a dramatic picture; in the other, a comment on a dramatic picture.

Perhaps, indeed, the place Arnold held and still holds as a critic is due more to his exquisite felicity in expressing his views than to the penetration of his criticism. Nothing can exceed the easy grace of his prose at the best. It is conversational and yet absolutely exact in the structure of the sentences; and in spite of every vagary, his distinguishing note is urbanity. Keen-edged as his satire could be, his writing for the most part is as urbane as Addison's own. His influence on contemporary criticism and contemporary ideals was considerable, and generally wholesome. His insistence on the necessity of looking at "the thing in itself," and the need for acquainting oneself with "the best that has been thought and said in the world," gave a new stimulus alike to originality and industry in criticism; and in his own selection of subjects—such as *Joubert*, or the *de Guerins*—he opened a new world to a larger class of the better sort of readers, exercising in this respect an awakening influence in his own time akin to that of Walter Pater a few years afterwards. The comparison with Pater might indeed be pressed further, and yet too far. Both were essentially products of Oxford. But Arnold, whose description of that "home of lost causes, and forsaken beliefs, and unpopular names, and impossible loyalties," is in itself almost a poem, had a classical austerity in his style that savoured more intimately of Oxford tradition, and an ethical earnestness even in his most flippant moments which kept him notably aloof from the more sensuous school of æsthetics.

(T. W.-D.)

Arnstadt, a town and watering-place of Germany, in the principality of Schwarzburg-Sondershausen, 14 miles by rail S.S.W. from Erfurt, on the river Gera. The church of Our Lady was restored in 1884-86. Its manufactures embrace gloves, shoes, iron safes, confectionery, and especially beer and market-gardening. Arnstadt possesses an industrial school, and is much frequented in summer for its saline and other baths. It dates back to the 8th century. Population (1885), 11,537; (1895), 13,595.

Arques, a town and railway station, arrondissement of St Omer, department of Pas-de-Calais, France, 37 miles in direct line N.W. of Arras. Near Arques, on the Canal de Neuffossés, is the Ascenseur des Fontinettes, a great hydraulic lift, completed in 1888, by which canal boats are enabled to avoid the series of locks constructed on the slope of the Fontinettes hill, to connect the Neuffossés with the Aa, at a difference of level of about 40 feet. Population, (1881), 2105; (1891), 1972; (1896), 2216, (comm.) 4355.

Arrah, a town of British India, headquarters of Shahabad district, in the Patna division of Bengal, situated on a navigable canal connecting the river Sone with the Ganges. It is a station on the East Indian railway, 368 miles from Calcutta. In 1891 the population was 46,905. It has a high school with over 400 pupils. Arrah is famous for an incident in the Mutiny, when a dozen Englishmen, with 50 Sikhs, defended an ordinary house against an army of many thousand insurgents. A British regiment, despatched to their assistance from Dinapur, was disastrously repulsed; but they were ultimately relieved, after eight days' continuous fighting, by a small force under Major (Sir Vincent) Eyre.

Arran, an island of Buteshire, Scotland, situated in the Firth of Clyde. The area is 165 square miles. Agriculture and the entertainment of summer visitors are the principal industries, and herrings, haddocks, whittings, and lobsters are fished; in 1898 there were 39 boats in the island, manned by seventy-three fishermen, and the value of the catch was £1220. There is an extensive steamer service connecting with the Caledonian and Glasgow and South-Western railways. Many improvements have been carried out in the principal villages, and Lamplash, in particular, has been largely extended. Population (1901), 4779.

Arras, chief town of department Pas-de-Calais, France, 109 miles N.N.E. of Paris, on railway from Paris to Dunkirk and Boulogne. Amongst public buildings to be noted are the restored Hôtel de Ville, the Hôpital St Jean, and the railway station. The last-named stands at one end of a fine thoroughfare, in the new quarter formed since the demolition of the fortifications. There are new boulevards, and statues of Vauban and of the Abbé Halluin (d. 1895). The manufacture of oils, especially poppy oil, and artistic and other metallurgical work, are now the leading industries, while textile manufactures are represented chiefly by hosiery. Population (1876), 21,689, (comm.) 21,689; (1886), 21,492; (1896), 20,599, (comm.) 21,086; (1901), 25,813.

Arrasà. See ERITREA.

Art Galleries.—An art gallery epitomizes so many phases of human thought and imagination that it connotes much more than a mere collection of paintings. In its technical and æsthetic aspect the gallery shows the treatment of colour, form, and composition. In its historical aspect we find the true portraits of great men of the past; we can observe their habits of life, their manners, their dress, the architecture of their times, and the religious worship of the period in which they lived. Regarded collectively, the art of a country epitomizes the whole development of the people that produced it. Most important of all is the emotional aspect of painting, which must enter less or more into every picture worthy of notice. To take examples from the British National Gallery: Pathos in its most intense degree will be found in Francia's "Pietà"; dignity in Velasquez' portrait of Admiral Pareja; homeliness in Van Eyck's portrait of Jan Arnolfini and his wife; the interpretation of the varying moods of nature in the work of Turner or Hobbema; nothing can be more devotional than the canvases of Bellini or his Umbrian contemporaries. So also the ruling sentiments of mankind—mysticism, drama, and imagination are the key-notes of other great conceptions of the artist. All this may be at the command of those who visit the art gallery; but without patience, care, and study the higher meaning will be lost to the spectator. The picture which "tells its own story" is often the least didactic, for it has no inner or deeper lesson to reveal; it gives no stimulus or training to the eye, quick as that organ may be—*segnius irritant animos*—to translate sight into thought. In brief, the painter asks that his $\eta\theta\omicron\varsigma$ may be shared as much as possible by the man who looks at the painting—the art above all others in which it is most needful to share the master's spirit if his work is to be fully appreciated. So, too, the art gallery, recalling the gentler associations of the past amidst surroundings of harmonious beauty and its attendant sense of comfort, is essentially a place of rest for the mind and eye. In the more famous galleries where the wealth of paintings allows a grouping of pictures according to their respective schools, one may choose the country, the epoch, the style, or even the emotion best suited to one's taste. According to this theory, though

imperfectly realized owing to the paucity of examples, the philosophic influence of art galleries is becoming more widely extended; and in its further development will be found an ever-growing source of interest, instruction, and scholarship to the community. The most suitable method of describing art galleries is to classify them by their types and contents, rather than by the various countries to which they belong. Thus the great representative galleries of the world which possess works of every school are grouped together, followed by State galleries which are not remarkable for more than one school of national art. Municipal galleries are divided into those which have general collections, and those which are notable for special collections. Churches which have good paintings, together with those which are now secularized, are treated separately; while the collections in the Vatican and private houses are described together. The remaining galleries, such as the Salon or the Royal Academy, are periodical or commercial in character, and are important in the development of modern art.

The collections most worthy of attention are the State galleries representative of international schools. Their number is restricted, not more than a dozen being in the very first rank. Among these the British National Gallery holds a high place. Though the collection is small and modern, having been founded in 1824 by the acquisition of the Angerstein pictures, it is among the most representative of State galleries. Its accessions are governed by the parliamentary grant of £5000 to £10,000 a year, a sum which has occasionally been enlarged to permit special purchases. Thus, in 1871, the Peel collection of seventy-seven pictures was bought for £75,000, and in 1885 the *Ansdei Madonna* (Raffaello) and Van Dyck's portrait of Charles I. were bought, the one for £70,000 and the other for £17,500. In 1890 the Government gave £25,000 to meet a gift of £30,000 made by three gentlemen to acquire three portraits by Moroni, Velasquez, and Holbein. The most important gifts were the Vernon gift in 1847, the Turner bequest in 1856, and

State galleries of International schools.

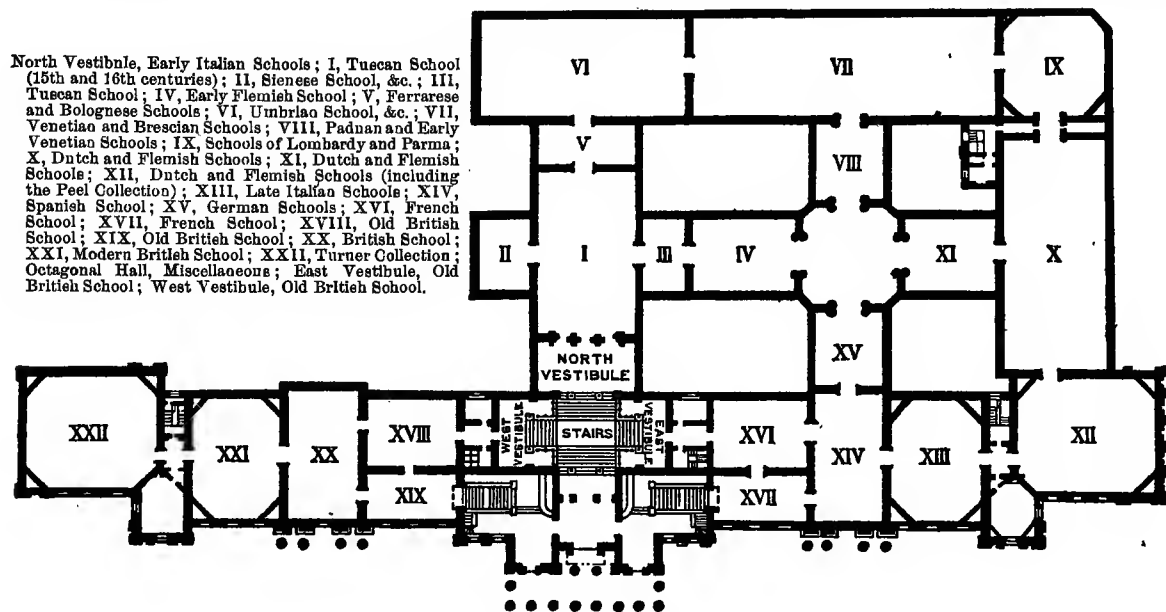

FIG. 1.—Plan of the National Gallery, London.

the Wynne-Ellis legacy in 1876. The gallery contains very few poor works, and all schools are well represented with the sole exception of the French school. This, however, can be amply studied at Hertford House, which, besides Dutch, Spanish, and British pictures of the highest value, contains twenty examples of Greuze, fifteen by Pater, nineteen by Boucher, eleven by Watteau, and fifteen by Meissonier. The Royal Gallery at Berlin (Old Museum), like the British National Gallery, is remarkable for its variety of schools and painters, and for the select type of pictures shown. During the last twenty-five years of the 19th century, the development of this collection was even more striking than that of the English gallery. Italian and Dutch examples are specially numerous, though every school but the British (here as elsewhere) is really well seen. The purchase grant is considerable, and is well applied. Two other German capitals have collections of international importance—Dresden and Munich. The former is famous for the *Sistine Madonna* by Raffaello, a work of such supreme excellence that there is a tendency to overlook other Italian pictures of celebrity by Titian, Giorgione, and Correggio. Munich (Old Pinakothek) has examples of all the best masters, the South German school being particularly noticeable. The arrangement is good,

and the methods of exhibition make this one of the most pleasant galleries on the Continent. Vienna has the Imperial Gallery, a collection which in point of number cannot be considered large, as there are not more than 1700 pictures. This, however, is in itself a safeguard, like the wise provision enabling the English authorities to dispose of pictures "unfit for the collection, or not required" (19 and 20 Vict. c. 29). It avoids the undue multiplication of canvases, and the overcrowding so noticeable in many Italian galleries where first-rate pictures hang too high to be examined. Thus the Viennese gallery, besides the intrinsic value of its pictures (Albert Dürer's chief work is there), is admirably adapted for study. The best gallery in Russia (St Petersburg, Hermitage) was made entirely by royal efforts, having been founded by Peter the Great, and much enlarged by the Empress Catharine. It contains the collections of Crozat, Brühl, and Walpole. There are about 1800 works, the schools of Flanders and Italy being of signal merit; and there are at least thirty-five genuine examples by Rembrandt. The French collection (Louvre Palace, Paris) is one of the most important of all. In 1880 it was undoubtedly the first gallery in Europe, but its supremacy has since been menaced by other establishments where acquisitions are

made more frequently and with greater care, and where the system of classification is such that the value of the pictures is enhanced rather than diminished by their display. In 1900 it was partly rearranged with great effect. The feature of the Louvre is the Salon Carré, a room in which the supposed finest canvases in the collection are kept together, pictures of world-wide fame, representing all schools. It is now generally accepted that this system of selection not only lowers the standard of individual schools elsewhere by withdrawing their best pictures, but

does not add to the æsthetic or educational value of the masterpieces themselves. In Florence the Tribuna of the Uffizi gallery is a similar case in point, while in London the danger that such a central gallery should be made within the national collection passed away thirty years ago. Probably the two most widely known pictures in the Louvre are Watteau's second "Embarquement pour Cythère" and the "Mona Lisa," a portrait by Leonardo da Vinci, but each school has many unique examples. The original drawings should be noted, being of equal importance to

I.

FIG. 2.—Plan of the first and second floors of the Imperial Gallery, Vienna.

the collection preserved at the British Museum. The last collection to be mentioned under this heading is that known as the Royal Galleries in Florence, housed in the Pitti and Uffizi palaces. In some ways this collection does not represent general painting sufficiently to justify its inclusion with the galleries of Berlin, Paris, and London. On the other hand, the great number of Italian pictures of vital importance to the history of international art makes this one of the finest existing collections. The two great palaces, dating from the 15th and 16th centuries, are joined together and contain the Medici pictures. They form the largest gallery in the world, and though many of the rooms are small and badly lighted, and although many paintings have suffered from thoughtless restoration, there is a charm and attraction which certainly

make them the most popular galleries in Europe. The Pitti has ten Raffaelles, and excellent examples of Andrea del Sarto, Giorgione, and Perugino. The Uffizi is more representative of non-Italian schools, but is best known for its works by Botticelli, Leonardo da Vinci, Michael Angelo, and Sodoma, the schools of Tuscany and Umbria forming the bulk of both collections. Admission to the galleries is by payment, and the small income derived from this source (in 1890 all the galleries and museums in Florence only received £4000) is devoted to maintaining and enlarging the collections.

As to the ground plans of the National Gallery, London (Fig. 1), and of the Royal Gallery at Vienna (Fig. 2), it will be observed that while the former has the advantage of uniform top-light, the new galleries at Vienna

possess the most ample facilities for minute classification, small rooms or "cabinets" opening from each large room. Special rooms are also provided for drawings and water-colours, while special ranges of rooms are used by copyists and those responsible for the repair and preservation of the pictures.

Though not so comprehensive as the great collections just described, the State galleries showing national schools of painting and little else are of striking interest. In England the National Gallery of British Art (known as the Tate Gallery) contains British pictures. The corresponding collection of modern French art is at Paris (Luxembourg Palace), Berlin, Rome, Dresden, Vienna, and Madrid having analogous galleries. The Victoria and Albert Museum has also numerous British pictures, especially in water-colour, and the National Portrait Gallery, founded in 1856, and since 1896 housed in its permanent home, is instructive in this connexion, though many of its pictures are the work of foreign artists. The national collections at Dublin and Edinburgh may be mentioned here, though most schools are represented. Brussels and Antwerp are remarkable for fine examples of Flemish art—Matsys, Memlinc, and Van Eyck of the primitive schools, Rubens and Van Dyck of the later period. The collections at Amsterdam (Ryks Museum) and the Hague (Mauritshuis) are a revelation to those who have only studied Rembrandt, Franz Hals, Van der Helst, and other Dutch portrait painters outside Holland; and in the former gallery especially, the pictures are arranged in a manner showing them to the best advantage. The Museo del Prado is even more noteworthy, for the fifty examples of Velasquez (outrivalling the Italian pictures, important as they are) make a visit to Madrid imperative to those who wish to realize the achievements of Spanish art. Christiania, Stockholm, and Copenhagen have large collections of Scandinavian art, and the cities of Budapest and Bâle have galleries of some importance. In Italy the State maintains twelve collections, mainly devoted to pictorial art. Of these the best are situated at Bologna, Lucca, Parma, Venice, Modena, Turin, and Milan. In each case the local school of painting is fully represented. In Rome the Corsini and Borghese Galleries, the latter being the most catholic in the city, contain superb examples, some of them accepted masterpieces of Italian art; there are also good foreign pictures, but their number is limited. The Accademia at Florence should also be noted as the most important State gallery of early Italian art. The central Italian Renaissance can be more adequately studied here than in the Pitti. The "Primavera" of Botticelli, and the "Last Judgment" by Fra Angelico are perhaps the best known works. The large statue of David by Donatello is also in this gallery, which, on the whole, is one of the most remarkable in Italy. Speaking broadly, these national galleries scattered throughout the country are not well arranged or classified; and though some are kept in fine old buildings, beautiful in themselves, the lighting is often indifferent, and it is with difficulty that the pictures can be seen. In nearly every case admission fees are charged every day, festivals and Sundays excepted; few pictures are bought, acquisitions being chiefly made by removing pictures from churches.

Many towns own collections of well-merited repute. In Italy such galleries are common, and among them may be noted Siena, with Sodoma and his school; Venice with Tintoretto (Doge's Palace); Genoa, with the great palaces Balbi and Rosso; Vicenza (Montagna and school), Ferrara (Dosso and school), Bergamo and Milan (north Italian schools). Other civic collections of Italian art are maintained at Verona,

State galleries of national schools.

Municipal galleries of general schools.

Churches.

Pisa, Rome, Perugia, and Padua. In Holland, Haarlem, Leyden, Rotterdam, and the Hague have galleries supplemental to those of the State, and are remarkable in showing the brilliance of artists like Grebber, De Bray, and Ravesteyn, who are usually ignored. Birmingham and Manchester have good examples of modern British art. Moscow (Tretiakoff collection) has modern Russian pictures, and contemporary German and French work will be found in all the galleries of these two countries included in the municipal group. Collections of French work are found at Amiens, Rouen, Nancy, Tours, Lemans, and Angers, but large as these civic collections are, sometimes containing six and eight hundred canvases, few of their pictures are really good, many being the enormous patriotic canvases marked "Don de l'État," which do not confer distinction on the galleries. Cologne has the central collection of the early Rhenish school; Nuremberg is remarkable for early German work (Wohlgemut, &c.). Stuttgart, Cassel (Dutch), and Hamburg (with a considerable number of British pictures) are also noteworthy, together with Brunswick, Hanover, Augsburg, Darmstadt, and Düsseldorf where German and Dutch art preponderate. Seville is famous for twenty-five examples of Murillo, and there are old Spanish paintings at Valencia, Cordova, and Cadiz.

In Great Britain the best of the municipal galleries of general schools are at Liverpool (early Flemish and British), and at Glasgow (Scottish painters, Rembrandt, Van der Goes, and Venetian schools). In France there are very large galleries at Tours, Montpellier, Lyons (Perugino, Rubens), Dijon, and Grenoble (Italian), Valenciennes (Watteau and school), while Rennes, Lille, and Marseilles have first-rate collections. Nantes, Orleans, Besançon, Cherbourg, and Caen have also many paintings, French for the most part, but with occasional foreign pictures of real importance, presented by the State during the Napoleonic conquests, and not returned on the declaration of peace as were the works of art amassed in Paris. Some of the American collections, though still in their early stages of development, have very good pictures. At Boston (Museum of Fine Arts) all schools are represented, so too at the Metropolitan Museum of Art in New York, which is strong in Italian and Dutch works. Modern French and Flemish art is a feature of the Academy at Philadelphia, at the Lenox Library (New York), and at Chicago, where there are good examples of Millet, Constable, and Rembrandt. The Corcoran bequest at Washington is of indifferent worth. The best civic collection in Germany of this class is the Städel Institute at Frankfort (Van Eyck, Christus, early Flemish and Italian).

As the great bulk of religious painting was executed for church decoration, there are still numberless churches which may be considered picture galleries. Thus at Antwerp Cathedral the Rubens paintings are remarkable; at Ghent, Van Eyck; at Bruges (hospital of St John), Memlinc; at Pisa, the Campo Santo (early Tuscan schools); at Sant' Apollinare, Ravenna, primitive Italo-Byzantine mosaics; at Siena, Pinturricchio. Examples could be multiplied indefinitely—in Italy alone there are 80,000 churches and chapels, in all of which pictorial art has been employed. In Italy, besides the church "galleries" still used for religious services, there are some which have been secularized and are now used as museums, e.g., Certosa at Pavia, and San Vitale at Ravenna (mosaics); at Florence, the Scalzi (Andrea del Sarto); San Marco (Fra Angelico); the Riccardi and Pazzi chapels (Gozzoli and Perugino); at Milan, in the Santa Maria delle Grazie, the "Last Supper," by Leonardo, and at Padua, the famous Arena chapel (Giotto).

The Vatican galleries, though best known for their

statuary, have fine examples of painting, chiefly of the Italian school; the most famous easel picture is Raffaele's "Transfiguration," but the Stanze, apartments entirely decorated by painting, are even more famous. In England three royal palaces are open to the public—Hampton Court (Mantegna), Windsor (Van Dyck, Zuccarelli), and Kensington (portraits). At Buckingham Palace the Dutch pictures are admirable, and Queen Victoria lent the celebrated Raffaele cartoons to the Victoria and Albert Museum. Semi-private collections belong to Dulwich College (Velasquez and Watteau), Oxford University (Italian drawings), the Soane Museum (Hogarth and English school), and the Royal Academy (Leonardo). Among private collections the most important are the Harrach, and Prince Liechtenstein (Vienna), the Six Gallery (Amsterdam), Mrs J. Gardner, of Boston (Italian), Prince Corsini (Florence). In Great Britain there are immense riches in private houses, though many collections have been dispersed. The most noteworthy belong to the dukes of Devonshire and Westminster, Lord Ellesmere, Captain Holford (including the masterpiece of Cnyp), Mr L. Mond, Lord Lansdowne, Miss Rothschild. The finest private collection belongs to Lord Cowper, his gallery of Van Dyck's work being quite the best in the world.

Many galleries are devoted to periodical exhibitions in London; the Royal Academy is the leading agency of this character, having held exhibitions since 1769. Its loan exhibitions of Old Masters are most important. Similar enterprises, heralded by the Grosvenor Gallery, are the New Gallery, opened in 1888, the Grafton Gallery, and others. There are also old-established societies of etchers, water-colourists, &c. A feature common to these exhibitions is that the public always pays for admission, though they differ from the commercial exhibitions, becoming more common every year, in which the work of a single school or painter is shown for profit. But the annual exhibitions at the Guildhall, under the auspices of the Corporation, are free. The great periodical exhibition of French art is known as the Salon, and for some years it has had a rival in the Champ de Mars exhibition. These two societies are now respectively housed in the Grand Palais and Petit Palais, in the Champs Elysées, which were erected in connexion with the Paris Exhibition of 1900, but with the ultimate object of being devoted to the service of the two Salons. Berlin, Rome, Vienna, and other Continental towns have regular exhibitions of original work.

The best history of art galleries is found in their official and other catalogues, see article MUSEUMS. See also L. VIARDOT, *Les musées d'Italie*, &c., 3 vols. Paris, 1842, 1843, 1844.—Annual Reports, official, of National Portrait Gallery, National Galleries of England, Ireland, and Scotland; Civil Service Estimates, class iv. official. Art Museums. See MUSEUMS.

Art Sales.—The practice of selling objects of art by auction in England dates from the latter part of the 17th century, when in most cases the names of the auctioneers were suppressed. Evelyn (under date 21st June 1693) mentions a "great auction of pictures (*Lord Melford's*) in the Banqueting House, Whitehall," and the practice is frequently referred to by other contemporary and later

writers. Before the introduction of regular auctions the practice was, as in the case of the famous collection formed by *Charles I.*, to price each object and invite purchasers, just as in other departments of commerce. But this was a slow process, especially in the case of pictures, and lacked the incentive of excitement. The first really important art collection to come under the hammer was that of *Edward, Earl of Oxford*, dispersed by Cock, under the Piazza, Covent Garden, on 8th March 1741-42 and the five following days, six more days being required by the coins. Nearly all the leading men of the day, including Horace Walpole, attended or were represented at this sale, and the prices varied from five shillings for an anonymous bishop's "head" to 165 guineas for Vandyck's group of "Sir Kenelm Digby, lady, and son." The next great dispersal was *Dr Richard Mead's* extensive collection, of which the pictures, coins, and gems, &c., were sold by Langford in February and March 1754, the sale realizing the total, unprecedented up to that time, of £16,069. The thirty-eight days' sale (1786) of the *Duchess of Portland's* collection is very noteworthy, from the fact that it included the celebrated Portland vase, now in the British Museum. Many other interesting and important 18th-century sales might be mentioned. High prices did not become general until the *Calonne, Trumbull* (both 1795), and *Bryan* (1798) sales. As to the quality of the pictures which had been sold by auction up to the latter part of the 18th century, it may be assumed that this was not high. The importation of pictures and other objects of art had assumed extensive proportions by the end of the 18th century, but the genuine examples of the Old Masters probably fell far short of 1 per cent. England was felt to be the only safe asylum for valuable articles, but the home which was intended to be temporary often became permanent. Had it not been for the political convulsions on the Continent, England, instead of being one of the richest countries in the world in art treasures, would have been one of the poorest. This fortuitous circumstance had, moreover, another effect, in that it greatly raised the critical knowledge of pictures. Genuine works realized high prices, as, for example, at *Sir William Hamilton's* sale (1801) when Beckford paid 1300 guineas for the little picture of "A Laughing Boy" by Leonardo da Vinci; and when at the *Lafontaine* sales (1807 and 1811) two Rembrandts each realized 5000 guineas, "The Woman taken in Adultery," now in the National Gallery, and "The Master Shipbuilder," now at Buckingham Palace. The *Beckford* sale of 1823 (41 days, £43,869) was the forerunner of the great art dispersal of the 19th century; *Horace Walpole's* accumulation at Strawberry Hill, 1842 (24 days, £33,450), and the *Stowe* collection, 1848 (41 days, £75,562), were also celebrated. They comprised every phase of art work, and in all the quality was of a very high order. They acted as a most healthy stimulus to art collecting, a stimulus which was further nourished by the sales of the superb collection of *Ralph Bernal* in 1853 (32 days, £62,690), and of the almost equally fine but not so comprehensive collection of *Samuel Rogers*, 1856 (18 days, £42,367). Three years later came the dispersal of the 1500 pictures which formed *Lord Northwick's* gallery at Cheltenham (pictures and works of art, 18 days, £94,722).

Towards the latter part of the first half of the 19th century an entirely new race of collectors gradually came into existence; they were for the most part men who had made, or were making, large fortunes in the various industries of the midlands and north of England and other centres. They were untrammelled by "collecting" traditions, and their patronage was almost exclusively

extended to the artists of the day. The dispersals of these collections began in 1863 with the *Bicknell Gallery*, and continued at irregular intervals for many years, e.g., *Gillott* (1872), *Mendel* (1875), *Wynn Ellis* and *Albert Levy* (1876), *Albert Grant* (1877), and *Munro of Novar* (1878). These patrons purchased at munificent prices either direct from the easel or from the exhibitions not only pictures in oils but also water-colour drawings. As a matter of investment their purchases frequently realized far more than the original outlay; sometimes, however, the reverse happened, as, for instance, in the case of Landseer's "Otter Hunt," for which Baron Grant is said to have paid £10,000 and which realized shortly afterwards only 5650 guineas. One of the most striking features of the sales of the 'seventies was the high appreciation of water-colour drawings. At the *Gillott* sale 160 examples realized a total of £27,423, when Lord Dudley paid 3150 guineas for Turner's "Bam-borough Castle"; and three years later at the *Quilter* sale (1875), when David Cox's "Hayfield," for which a dealer had paid the artist 50 guineas in 1850, realized 2810 guineas. Water-colour drawings have never recovered the inevitable effect of the "boom" in the 'seventies, but even within late years prices at auction indicate a distinctly upward tendency; in 1895 David Cox's "Welsh Funeral" (which cost about £20) sold for 2400 guineas, and in the same sale Sir Edward Burne-Jones's "Hesperides" realized 2560 guineas. The demand for works by modern artists, whose works sold at almost fabulous prices thirty years ago, has greatly declined; but during all its *furor* there was still a small band of collectors to whom the works of the Old Masters more especially appealed. The dispersal of such collections as the *Bredel* (1875), *Watts Russell* (1875), *Foster of Clewer Manor* (1876), the *Hamilton Palace* (17 days, £397,562)—the greatest art sale in the annals of Great Britain—*Bale* (1882), *Leigh Court* (1884), and *Dudley* (1892) contained, as did many minor collections sold each season, many very fine examples of the Old Masters which found eager purchasers at high prices. It has been frequently said that the Old Masters are no longer in fashion with collectors, but the fact is that first-rate examples are now rarely offered for sale; when they do occur prices are invariably high. Scarcely a season passes without affording a proof of this, the most striking one of all being the £24,250 realized by the pair of Vandyck portraits of a Genoese senator and his wife in the *Peel* sale, 1900.

The chief feature of the picture sales of the last quarter of the 19th century was the demand for works—more particularly female portraits—by Reynolds and his contemporaries. The origin of this fashion is perhaps traceable to the exhibitions held at South Kensington, 1867 and 1868, and the annual winter exhibitions at Burlington House, which revealed an unsuspected wealth and charm in the works of many English artists who had almost fallen into oblivion. The prices which have been paid at auction during recent years for such pictures can only be described as fabulous, and a few of the records may be quoted—Reynolds's "Lady Betty Delmé," 1894, 11,000 guineas; Romney's "The Ladies Spencer," 1896, 10,500 guineas; Gainsborough's "Duchess of Devonshire" (the picture which so mysteriously disappeared a few days after the sale, and which was as mysteriously restored to its owners, Messrs Agnew, in April 1901), 1876, 10,100 guineas; Constable's "Stratford Mill," 1895, 8500 guineas; and Turner's "Wreckers," 1897, 7600 guineas. Since 1880 works of the modern Continental schools—more especially the French—have become popular with English collectors, and high prices have accordingly figured in auction sales. The "appreciation" is, how-

ever, circumscribed, and perhaps does not extend much beyond a dozen well-known names, of which the principal—with a few of their chief pictures—are Rosa Bonheur, "Denizens of the Highlands," *Bolckow* sale, 1888, 5550 guineas; Jules Breton, whose "Girls going to the First Communion" realized £9100 in New York in 1886; Corot, Fortuny, Gallait, Gérôme, Greuze, Israëls; Meissonier (of whose works sold by auction two may be mentioned): "Napoleon I. in the Campaign of Paris," 12¼ inches by 9½ inches, for which Mr Ruskin gave 1000 guineas in 1869 and which realized 5800 guineas in 1882, and "The Sign Painter," which in the *Bolckow* sale of 1891 realized 6450 guineas; Munkacsy, Troyon, and Verboeckhoven.

"Specialism" is the one important development in art collecting which has manifested itself during the last half century. This accounts for and explains the high average quality of the *Wellesley* (1866), the *Buccleuch* (1888), and the *Holford* (1893) collections of drawings by the Old Masters; for the *Sibson* Wedgwood (1877), the *Duc de Forli* Dresden (1877), the *Shuldham* blue and white porcelain (1880), the *Warwick* enamels (1896), the *Dudley* porcelain (1886), the *Massey-Mainwaring* gold boxes (1897), and also for the objects of art collected by *Mr Magniac* (1892) and by *Herr Heckscher* (1898). Very many other illustrations in nearly every department of art collecting might be quoted—the superb series of *Marlborough gems* (1875 and 1899) might be included in this category but for the fact that it was formed chiefly in the 18th century. The appreciation—commercially at all events—of mezzotint portraits and of portraits printed in colours, after masters of the early English school, was one of the most remarkable features in art sales during the last years of the 19th century. The shillings of fifty years before were then represented by pounds. The *Fraser* collection (4th to 6th December 1900) realized about ten times the original outlay, the mezzotint of the "Sisters Frankland," after Hoppner, by W. Ward, selling for 290 guineas as against 10 guineas paid for it about thirty years previously. The H. A. Blyth sale (11th to 13th March 1901, 346 lots, £21,717: 10s.) of mezzotint portraits was even more remarkable, and as a collection it was the choicest sold within recent times, the engravings being mostly in the first state. The record prices were numerous, and, in many cases, far surpassed the prices which Sir Joshua Reynolds received for the original pictures; e.g., the exceptionally fine example of the first state of the "Duchess of Rutland," after Reynolds, by V. Green, realized 1000 guineas, whereas the artist received only £150 for the painting itself. Even this unprecedented price for a mezzotint portrait was exceeded on 30th April 1901, when an example of the first published state of "Mrs Carnac," after Reynolds, by J. R. Smith, sold for 1160 guineas. Such prices as these and many others which might be quoted are exceptional, but they were paid for objects of exceptional rarity or quality. The demand for the finest works of art of all descriptions is much greater than the supply. As an illustration of the magnitude of the art sale business it may be mentioned that the "turnover" of one firm in London alone has occasionally exceeded £1,000,000 annually.

BIBLIOGRAPHY.—The chief compilations dealing with art sales in Great Britain are—*Art Sales*, by G. REDFORD (1888), and *Memorials of Christie's*, by W. ROBERTS (1897); whilst other books containing much important matter are W. BUCHANAN'S *Memoirs of Painting*; *The Year's Art*, 1880 and each succeeding year; *The Connoisseur*, by F. S. ROBINSON; and *Les ventes de tableaux, dessins et objets d'art au XIX^e Siècle* (chiefly French), by L. SOULLIÉ.

(W. R.*)

Art Societies.—In banding themselves into societies and associations artists have always been especially remarkable. The fundamental motive of such leagu-

together is apparent, for, by the establishment of societies, it becomes possible for the working members of these to hold exhibitions and thereby to obtain some compensation or reward for their labours. With the growth of artistic practice and public interest, however, art societies have been instituted where this primary object is either absent or is allied to others of more general scope. The furtherance of a cult and the specializing of work have also given rise to many new associations in Great Britain, besides the Royal Academy (*q.v.*). At the outset, therefore, it will be well to mention the leading art societies thus described. The (now *Royal Society of Painters in Water Colours*), founded in 1804, and the (now *Royal Society of British Artists*) (1823), are typical of those societies which exist merely for purposes of holding exhibitions and conferring diplomas of membership. The *Artists' Society* formed in 1830, has for its object the providing of facilities to enable its members to perfect themselves in their art. To this end there is a good library of works on art, and abundant opportunities are afforded for general study from the life. In the furtherance of a cult the *Japan Society*, devoted to the encouragement of the study of the arts and industries of Japan, is a typical example; and the *Society of Mezzotint Engravers* is representative of those bodies formed in the interests of particular groups of workers. One of the remarkable features in the history of art in Great Britain has been the rapid increase of the artistic rank and file. Taking the number of exhibitors at the principal London and provincial exhibitions, it is found that in the period 1885-1900 the ranks were doubled. At the end of the 19th century it was estimated that there were quite 7000 practising artists. Coincident with this astonishing development there has been a corresponding addition of new art societies and the enlargement of older bodies. For instance, the membership of the *Royal Society of British Artists* advanced in the period mentioned from 80 to 150. Similar extensions can be noted in other societies, or in such a case as that of the *Royal Institute of Painters in Water Colours*, where the membership has remained fixed, it is to be noticed that more space is given to the works of outsiders. But the expansion of older exhibiting societies has not proved sufficient. Portrait painters, pastellists, designers, miniaturists, and women artists have felt the necessity of forming separate coteries. Interesting though these movements from within may be, the growth of societies originating in the spirit of altruism associated with such names as *Ruskin* and *Kyle* is equally instructive. Nearly all these are the products of the last quarter of a century and include the *Sunday Society*, which in 1896 secured the Sunday opening of the National Museums and Galleries in the Metropolis.

The specializing of study and work has also given rise to much artistic endeavour. For a long time archæology—British and Egyptian—claimed almost exclusive attention. Latterly the arts of India and Japan have engaged much notice, and societies have been organized to further their study. Finally, bands of workers in particular branches of art have felt the need of clubbing together in order to protect their special interests. A slight suspicion of trade-unionism is attached to some of these; but on the whole the establishment of such bodies as the *Society of Illustrators*, the *Society of Designers*, and the *Society of Mezzotint Engravers* has been with a view to advancing the public knowledge of the merits of these branches of artistic enterprise.

EXHIBITING SOCIETIES.—(a) *Old Established*.—These in London are: The *Royal Academy*, the *Royal Water Colour Society*, the *Royal Institute of Painters in Water Colours*, the *Society of Oil Painters*, and the *Royal Society of British Artists*. In the provinces, the *Birmingham Royal Society of Artists* has been in existence seventy-

four years, and has a life academy with professors attached. (b) *Modern*.—In this category are many which reflect the freshness and spirit of the enterprise shown during the last twenty-five years. Such a body as the *New English Art Club*, founded in 1885 as a protest against all other art societies, achieves its purpose by exhibition only. The *Royal Society of Painter-Etchers and Engravers*, consisting of fellows and associates, not exceeding 150 in all, conserves the interests of a numerous body of workers, and, in addition to holding exhibitions, confers diplomas (R.E. and A.R.E.) on the exhibitors of meritorious etchings or engravings. The *Society of Women Artists* (formerly the *Society of Lady Artists*) is wholly devoted to the display of works by female artists, and in 1891 the *Society of Portrait Painters* was formed to carry out the object conveyed in its title. Two associations advance the art of the miniature painter, and the *Pastel Society*, formed in 1898, holds displays of members' work at the Royal Institute Galleries. In Scotland there is the *Royal Scottish Academy*. The *Royal Scottish Society of Painters in Water Colours* (Glasgow) grants the title R.S.W. to its members, and the *Society of Scottish Artists* (Edinburgh), founded in 1891, has a membership of nearly 500 young artists. Other exhibiting societies which call for mention are: The *Yorkshire Union of Artists* (Leeds), which consolidates many local societies; the *Nottingham Society of Artists*, which also encourages drawing from the living model; and similarly the *Liver Sketching Club* (Liverpool), founded nearly thirty years ago, which, in addition to holding an annual exhibition, devotes four nights a week to drawing from life.

SOCIETIES OF INSTRUCTION AND POPULAR ENCOURAGEMENT.—It is under this head that the chief evidence of the modern art revival will be found. First it should be noted that there are very few societies designed for the artistic improvement of artists. The *Artists' Society* has already been mentioned; and the *Art Workers' Guild*, which meets at Clifford's Inn Hall, provides meetings, from which the public is excluded, where profitable discussions take place on questions of craft and design. But, as a rule, the art society, of which only artists are members, is organized for exhibition purposes or for the protection of interests. With regard to those societies of popular and educational intention the old *Society of Arts* in the Adelphi, founded in 1754, enjoys a good record. Numerous lectures on art subjects have from time to time been given, and in 1887 a scheme was devised by which awards are made to student-workers in design. The *Society for the Encouragement of the Fine Arts* (Conduit Street) has also laboured during the last half-century to increase a technical knowledge, its members holding conversazioni at various picture galleries. The *Artists' and Amateurs' Conversazione*, instituted in 1831, which used to meet at the Piccadilly Galleries and is now defunct, carried out a similar plan. Two other societies, now obsolete, should be mentioned whose methods were directly educational. The *Arundel Society*, which for many years promoted the knowledge of art by copying and publishing important works of ancient masters, issued to its members on payment of annual subscriptions, was eventually wound up on the last day of 1897. The *International Chalcographical Society*, formed for the study of the early history of engraving—its committee consisting of Messrs Sidney Colvin, Georges Duplessis, F. Lippmann, and Baron Edmond de Rothschild—also did useful work. Another association of painters, sculptors, architects, and engravers, the *Graphic Society*, ceased on the 29th October 1890. This was one of the most interesting of societies, and its meetings, at which rare works of art were exhibited and discussed, were held in the Flaxman Gallery at University College. A very active educational

body, originated in 1888, namely the *Royal Drawing Society*, has for its definite object the teaching of drawing as a means of education. The methods of instruction are based on the facts that very young children try to draw before they can write, and that they have very keen perception and retentive memory. The society aims, therefore, at using drawing as a means of developing these innate characteristics of the young, and already nearly 300 important schools follow out its system. Lord Leighton, Sir John Millais, and Sir Edward Burne-Jones took an active part in the society's labours. The *Art for Schools Association*, founded in 1883, has also done steady work in endeavouring to provide schools with works of art. These are chiefly reproductions of standard works of art or of historical and natural subjects. The wave of enthusiasm aroused by Mr Ruskin's teachings caused *Societies of the Rose* to be founded in London, Manchester, Sheffield, Birmingham, Aberdeen, and Glasgow; but some of these eventually ceased active work, to be revived again, however, by the *Ruskin Union*, formed in the year of the great writer's death (1900). Most of these societies were formed in 1879; but it should not be forgotten that two years earlier the *Kyrle Society* was started with the object of bringing the refining and cheering influences of natural and artistic beauty to the homes of the people. Under the presidency of Earl Brownlow, the *Home Arts and Industries Association* continues a work which was started in 1884, and anticipated much of the present system of technical education. Voluntary teachers organize classes for working people, at which a practical knowledge of art handiwork is taught. In remote or poor districts isolated workers are also assisted. Training classes for voluntary teachers are held in such varied pursuits as bent iron work, spinning, embroidery, and smocking. An interesting type of society has been established in Bolton, Lancashire. Under the title of an *Arts Guild* the members, numbering over 200, devote themselves to the advancement of taste in municipal improvements.

SOCIETIES OF SPECIAL STUDY, PRACTICE, AND PROTECTION.—Under this head should be placed those associations which affect a cult, or are composed of particular workers, or which protect public or private interests. Perhaps the chief of the first kind is the *Japan Society*, which, since its inception in 1892, has been joined by over 900 members interested in matters relating to Japanese art and industries. The *Dürer Society*, formed in 1897, has for its main object the reproduction of works by Albert Dürer, and his German and Italian contemporaries, and is in a way the successor to the defunct Arundel Society. In this category of special study the *Society for the Encouragement and Preservation of Indian Art* may also be placed, and the *Egypt Exploration Fund*. The *Ruskin Union* may also be mentioned again in this connexion. Of the societies of special practice it has already been noticed that some are purely exhibiting associations, such as the *Portrait Painters*, the *Pastel Society*, and the two miniature bodies. The formation of the *Society of Mezzotint Engravers* in 1898 is an example of the leaguering together of particular workers to call attention to their interests. Original and translator engravers, together with collectors and connoisseurs, comprise the membership. The decaying art of wood engraving is also fostered by the *International Society of Wood Engravers*, and the *Society of Designers*, founded in 1896, safeguards the interests of professional designers for applied art, without holding exhibitions. Special practice and protection are also considered by the *Society of Illustrators*, composed of artists who work in black and white for the illustrated press. This society was inaugurated in 1894, and fifteen of the members of the committee

must be active workers in illustration. As an instance of the tendency of art workers to combine, the *Society of Art Masters* is a good illustration. This is an association of teachers of art schools, controlled by the art branch of the Board of Education, and has a membership of over 200. Good work of another kind occupies the *National Trust for Places of Historic Interest or Natural Beauty*. The Council of the Trust includes representatives of such bodies as the National Gallery, the Royal Academy, the Royal Society of Painters in Water Colours, the Society of Antiquaries, the Royal Institute of British Architects, the Universities, Kyrle Society, Society for the Protection of Ancient Buildings, and the Selborne Society.

FOREIGN ART SOCIETIES.—The following are brief particulars of the chief art societies elsewhere than in Great Britain:—

AUSTRIA.—Vienna, *Vereinigung bildender Kuenstler Oesterreichs* (Society of Austrian Painters) and the *Association of Viennese Artists* (L'Association des artistes de Vienne).

BELGIUM.—Brussels, *Société des Beaux Arts*, the *Libre Esthétique*, *Société des Aquarellistes et Pastellistes*, *Société royale Belge des Aquarellistes*, and numerous private societies (*cercles*) in Brussels, Antwerp, Liège, Ghent, and other cities.

FRANCE.—Paris, the *Société des Artistes Français* (The Salon), *Société Nationale des Beaux Arts* (The New Salon), *Société des Aquarellistes*. Exhibiting societies are the *Société des Artistes Indépendants*, *Société des Orientalistes*, and *Salon des Pastellistes*.

GERMANY.—The small local societies are affiliated to one large parent body, the *Deutsche Kunstlergenossenschaft*, in Berlin under the presidency of Anton von Werner. The *Deutsche Illustratorenverband* watches over the interests of illustrators and designers. In Munich there are two bodies—the Old Society of Artists, holding its exhibitions in the Glaspalast, and the *Secession*.

ITALY.—Four exhibiting societies: Rome, *Società in Arte Libertas*, *Scuola degli Aquarellisti*; Milan, *Famiglia Artistica*, *Società degli Artisti*; Florence, *Circolo Artistico*; Naples, *Istituto di Belli Arti*.

PORTUGAL.—*Sociedade promotora das Bellas-Artes* and *Gremio Artistico*.

RUSSIA.—There is no exclusively art society of importance, but there is at St Petersburg the *Société Littéraire et Artistique*.

SPAIN.—Madrid, *L'Association des Artistes Espagnols*.

SWEDEN.—Stockholm, *Svenska Koustuareruas Forening*.

SWITZERLAND.—Berne, *La Société des Peintres et Sculpteurs Suisses*.

UNITED STATES.—New York, the *Academy of Fine Arts*, the *French Institute*; Boston, *Massachusetts Institute of Technology* (founded 1861). (A. C. R. C.)

Art Teaching.—It is the tendency of all departments of the human mind to outgrow their original limits. Traditions of teaching are long-lived, especially in art, and new ideas only slowly displace the old, so that art teaching as a whole is seldom abreast of the ideas and practice of the more advanced artists. The old academic system adapted to the methods and aims in art in the 18th century, which has been carried on in the principal art schools of Great Britain with but slight changes of method, consisted chiefly of a course of drawing from casts of antique statues in outline, and in light and shade, without backgrounds, of anatomical drawings, perspective, and drawing and painting from the living model. Such a training seems to be more or less a response to Lessing's definition of painting as "the imitation of solid bodies upon a plane surface." It seems to have been influenced more by the sculptor's art than any other. Indeed, the academic teaching from the time of the Italian Renaissance was no doubt principally derived from the study of antique sculpture; the proportions of the figure, the style, pose, and sentiment being all taken from Græco-Roman and Roman sculptures, discovered so abundantly in Italy from the 16th century onwards. As British ideas of art were principally derived from Italy, British academies endeavoured to follow the methods of teaching in vogue there in later times, and so the art student in Great Britain has had his attention and efforts directed almost exclusively to the representation of the abstract human form in abstract relief. Traditions in

art, however, may sometimes prove helpful and beneficial, and preservative of beauty and character, as in the case of certain decorative and constructive arts and handicrafts in common use, such as those of the rural waggon-maker and wheelwright, and horse-harness maker (see ACADEMY, ROYAL).

Some schools of painting, sculpture, and architecture have preserved fine and noble traditions which yet allowed for individuality. Such traditions may be said to have been characteristic of the art of the Middle Ages. It often happens, too, when many streams of artistic influence meet, there may be a certain domination or ascendancy of the traditions of one art over the others, which is injurious in its effects on those arts and diverts them from their true path. The domination of individualistic painting and sculpture over the arts of design during the last century or two is a case in point.

With the awakening of interest in industrial art—sharply separated by pedantic classification from fine art—which began about the middle of the 19th century, schools of design were established which included more varied studies. Even as early as 1836 a Government grant was made towards the opening of public galleries and the establishment of a normal school of design with a museum and lectures, and in 1837 the first school of design was opened at Somerset House. In 1840 grants were made to establish schools of the same kind in provincial towns, such as Manchester, Birmingham, Glasgow, Leeds, and Paisley. The names of G. Wallis in 1847, and Ambrose Poynter in 1850, are associated with schemes of art instruction adopted in the Government art schools, and the year 1851, the year of the Great Exhibition, was also marked by the first public exhibition of students' works, and the first institution of prizes and scholarships. In 1852 "the Department of Practical Art" was constituted, and a museum of objects collected at Marlborough House which afterwards formed the nucleus of the future museum at South Kensington. In 1853 "The Department of Science and Art" was established, and in 1857, under the auspices of Henry Cole, the offices of the department and the National Art Training School were removed from Marlborough House to South Kensington. Classes for instruction in various crafts had been carried on both at Somerset House and Marlborough House, and the whole object of the Government schools of design was to give an artistic training to the designer and craftsman, so that he could carry back to his trade or craft improved taste and skill. The schools, however, became largely filled by students of another type—leisured amateurs who sought to acquire some artistic accomplishment, and even in the case of genuine designers and craftsmen who developed pictorial skill in their studies, the attraction and superior social distinction and possibility of superior commercial value accruing to the career of a painter of easel pictures, diverted the schools from their original purpose.

For some time after the removal to South Kensington, during the progress of the new buildings, and under the direction of Godfrey Sykes and F. W. Moody, practical decorative work both in modelling and painting was carried out in the National Art Training School; but on the completion of these works, the school relapsed into a more or less academic school on the ordinary lines, and was regarded chiefly as a school for the training of art teachers and masters who were required to pass through certain stereotyped courses, and execute a certain series of drawings in order to obtain their certificates. Thus model-drawing, freehand outline, plant-drawing in outline, outline from the cast, light and shade from the cast, drawing of the antique figure, still life, anatomical drawings, drawing and painting from the life, ornamental

design, historic studies of ornament, perspective, and geometry, were all taken up in a cut-and-dried way, as isolated studies, and with a view solely to obtaining the certificate or passing an examination. This theoretic kind of training though still in force, and though it enabled the department to turn out certificated teachers for the schools of the country of a certain standard, and to give to students a general theoretic idea of art, has been found wanting, since, in practice, when the student in design leaves his school and desires to take up practical work as a designer or craftsman, he requires *special* knowledge, and specialized skill in design for his work to be of use; and though he may be able to impart to others what he himself has laboriously acquired, the theoretic and general character of his training proves of little or no use, face to face with the ever shifting and changing demands of the modern manufacturer and the modern market.

A growing conviction of the inadequacy of the schools of the Science and Art Department (now the Board of Education), considered as training grounds for practical designers and craftsmen, led to the establishment of new technical schools in the principal towns of Great Britain. The circumstance of certain large sums, diverted from their original purpose of compensation to brewers, being available for educational purposes and at the disposal of the county councils and municipal bodies, provided the means for the building and equipment of these new technical schools, which in many cases are under the same roof as the art school in the provincial towns, although the connexion between the two is not so close as might be desirable. The art schools formerly managed by private committees and supported by private donors, assisted by the Government grants, are now, in the principal industrial towns of Great Britain, taken over by the municipality. Birmingham is singularly well organized in this respect, and its art school has long held a leading position. The school is well housed in a new building with class-rooms with every appliance, not only for the drawing, designing, and modelling side, but also for the practice of artistic handicrafts such as metal repoussé, enamelling, wood-carving, embroidery, &c. The municipality have also established a jewellery school, so as to associate the practical study of art with local industry. Manchester will shortly have a large new technical school, intended to combine the work of the existing technical school in Princess Street and the weaving school in Peter Street under one roof, with special classes for design; while the art school in Cavendish Street, with its museum, may remain as a high school of design, painting, and modelling. In Glasgow, which has now a distinct place in the modern development of art, both decorative and pictorial, under the headmastership of Mr Francis H. Newbery, the art schools are also under municipal management, and large new premises have been completed for the extension of work in the technical and practical direction. Leicester has an admirably equipped and organized art school in a fine building.

The important change involved in the incorporation of the Science and Art Department with the Board of Education has also led to a reorganization of the Royal College of Art. A special Council of Advice on art matters has been appointed, consisting of representatives of painting, sculpture, architecture, and design, who deal with the Royal College of Art, and appoint the professors who control the teaching in the classes for architecture, design and handicraft, decorative painting and sculpture, modelling, and carving. The council decide upon the curriculum, and examine and criticize the work of the college from time to time. They also advise the Board in

regard to the syllabus issued to the art schools of the country, and act as referees in regard to purchases for the museum. New buildings for the Royal College of Art will be added to the new museum building now in course of erection. There will be a lower and a higher school in the college, and provision will be made for the practice of the artistic handicrafts. An etching and engraving class has existed since 1864. A stained-glass class was instituted in 1899, and these will be followed by classes for stone and marble carving, for metal work, and for pottery, while others will be added as space and organization admit.

Of other institutions for the teaching of art, outside the Science and Art Department, the following may be named: The Royal Drawing Society of Great Britain and Ireland, which was formed principally to promote the teaching of drawing in schools as a means of education. The system therein adopted differs from the ordinary drawing courses, and favours the use of the brush. Brush-work has generally been adopted for elementary work, too, by London school-board teachers, drawing being now a compulsory subject. Remarkable results have been obtained by the Alma Road board schools in the teaching of boys from eight to twelve by giving them spaces to fill with given forms—leaf shapes—from which patterns are constructed to fill the spaces, brush and water-colour being the means employed. At the Female School of Art in Queen Square, London, classes in drawing and painting from life are held, and decorative design is also studied. At the Herkomer Incorporated School, at Bushey, directed by Prof. H. von Herkomer, R.A., according to his own methods, students are instructed in drawing, painting, and engraving. The school is limited to 100 students. The City and Guilds of London Institute has two departments for what is termed "applied" art, one at the South London School of Technical Art, and the other at the Art Department in the Technical College, Finsbury. There are also the Royal School of Art Needlework; the School of Art Wood-carving; and the School of Art at the Crystal Palace. The Slade School of Drawing, Painting, and Sculpture, University College, Gower Street, confines itself to drawing and painting from the antique and life, and exercise in pictorial composition. There are also lectures on anatomy and perspective. The Slade Professorships at Oxford and Cambridge Universities are concerned with the teaching and literature of art, but they do not concern themselves with the practice. There are also, in addition to the schools of art named and those in connexion with the Board of Education in the various districts of London and the country, many and various private schools and clubs, such as the Langham and "Heatherley's," chiefly concerned in encouraging drawing and painting from the life, and for the study of art from the pictorial point of view, or for the preparation of candidates for admission into the Royal Academy or other schools.

A general survey, therefore, of the various institutions which are established for the teaching of art in Great Britain gives the impression that the study of art is not neglected, although, perhaps, further inquiry might show that, compared to the great educational establishments, the proportion is not excessive. With the board schools teaching art, as well as the municipal art schools and schools in connexion with the Board of Education, the danger is of waste of energy and of overlapping in the various courses. This danger suggests that a well-defined progressive system might be arranged so that a school-board scholar who shows artistic ability might be enabled to pass on from the elementary classes in one school to the higher art and technical schools, secondary and advanced,

without retracing his steps, thus escaping the depression of going over old ground.

The general movement of revival of interest in the arts of decorative design and the allied handicrafts, with the desire to re-establish their influence in art-teaching, has been due to many causes, among which the work of the Arts and Crafts Exhibition Society may count as important. From the leading members of this body the London County Council Technical Education Board, when it was face to face with the problem of organizing its new schools and its technical classes, sought advice and aid. Success has attended their schools, especially the Central School of Arts and Crafts at Morley Hall, Regent Street. The object of the school is to provide the craftsman in the various branches of decorative design with such means of improving his taste and skill as the amateur or with theoretic drawing. The main difference in principle adopted in this school in the teaching of design is the absence of teaching design *apart from handicraft*. It is considered that a craftsman thoroughly acquainted with the natural capacities of his material and strictly understanding the conditions of his work, would be able, if he had any feeling or invention, to design appropriately in that material, and no designing can be good apart from a knowledge of the material in which it is intended to be carried out. It should be remembered too that graphic skill in representing the appearances of natural objects is one sort of skill, and the executive skill of the craftsman in working out his design, say, in wood or metal, is quite another. It follows that the works of drawing or design made by the craftsman would be of quite a different character from a pictorial drawing, and might be quite simple and abstract, while clear and accurate. The training for the pictorial artist and for the craftsman would, therefore, naturally be different.

The character of the art-teaching adopted in any country must of course depend upon the dominant conception of art and its function and purpose. If we regard it as an idle accomplishment for the leisured few, its methods will be amateurish and superficial. If we regard art as an important factor in education, as a language of the intelligence, as an indispensable companion to literature, we shall favour systematic study and a training in the power of direct expression by means of line. We shall value the symbolic drawing of early civilizations like the Egyptian, and symbolic art generally, and in the history of decorative art we shall find the true accompaniment and illustration of human history itself. From this point of view we shall value the acquisition of the power of drawing for the purpose of presenting and explaining the facts and forms of nature. Drawing will be the most direct means at the command of the teacher to explain, to expound, to demonstrate where mere words are not sufficiently definite or explicit. Drawing in this sense is taking a more important place in our education, especially in primary education, though there is no need for it to stop there, and one feels it may be destined to take a more important position both as a training for the eye and hand and an aid to the teacher. Then, again, we may regard art more from its social aspect as an essential accompaniment of human life, not only for its illustrative and depicting powers, but also and no less for its pleasure-giving properties, its power of awakening and stimulating the observation and sympathy with the moods of nature, its power of touching the emotions, and above all of appealing to our sense of beauty. We shall regard the study of art from this point of view as the greatest civilizer, the most permeating of social and human forces. Such ideas as these, shared no doubt by all who take pleasure and interest in art, or feel it to be an important element in their lives, are crossed and often obscured by a multitude of mundane considerations, and it is probably out of the struggle for ascendancy between these that our systems of art teaching are evolved. There is the demand of the right to live on the part of the artist, and the teacher of art. There is the demand on the part of the manufacturer and salesman for such art as will help him to dispose of his goods. In the present commercial rivalry between nations this latter demand is brought into prominent relief, and art is apt to be made a minister, or perhaps a slave to the market. These are but accidental relationships with art. All who care for art value it as a means of expression and for the pleasure and beauty it infuses into all it touches, or as essential and inseparable from life itself. Seeing then the importance of art from any point of view, individual, social, commercial, intellectual, emotional, economic, it should be important to us in our systems of art-teaching not to lose sight of the end in arranging the means—not to allow our teaching to be dominated by either dilettantism or commercialism, neither to be feeble for want of technical skill, nor to sacrifice everything to technique. The true object of art-teaching is very much like that of all education—to inform the mind, while you give skill to the hand—not to impose certain rigid rules, or fixed recipes and methods of work, but while giving instruction in definite methods and the use of materials, to allow for the individual development of the student

and enable him to acquire the power to express himself through different media without forgetting the grammar and alphabet of design. Practice may vary, but principles remain, and there is a certain logic in art, as well as in reasoning. All art is conditioned in the mode of its expression by its material, and even the most individual kind of art has a convention of its own by the very necessities and means of its existence. Methods of expression, conventions, alter as each artist, each age seeks some new interpretation of nature and the imagination—the well-springs of artistic life, and from these reviving streams continually flow new harmonies,

new inventions, and recombinations, taking form and colour according to the temperaments which give them birth. (W. Cr.)

Arta, a town of Thessaly, in Greece, in the province of Arta, 59 miles N.N.W. of Mesolonghi, on the river Arta, which enters the Gulf of Arta some distance south of the town. The battle of Actium was fought near the mouth of the gulf in 29 B.C. The population is now about 7000.

ARTHROPODA.

ARTHROPODA is the name of one of the three sub-phyla into which one of the great phyla (or primary branches) of coelomocelous animals—the **APPENDICULATA**—is divided; the other two being respectively the **Chætopoda** and the **Rotifera**. The word "Arthropoda" was first used in classification by Siebold and Stannius (*Lehrbuch der vergleich Anatomie*, Berlin, 1845) as that of a primary division of animals, the others recognized in that treatise being Protozoa, Zoophyta, Vermes, Mollusca, and Vertebrata. The names **Condylopoda** and **Gnathopoda** have been subsequently proposed for the same group. The word refers to the jointing of the chitinized exo-skeleton of the limbs or lateral appendages of the animals included, which are, roughly speaking, the Crustacea, Arachnida, Hexapoda (so-called "true insects"), Centipedes, and Millipedes. This primary group was set up to indicate the residuum of Cuvier's **Articulata** when his class **Annelides** (the modern **Chætopoda**) was removed from that "embranchement." At the same time Siebold and Stannius renovated the group **Vermes** of Linnæus, and placed in it the **Chætopods** and the parasitic worms of Cuvier, besides the **Rotifers** and **Turbellarian** worms.¹

The result of the knowledge gained in the last quarter of the 19th century has been to discredit altogether the group **Vermes**, thus set up and so largely accepted by German writers even at the present day. We have, in fact, returned very nearly to Cuvier's conception of a great division or branch, which he called **Articulata**, including

the **Arthropoda** and the **Chætopoda** (**Annelides** of Lamarck, a name adopted by Cuvier), and differing from it only by the inclusion of the **Rotifera**. The name **Articulata**, introduced by Cuvier, has not been retained by subsequent writers. The same, or nearly the same, assemblage of animals has been called **Entomozoaria** by De Blainville (1822), **Arthrozoa** by Burmeister (1843), **Entomozoa** or **Annellata** by Milne-Edwards (1855), and **Annulosa** by McLeay (1819), who was followed by Huxley (1856). The character pointed to by all these terms is that of a ring-like segmentation of the body. This, however, is not the character to which we now ascribe the chief weight as evidence of the genetic affinity and monophyletic (uni-ancestral) origin of the **Chætopods**, **Rotifers**, and **Arthropods**. It is the existence in each ring of the body of a pair of hollow *lateral appendages* or *parapodia*, moved by intrinsic muscles and penetrated by blood-spaces, which is the leading fact indicating the affinities of these great sub-phyla, and uniting them as blood-relations. The *parapodia* (Fig. 7) of the marine branchiate worms are the same things genetically as the "legs" of Crustacea and Insects (Figs. 9 and 10). Hence the term **APPENDICULATA** was introduced by Lankester (preface to the English edition of Gegenbaur's *Comparative Anatomy*, 1878) to indicate the group. The relationships of the **Arthropoda** thus stated are shown in the sub-joined table:—

Phylum-APPENDICULATA	{	Sub-phylum 1. Rotifera.
		,, 2. Chætopoda.
		,, 3. Arthropoda.

The **ROTIFERA** are characterized by the retention of what appears in Molluscs and **Chætopods** as an embryonic organ, the velum or ciliated præoral girdle, as a locomotor and food-seizing apparatus, and by the reduction of the muscular *parapodia* to a rudimentary or non-existent condition in all present surviving forms except *Pedalion*. In many important respects they are degenerate—reduced both in size and elaboration of structure.

The **CHÆTOPODA** are characterized by the possession of horny epidermic *chætæ* embedded in the integument and moved by muscles. Probably the *chætæ* preceded the development of *parapodia*, and by their concentration and that of the muscular bundles connected with them at the sides of each segment, led directly to the evolution of the *parapodia*. The *parapodia* of **Chætopoda** are never coated with dense chitin, and are, therefore, never converted into jaws; the primitive "head-lobe" or *prostomium* persists, and frequently carries eyes and sensory tentacles. Further, in all members of the sub-phylum **Chætopoda** the relative position of the *prostomium*, mouth, and *peristomium* or first ring of the body, retains its primitive character. We do not find in **Chætopoda** that *parapodia*, belonging to primitively postoral rings or body-segments (called "somites," as proposed

¹ As a matter of fact the group **Arthropoda** itself, thus constituted, was precisely identical in its area with the class **Insecta** of Linnæus, the **Entoma** of Aristotle. But by causes which it is not easy to trace the word "Insect" had become limited since the days of Linnæus to the **Hexapod Pterygote** forms to the exclusion of his **Aptera**. Lamarck's penetrating genius is chiefly responsible for the shrinkage of the word **Insecta**, since it was he who, forty years after Linnæus's death, set up and named the two great classes **Crustacea** and **Arachnida** (included by Linnæus under **Insecta** as the order "Aptera"), assigning to them equal rank with the remaining **Insecta** of Linnæus, for which he proposed the very appropriate class-name "Hexapoda." Lamarck, however, appears not to have insisted on this name **Hexapoda**, and so the class of **Pterygote Hexapods** came to retain the group-name **Insecta**, which is, historically or etymologically, no more appropriate to them than it is to the classes **Crustacea** and **Arachnida**. The tendency to retain the original name of an old and comprehensive group for one of the fragments into which such group becomes divided by the advance of knowledge—instead of keeping the name for its logical use as a comprehensive term, including the new divisions, each duly provided with a new name—is most curiously illustrated in the history of the word **Physiology**. Cicero says, "Physiologia naturæ ratio," and such was the meaning of the name *Physiologus*, given to a cyclopædia of what was known and imagined about earth, sea, sky, birds, beasts, and fishes, which for a thousand years was the authoritative source of information on these matters, and was translated into every European tongue. With the revival of learning, however, first one and then another special study became recognized—**anatomy**, **botany**, **zoology**, **mineralogy**, until at last the great comprehensive term **Physiology** was bereft of all its once-included subject-matter, excepting the study of vital processes pursued by the more learned members of the medical profession. Professional tradition and an astute perception on their part of the omniscience suggested by the terms, have left the medical men in English-speaking lands in undisturbed but illogical possession of the words **physiology**, **physic**, and **physician**.

by H. Milne-Edwards), pass in front of the mouth by adaptational shifting of the oral aperture. (See, however, 8.)

The ARTHROPODA might be better called the "Gnathopoda," since their distinctive character is, that one or more pairs of appendages behind the mouth are densely chitinized and turned (fellow to fellow on opposite sides) towards one another so as to act as jaws. This is facilitated by an important general change in the position of the parapodia; their basal attachments are all more ventral in position than in the Chætopoda, and tend to approach from the two sides towards the mid-ventral line. Very usually (but not in the Onychophora=*Peripatus*) all the parapodia are plated with chitin secreted by the epidermis, and divided into a series of joints—giving the "arthropodous" or hinged character.

There are other remarkable and distinctive features of structure which hold the Arthropoda together, and render it impossible to conceive of them as having a polyphyletic origin, that is to say, as having originated separately by two or three distinct lines of descent from lower animals; and, on the contrary, establish the view that they have been developed from a single line of primitive Gnathopods which arose by modification of parapodiate annulate worms not very unlike some of the existing Chætopods. These additional features are the following—(1) All existing Arthropoda have an ostiate heart and have undergone "phlebædesis," that is to say, the peripheral portions of the blood-vascular system are not fine tubes as they are in the Chætopoda and as they were in the hypothetical ancestors of Arthropoda, but are swollen so as to obliterate to a large extent the coelom, whilst the separate veins entering the dorsal vessel or heart have coalesced, leaving valvate ostia (see Fig. 1*) by which the blood passes from a pericardial blood-sinus formed by the fused veins into the dorsal vessel or heart (see Lankester's *Zoology*, part ii., introductory chapter. A. & C. Black, 1900). The only exception to this is in the case of minute degenerate forms where the heart has disappeared altogether. The rigidity of the integument caused by the deposition of dense chitin upon it is intimately connected with the physiological activity and form of all the internal organs, and is undoubt-

FIG. 1*.—Diagram to show the gradual formation of the Arthropod pericardial blood-sinus and "ostiate" heart by the swelling up (phlebædesis) of the veins entering the dorsal vessel or heart of a Chætopod-like ancestor. The figure on the left represents the condition in a Chætopod, that on the right the condition in an Arthropod, the other two are hypothetical intermediate forms. (After Lankester, *Q. J. Mic. Sci.* vol. xxxiv. 1898.)

edly correlated with the total disappearance of the circular muscular layer of the body-wall present in Chætopods. (2) In all existing Arthropoda the region in front of the mouth is no longer formed by the primitive prostomium or head-lobe, but one or more segments, originally post-oral, with their appendages have passed in front of the mouth (prosthomeres). At the same time the prostomium and its appendages cease to be recognizable as distinct elements of the head. The brain no longer consists solely of the nerve-ganglion-mass proper to the prostomial lobe, as in Chætopoda, but is a composite (syncerebrum) produced by the

fusion of this and the nerve-ganglion-masses proper to the prosthomeres or segments which pass forwards, whilst their parapodia (=appendages) become converted into eye-stalks, and antennæ, or more rarely grasping organs. (3) As in Chætopoda, coelomic funnels (coelomoducts) may occur right and left as pairs in each ring-like segment or somite of the body, and some of these are in all cases retained as gonoducts and often as renal excretory organs (green glands, coxal glands of Arachnida, not crural glands, which are epidermal in origin); but true nephridia, genetically identical with the nephridia of earthworms, do not occur (on the subject of coelom, coelomoducts, and nephridia, see the introductory chapter of part ii. of Lankester's *Treatise on Zoology*).

Tabular Statement of the Grades, Classes, and Sub-classes of the Arthropoda.—It will be convenient now to give in the clearest form a statement of the larger subdivisions of the Arthropoda which it seems necessary to recognize at the present day. The justification of the arrangement adopted will form the substance of the rest of the present article. The orders included in the various classes are not discussed here, but are treated of under the following titles:—PERIPATUS (Onychophora), MYRIAPODA (Diplopoda and Chilopoda), ARACHNIDA, INSECTA (Hexapoda), and CRUSTACEA.

SUB-PHYLUM ARTHROPODA (of the Phylum Appendiculata).

Grade A. **Hyparthropoda** (hypothetical forms connecting ancestors of Chætopoda with those of Arthropoda).

Grade B. **Protarthropoda.**

Class ONYCHOPHORA.

Ex.—*Peripatus*.

Grade C. **Euarthropoda.**

Class 1. DIPLOPODA.

Ex.—*Julus*.

Class 2. ARACHNIDA.

Grade a. Anomomeristica.

Ex.—*Phacops*.

Grade b. Nomomeristica.

(a) Pantopoda.

Ex.—*Pycnogonum*.

(b) Euarachnida.

Ex.—*Limulus*, *Scorpio*, *Mygale*, *Acarus*.

Class 3. CRUSTACEA.

Grade a. Entomostraca.

Ex.—*Apus*, *Branchipus*, *Cyclops*, *Balanus*.

Grade b. Malacostraca.

Ex.—*Nebalia*, *Astacus*, *Oniscus*, *Gammarus*.

Class 4. CHILOPODA.

Ex.—*Scolopendra*.

Class 5. HEXAPODA (syn. Insecta Pterygota).

Ex.—*Locusta*, *Phryganea*, *Papilio*, *Apis*, *Musca*, *Cimex*, *Lucanus*, *Machilis*.

Incerta sedis—Tardigrada, Pentastomidæ (degenerate forms).

The Segmentation of the Body of Arthropoda.—The body of the Arthropoda is more or less clearly divided into a series of rings, segments, or somites which can be shown to be repetitions one of another, possessing identical parts and organs which may be larger or smaller, modified in shape or altogether suppressed in one somite as compared with another. A similar constitution of the body is more clearly seen in the Chætopod worms. In the Vertebrata also a repetition of units of structure (myotomes, vertebræ, &c.)—which is essentially of the same nature as the repetition in Arthropods and Chætopods, but in many respects subject to peculiar developments—is observed. The name "metamerism" has been given to this structural phenomenon because the "meres," or repeated units, follow one another in line. Each such "mere" is often called a "metamere." This is not the place in which to discuss the origin and essential nature of "metamerism" or "metameric segmentation." Nevertheless, a satisfactory

consideration of the structure of the Arthropoda demands a knowledge of what may be called the laws of metamerism. These are not so fully ascertained or formulated as might be expected. The repetition of parts, which we note as metamerism, is, as Haeckel, Bateson, and others have recognized, only a special case of a tendency of the organic body to repetition of structural units or parts which finds one expression in bilateral symmetry. In certain worms (the Cestoidea and some Planarians) metameric segmentation is accompanied by the separation of the completed metameres one by one from the older (anterior) extremity of the chain (strobilation), but it by no means follows that metameric segmentation has a necessary origin in such completion and separation of the "meres." On the contrary, metamerism seems to arise from a property of organisms which is sometimes more (eumerogenesis) and sometimes less (dysmerogenesis) fully exhibited, and in some groups not exhibited at all. The most complete and, at the same time, simplest instances of metameric segmentation are to be seen in the larger Chætopods, where some hundreds of segments succeed one another—each practically indistinguishable in structure from the segment in front or from that behind; muscles, right and left appendage or parapodium, colour-pattern of the skin, gut, blood-vessels, cœlum, nephridia, nerve-ganglion, and nerves are precisely alike in neighbouring segments. The segment which is least like the others is the first, for that carries the mouth and a lobe projecting beyond it—the prostomium. If (as sometimes happens) any of the hinder segments completes itself by developing a prostomium, the chain breaks at that point and the segment which has developed a prostomium becomes the first or head-bearing segment of a new individual. Compare such an instance of metameric segmentation with that presented by one of the higher Arthropods—*e.g.*, the crayfish. Here the somites are not so clearly marked in the tegumentary structures; nevertheless, by examining the indications given by the paired parapodia, we find that there are twenty-one somites present—a limited definite number which is also the precise number found in all the higher Crustacea.

We can state as a **FIRST LAW**¹ of metamerism or somite formation that it is either indefinite in regard to number of metameres or somites produced or is definite. Animals in the first case we call anomomeristic; those in the second case, nomomeristic. The nomomeristic condition is a higher development, a specialization, of the anomomeristic condition.

The **SECOND LAW**, or generalization, as to metamerism which must be noted is that the meres or somites (excepting the first with its prostomium) may be all practically alike or may differ from one another greatly by modification of the various constituent parts of the mere or somite. Metamerized animals are either homœomeric or heteromeric. The reference to the variation in the form of the essential parts contained in a "metamere" or "somite" introduces us to the necessity of a general term for these constituent or subordinate parts; they may be called "meromes" (*μέρος*). The meromes present in a metamere or somite differ in different annulate or segmented animals according to the general organization of the group to which the animal belongs. As a matter of convenience we distinguish in the Arthropod as meromes, first, the tegumentary chitinized plates called terga, placed on the dorsal aspect of the somites; second, the similar sternal plates. In Chætopods we should take next to these the masses of circular and longitudinal muscular fibres of the body-wall and the dorso-ventral muscles. The latter form the third sort of merome present in the Arthropods. The fourth kind of merome is constituted by the parapodia or appendages; the fifth by the coelomic pouches and their ducts and external apertures (cœlomoducts), whether renal or genital. The sixth by the blood-vessels of the somite; the seventh by the bit of alimentary tract which traverses it; and the eighth by the neuromere (nerve ganglion pair, commissures, connectives, and nerve branches).

It becomes apparent from this enumeration that there are a good many important elements or "meromes" in an Arthropod metamere or somite which can become the subject of heteromerism, or, to use a more apt word, of "heterosis." It is all the more necessary to insist upon this inasmuch as there is a tendency in the discussion of the segmentation of the Arthropod body to rely exclusively upon the indications given by the tegumentary chitinous plates and the parapodia.

The **THIRD LAW** of metamerism is that heteromerism may operate in such a way as to produce definite regions of like modification of the somites and their appendages, differing in their modification from that observed in regions before and behind them. It is convenient to have a special word for such regions of like meres, and we call each a tagma (*τάγμα*, a regiment). The word "tagmosis" is applicable to the formation of such regions. In the Chætopods tagmosis always occurs to a small extent so as to form the head. In some Chætopods, such as Chætopterus and the sedentary forms, there is marked tagmosis, giving rise to three or even more tagmata. In Arthropods, besides the head, we find very frequently other tagmata developed. But it is to be noted that in the higher members of each great class or line of descent, the tagmosis becomes definite and characteristic just as do the total number of meres or somites, whilst in the lower grades of each great class we find what may be regarded as varying examples of tentative tagmosis. The terms nomotagmic and anomotagmic are applicable with the same kind of implication as the terms nomomeristic and anomomeristic.

The **FOURTH LAW** of metamerism (auto-heterosis of the meromes) is that the meromes of a somite or series of somites may be separately and dissimilarly affected by heteromerism. It is common enough for small changes only to occur in the inner visceral meromes whilst the appendages and terga or sterna are largely changed in form. But of equal importance is the independent "heterosis" of these visceral meromes without any corresponding heterosis of the body-wall. As instances, we may cite the gizzards of various earthworms and the special localization of renal, genital, and gastric meromes, with obliteration elsewhere, in a few somites in Arthropoda.

The **FIFTH LAW**, relating also to the independence of the meromes as compared with the whole somite, is the law of autorhythmus of the meromes. Metamerism does not always manifest itself in the formation of complete new segments; but one merome may be repeated so as to suggest several metameres, whilst the remaining meromes are, so to speak, out of harmony with it and exhibit no repetition. Thus in the hinder somites of the body of *Apus* the Crustacean we find a series of segments corresponding apparently each to a complete single somite, but when the appendages are examined we find that they have multiplied without relation to the other meromes of a somite; we find that the somites carry from two to seven pairs of appendages, increasing in number as we pass backwards from the genital segment. The appendages are autorhythmic meromes in this case. They take on a quasi-independent metamerism and are produced in numbers which have no relation to the numbers of the body-rings, muscles, and neuromeres. This possibility of the independent metameric multiplication of a single merome must have great importance in the case of dislocated meromes, and no doubt has application to some of the metameric phenomena of Vertebrates.

A case which appears at first sight to be one of "autorhythmus" of the parapodia is that of the Diplopods (*Julus*, etc.), in which each apparent somite carries two pairs of legs or parapodia. It looks at first as though this were due to the independent multiplication of the legs; but it is not. Contrary to what obtains in *Apus*, we find in *Julus* that there is a well-marked somite in the embryo corresponding to each pair of legs and that the adult condition arises from a fusion of the tegumentary meromes of adjacent somites (see below "Fusion").

The **SIXTH LAW** is the law of dislocation of meromes. This is a very important and striking phenomenon. A merome, such as a pair of appendages (*Araneæ*) or a neuromere or a muscular mass (frequent), may (by either a gradual or sudden process, we cannot always say which) quit the metamere to which it belongs, and in which it originated, and pass by actual physical transference to another metamere. Frequently this new position is at a distance of several metameres from that to which the wandering merome belongs in origin. The movement is more usual from behind forwards than in the reverse direction; but this, probably, has no profound significance and depends simply on the fact that, as a rule, the head must be the chief region of development on account of its containing the sense organs and the mouth.

In the Vertebrata the independence of the meromes is more fully developed than in other metamerized animals. Not only do we get auto-heterosis of the meromes on a most extensive scale, but the dislocation of single meromes and of whole series (tagmata) of meromes is a common phenomenon. Thus, in fishes the pelvic fins may travel forwards to a thoracic and even jugal position in

¹ The word "LAW" is used in this summary merely as a convenient heading for the statement of a more or less general proposition.

front of the pectoral fins; the branchiomeres lose all relation to the position of the meromes of muscular, skeletal, coelomic, and nervous nature, and the heart and its vessels may move backwards from their original metameres in higher Vertebrates carrying nerve-loops with them.

The SEVENTH LAW of metamerism is one which has been pointed out to the writer by Mr E. S. Goodrich of Merton College, Oxford. It may be called the law of "translation of heterosis." Whilst actual physical transference of the substance of meromes undeniably takes place in such a case as the passage of the pelvic fins of some fishes to the front of the pectorals, and in the case of the backward movement of the opisthosomatic appendages of spiders, yet the more frequent mode in which an alteration in the position of a specialized organ in the series or scale of metameres takes place is *not* by migration of the actual material organ from somite to somite, but by translation of the *quality* or morphogenetic peculiarity from somite to somite accompanied by correlative change in all the somites of the series. The phenomenon may be compared to the transposition of a piece of music to a higher or lower key. It is thus that the lateral fins of fishes move up and down the scale of vertebral somites; and thus that whole regions (tagmata), such as those indicated by the names cervical, thoracic, lumbar, and sacral, are translated (accompanied by terminal increase or decrease in the total number of somites) so as to occupy differing numerical positions in closely allied forms (cf. the varying number of cervical somites in allied Reptiles and Birds).

What, in this rapid enumeration, we will venture to call the EIGHTH LAW of metamerism is the law of homeösis, as it is termed by Bateson (1). Homeösis is the making of a merome into the likeness of one belonging to another metamere, and is the opposite of the process of "heterosis"—already mentioned. We cite this law here because the result of its operation is to *simulate* the occurrence of dislocation of meromes and has to be carefully distinguished from that process. A merome can and does in individual cases of abnormality assume the form and character of the corresponding merome of a distant somite. Thus the antenna of an insect has been found to be replaced by a perfectly well-formed walking leg. After destruction of the eye-stalk of a shrimp a new growth appears, having the form of an antenna. Other cases are frequent in Crustacea, as individual abnormalities. They prove the existence in the mechanism of metamericized animals, of structural conditions which are capable of giving these results. What those structural conditions are is a matter for separate inquiry, which we cannot even touch here. It is not improbable that homeösis of distant meromes may have given rise to permanent structural changes characteristic of whole groups of Arthropoda, supposing the abnormality once established to be favoured by natural selection. Possibly the chelate condition of the præ-oral appendages of Arachnida may be due to homeösis transferring the chelate form of post-oral limbs to what were previously antenniform rami.

We now come to the questions of the production of *new* somites or the addition of new somites to the series, and the converse problem of the suppression of somites, whole or partial. We state as the NINTH LAW of metamerism "that new somites or metameres are added to a chain consisting of two or more somites by growth and gradual elaboration—what is called 'budding'—of the anterior border of the hindmost somite." This hindmost somite is therefore different from all the other somites and is called the 'telson.' However long or short or heteromericized the chain may be, new metameres or somites are only produced at the anterior border of the telson, except in the Vertebrata." That is the general law. But amongst some groups of metamericized animals partial exceptions to it occur. It is probably absolutely true for the Arthropoda from lowest to highest. It is not so certain that it is true for the Chætopoda and would need modification in statement to meet the cases of fissiparous multiplication occurring among Syllids and Naidids. In the Vertebrata, where tagmosis and heterosis of meromes and dislocation of meromes and tagmata are, so to speak, rampant, new formation of metameres (at any rate as represented by important meromes) takes place at more than one point in the chain. Such points are found where two highly diverse "tagmata" abut on one another. It is possible, though the evidence at present is entirely against the supposition, that at such points in Arthropoda new somites may be formed.¹ Such new somites are said to be "intercalated." The question of the intercalation of vertebræ in the Vertebrata has received some attention. It must be remembered that a vertebra even taken with its muscular, vascular, and neural accessories is only a partial metamere—a merome, and that, so far as *complete* metameres are concerned, the Vertebrata do conform

¹ The curious case of superabundant parapodia in the hinder somites of *Apus* has already been cited and referred to as an example of autorhythmic multiplication of meromes. There is some reason for regarding the extra pairs of legs as being "intercalated" after the formation of the somite as a single unit or merome by growth from the telson. Supposing, as appears to be the case, that as the *Apus* increases

to the same law as the Arthropods. Intercalation of meromes, branchial, vertebral, and dermal (fin-supports) seems to have taken place in Vertebrata in the fishes, while in higher groups intercalation of vertebræ in large series has been accepted as the only possible explanation of the structural facts established by the comparison of allied groups. The elucidation of this matter forms a very important part of the work lying to the hand of the investigator of vertebrate anatomy, and it is possible that the application of Goodrich's law (the seventh of our list) may throw new light on the matter.

In regard to the diminution in the number of somites in the course of the historical development of those various groups of metamericized animals, which have undoubtedly sprung from ancestors with more numerous somites than they themselves possess, it appears that we may formulate the following laws as the tenth, eleventh, twelfth, and thirteenth laws of metamerism.

The TENTH LAW is that individual somites tend to atrophy and finally disappear as distinct structures, most readily at the anterior and the posterior ends of the series constituting an animal body. This is very generally exhibited in the head of Arthropoda, where, however, the operation of the law is largely modified by fusion (see below). With regard to the posterior end of the body, the atrophy of segments does not, as a rule, affect the telson itself so much as the somites in front of it and its power of producing new somites. Sometimes, however, the telson is very minute and non-chitinized (Hexapoda).

The ELEVENTH LAW may be stated thus: any somite in the series which is the anterior or posterior somite of a tagma may become atrophied, reduced in size, or partially aborted by the suppression of some of its meromes; and finally, such a somite may disappear and leave no obvious trace in the adult structure of its presence in ancestral forms. This is called the excalation of a somite. Frequently, however, such "excalated" somites are obvious in the embryo or leave some merome (*e.g.*, neuromere, muscle, or chitin-plate) which can be detected by minute observation (microscopic) as evidence of their former existence. The somite of the maxillipede (third post-oral appendage) of *Apus cancriformis* is a good example of a somite on its way to excalation. The third præ-oral and the premaxillary somites of Hexapod insects are instances where the only traces of the vanished somite are furnished by the microscopic study of early embryos. The prægenital somite of the Arachnida is an example of a somite which is preserved in some members of the group and partially or entirely excalated in other cases, sometimes with fusion of its remnants to neighbouring somites.

The TWELFTH LAW of metamerism might very well be placed in logical order as the first. It is the *law of lipomerism*, and asserts that just as the metameric condition is produced by a change in the bodies of the descendants of unisegmental ancestors, so highly metamericized forms—*i.e.*, strongly segmented forms with specialized regions of differentiated metameres—may gradually lose their metamericized structure and become apparently and practically unisegmental animals. The change here contemplated is not the atrophy of terminal segments one by one so as to *reduce* the size of the animal and leave it finally as a single somite. On the contrary, no loss of size or of high organization is necessary. But one by one, and gradually, the metameric grouping of the bodily structures disappears. The cuticle ceases to be thickened in rings—the muscles of the body-wall overrun their somite boundaries. Internal septa disappear. The nerve-ganglia concentrate or else become diffused equally along the cords; one pair of renal coelomoducts and one pair of genital coelomoducts grow to large size and remain—the rest disappear. The appendages atrophy or become limited to one or two pairs which are widely dislocated from their ancestral position. The animal ceases to present any indication of metameric repetition of parts in its entire structure. Degrees in this process are frequently to be recognized. We certainly can observe such a change in the posterior region of some Arthropods, such as the hermit-crabs and the spiders. Admitting that the Echiurids are descended from Chætopoda, such a change has taken place in them, amounting to little short of complete lipomerism, though not absolutely complete.

Recent suggestions as to the origin of the Mollusca involve the supposition that such an effacement of once well-marked metamerism has occurred in them, leaving its traces only in a few structures such as the multiple gill-plumes and shell-shields of the Chitons and the duplicated renal sacs of *Nautilus*.

A further matter of importance in this connexion is that when the old metameres have been effaced a new secondary segmentation

in size, the number of extra pairs of legs on a non-terminal somite increases in number, these added meromes are certainly intercalated and represent incomplete intercalated metameres. The intercalation of new elements does not really go much further than this in Vertebrata, for a vertebra with its myoskeletal tissues is only a merome and not a complete metamere.

may arise, as in the jointed worm-like body of the degenerate *Acarus*, *Demodex folliculorum*.

Such secondary annulation of the soft body calls to mind the secondary annulation of the metameres of leeches and some earth-worms. Space does not permit of more than an allusion to this subject; but it is worth while noting that the secondary annuli marking the somites of Leeches and Lumbricidæ in definite number and character are perhaps comparable to the redundant pairs of appendages on the hinder somites of Apus, and are in both cases examples of independent repetition of tegumentary meromes—a sort of ineffectual attempt to subdivide the somite which only prevails on the more-readily susceptible meromes of the integument.

The development of secondary metameric annulations within the area of a complete somite is not recorded among Arthropoda. It deserves distinct recognition as "hypo-metamerism" or formation of "somatidia."

The last law of metamerism which we shall attempt to formulate here, as the THIRTEENTH, relates to the fusion or blending of neighbouring somites. There are without doubt a large number of important generalizations, to be arrived at hereafter from the further study of the metamerism of Vertebrata and the peculiar phenomena exhibited by the dislocated meromes of the vertebrate's somites. But this is not the place in which to attempt an outline of the special laws of vertebrate metamerism. Fusion of adjacent somites has often been erroneously interpreted in the study of Arthropoda. There are, in fact, very varying degrees of fusion which need to be carefully distinguished. The following generalization may be formulated. "The homologous meromes of two or more adjacent somites tend to fuse with one another by a blending of their substance. Very generally, but not invariably, the fused meromes are found as distinct separated structures in the embryo of the animal, in which they unite at a later stage of growth." The fusion of neighbouring meromes is often preceded by more or less extensive atrophy of the somites concerned, and by arrest of development in the individual ontogeny. Thus, a case of fusion of partially atrophied somites may simulate the appearance of incipient merogenesis or formation of new somites, and, *vice versa*, incipient merogenesis may be misinterpreted as a case of fusion of once separate and fully-formed somites. Moreover, the two phenomena, merogenesis and fusion of meromes, actually occur side by side in some cases as in the pygidial shields of the Trilobites and Limulus.

The most commonly-noted cases of fusion of metameres are simply cases of the fusion of the tegumentary meromes—usually the terga only. Such a fusion has really very serious morphological importance, although superficial and readily acquired. It amounts to no more than the disposition of chitinous cuticle of equal thickness over the area of the terga of the somites concerned instead of the thinning of the cuticular deposit at the adjacent borders of the somites. The somites consequently lose their hinge; they can no longer be flexed one on the other. Atrophy of the muscles related to such flexure necessarily follows. The mesosomatic portion of the posterior carapace of Limulus is no more than such a superficial fusion: the other meromes of the ankylosed somites (appendages, neuromeres, blood-vessels, &c.) are unaffected. Such, too, is the case with the pygidial shields of many Trilobites. On the other hand, the telson, which is joined in both these cases with the superficially fused segments by a fusion of its chitinous cuticle with that of its last-formed or budded somite, can only take part in the fusion as a result of arrest in its activity, which amounts to a late supervening atrophy. This arrest of the telson's special bud-growth may take place very early, in which case we get a large telsonic shield and only a very few somites in front of it—none soldered to the telson as in *Agnostus* and *Ilenus*; or it may take place later when eight post-cephalic (opisthosomatic) somites have been formed as in *Limulus*—the last two incompletely. Or, again, thirty or more somites may have been produced before the arrest takes place and fifteen of these may be ankylosed with the telson to form the pygidial shield (*Phacops*, &c.).

A more complete fusion of somites is that seen in the head of Arthropoda. The head or prosoma of Arthropoda is a tagma consisting of one, two, or three prosthomeres or somites in front of the mouth and of one, two, three, up to five or six opisthomeres. The cephalic tagma or prosoma may thus be more or less sharply divided into two subtagmata, the præ-oral and the post-oral.

The shifting of the mouth backwards in Arthropoda so as to allow segments which once were post-oral to take up a præ-oral position, as prosthomeres, must be regarded as a case of dislocation of the meromes concerned (SIXTH law), like the forward travelling of a fish's pelvic fins. The anus does not appear to be liable to such dislocation in Arthropoda; but it certainly does travel away from its parental metamere in the Vertebrata, and may possibly do so in Chætopoda when what must be called "lipomerism" or general obliteration of a metameric ordering of parts sets in. Such

"lipomerism" must be supposed to have affected the Chætopod ancestors of the Sipunculids, if those latter worms are to be traced genetically to the former, and the anus has shifted to the anterior third of the body. However that may be, the conception (first put forward by Lankester in 1875, 2) of the backward movement of the mouth in Arthropoda from the first somite to the second, third, or even fourth in the original post-oral series, is not only justified by embryological observation of the shifting in question, but finds its parallel in other instances of the law of dislocation of meromes.

The fusion of the cephalic or prosomatic somites not only extends to tegumentary structures but to muscles, blood-vessels, and markedly to neuromeres. However, in the embryo of many Arthropoda the original neuromeres of the præ-oral somites can be distinguished, and in many cases the coelomic cavities. Also it is a noteworthy fact that the tegumentary fusion (cephalic carapace, prosomatic carapace) appears sometimes to break down secondarily (e.g., squilla among Crustacea and Galeodes and Tarassidæ among Arachnida). It appears that we must recognize as a principle that such fusions as the carapaces of Arthropoda can revert to the condition of free movable plates—and therefore we must not assume that forms with fused tergal plates are necessarily later, genetically, than allied forms with free movable tergal plates.

When such reversion to a movable series of dorsal plates occurs it must not be assumed that any corresponding change takes place in the deeper meromes. On the whole, fusion and ankylosis of somites is not in itself necessarily a deep-seated or far-reaching process. It may or may not be accompanied by dislocation of important meromes or by lipomerism; whilst, as for instance in the opisthosoma of the spiders, opiliones and acari, dislocation and lipomerism may occur without fusion of tegumentary plates, and with, on the contrary, a dwindling, and eventual atrophy of such plates.

The general considerations as to metamerism set forth above will enable us to proceed to a consideration of the characters which distinguish the various groups of Arthropoda, and to justify the classification with which we started.

The Theory of the Arthropod Head.—The arthropod head is a tagma or group of somites which differ in number and in their relative position in regard to the mouth, in different classes. In a simple Chætopod (Fig. 1) the head consists of the first somite only; that somite is perforated by the mouth, and is provided with a prostomium or præ-oral lobe. The prostomium is essentially a part or outgrowth of the first somite, and cannot be regarded as itself a somite. It gives rise to a nerve-ganglion mass, the prostomial ganglion. In the marine Chætopods (the Polychæta) (Fig. 2), we find the same essential structure, but the prostomium may give rise to two or more tactile tentacles, and to the vesicular eyes. The somites have well-marked parapodia, and the second and third, as well as the first, may give rise to tentacles which are directed forward, and thus contribute to form "the head." But the mouth remains as an pushing of the wall of the first somite.

FIG. 1.—Diagram of the head and adjacent region of an Oligochaet Chætopod. Pr, the prostomium; m, the mouth; A, the prostomial ganglion-mass or archi-cerebrum; I, II, III, coelom of the first, second, and third somites. (From Goodrich, *Q. J. Micr. Sci.* vol. xl. p. 247.)

The Arthropoda are all distinguished from the Chætopoda by the fact that the head consists of one or more somites which lie *in front of the mouth* (now called prosthomeres), as well as of one or more somites behind it (opisthomeres). The first of the post-oral somites invariably has its parapodia modified so as to form a pair of hemignaths (mandibles). Twenty-five years ago the question arose as to whether the somites in front of the mouth are to be considered as derived from the prostomium of a Chætopod-like ancestor. Milne-Edwards and Huxley had satisfied themselves with discussing and establishing, according to the data at their command, the number of somites in the Arthropod head, but had not considered the question of the nature of the præ-oral somites. Lankester (2) was the first to suggest that (as is actually the fact in the Nauplius larva of Crustacea) the præ-oral somites or prosthomeres and their appendages

were ancestrally post-oral, but have become præ-oral "by adaptational shifting of the oral aperture." This has proved to be a sound hypothesis and is now accepted as the basis upon which the Arthropod head must be interpreted (see Korschelt and Heider (3)). Further, the morphologists of the 'fifties appear, with few exceptions, to have accepted a preliminary scheme with regard to the Arthropod head and Arthropod segmentation generally, which was misleading and caused them to adopt forced conclusions and interpretations. It was conceived by Huxley, among others, that the same number of cephalic somites would be found to be characteristic of all the diverse classes of Arthropoda, and that the somites, not only of the head but of the various regions of the body, could be closely compared in their numerical sequence in classes so distinct as the Hexapods, Crustaceans, and Arachnids.

FIG. 2.—Diagram of the head and adjacent region of a Polychaet Chaetopod. Letters as in Fig. 1, with the addition of T, prostomial tentacle; Pa, parapodium. (From Goodrich.)

having a prosthomere in front of the mouth (instead of prostomium only) and a pair of hemignaths (mandibles) on the parapodia of the buccal somite. From this ancestor Arthropods with heads of varying degrees of complexity have been developed characteristic of the different classes, whilst the parapodia and somites of the body have become variously modified and grouped in these different classes. The resemblances which the members of one class often present to the members of another class in regard to the form of the limb-branches (rami) of the parapodia, and the formation of tagmata (regions) are not hastily to be ascribed to common inheritance, but we must consider whether they are not due to homoplasy—that is, to the moulding of natural selection acting in the different classes upon fairly similar elements under like exigencies.

The structure of the head in Arthropods presents three profoundly separated grades of structure dependent upon the number of prosthomeres which have been assimilated by the præ-oral region. The classes presenting these distinct plans of head-structure cannot be closely associated in any scheme of classification professing to be natural. *Peripatus*, the type-genus of the class Onychophora, stands at the base of the series with only a single prosthomere (Fig. 3). In *Peripatus* the prostomium of the Chaetopod-like ancestor is atrophied, but it is possible that two processes on the front of the head (FP) represent in the embryo the dwindled prostomial tentacles. The single prosthomere carries the retractile tentacles as its "parapodia." The second somite is the buccal somite (II, Fig. 3); its parapodia have horny jaws on their ends, like the claws on the following legs (Fig. 8), and act as hemignaths (mandibles). The study of sections of the embryo establishes these facts beyond doubt. It also shows us that the neuromeres, no less than the embryonic coelomic cavities, point to the existence of one, and only one, prosthomere in *Peripatus*, of which the "Protocerebrum," P, is the neuromere, whilst the Deuterocephalum, D, is the neuromere of the second or buccal somite. A brief indication of these facts is given by saying that the Onychophora are "deutero-gnathous"—that is to say, that the buccal somite carrying the mandibular hemignaths is the second of the whole series.

What has become of the nerve-ganglion of the prostomial lobe of the Chaetopod in *Peripatus* is not clearly ascertained, nor is its fate indicated by the study of the embryonic head of other Arthropods so far. Probably it is fused with the Protocerebrum, and may also be concerned in the history of the very peculiar paired eyes of *Peripatus*, which are like those of Chaetopods in structure—viz., vesicles with an intra-vesicular lens, whereas the eyes of all other Arthropods have essentially another structure, being "cups" of the epidermis, in which a knob-like or rod-like thickening of the cuticle is fitted as refractive medium.

In Diplopoda (*Julus*, &c.) the results of embryological study point to a composition of the front part of the head exactly similar to that which we find in Onychophora. They are deutero-gnathous.

The Arachnida present the first stage of progress. Here embryology shows that there are two prosthomeres (Fig. 4), and that the gnathobases of the chelæ which act as the first pair of hemignaths, are carried by the third somite. The Arachnida are therefore tritognathous. The two prosthomeres are indicated by their coelomic cavities in the embryo (I and II, Fig. 4), and by two neuromeres, the Protocerebrum and the Deuterocephalum. The appendages of the first prosthomere are not present as tentacles, as in *Peripatus* and Diplopods, but are

FIG. 4.—Diagram of the head and adjacent region of an Arachnid. Diprosthomeric in the adult condition, though embryologically the appendages of somite II and the somite itself are, as here drawn, not actually in front of the mouth; E, lateral eye; Ch, chelicera; m, mouth; P, protocerebrum; D, deuterocephalum; I, II, III, IV, coelom of the first, second, third, and fourth somites. (After Goodrich.)

possibly represented by the eyes or possibly altogether aborted. The appendages of the second prosthomere are the well-known chelicerae of the Arachnids, rarely, if ever, antenniform, but modified as "retroverts" or clasp-knife fangs in spiders.

The Crustacea (Fig. 5) and the Hexapoda (Fig. 6) agree in having three somites in front of the mouth, and it is probable, though not ascertained, that the Chilopoda (*Scolopendra*, &c.) are in the same case. The three prosthomeres or præ-oral somites of Crustacea due to the sinking back of the mouth one somite farther than in Arachnida are not clearly indicated by coelomic cavities in the embryo, but their existence is clearly established by the development and position of the appendages and by the neuromeres.

The eyes in some Crustacea are mounted on articulated stalks, and from the fact that they can after injury be replaced by antenna-like appendages, it is inferred that they represent the parapodia of the most anterior prosthomere. The second prosthomere carries the first pair of antennæ and the third the second pair of antennæ. Sometimes this pair of appendages has not a merely tactile jointed ramus, but is converted into a claw or

FIG. 3.—Diagram of the head and adjacent region of *Peripatus*. Mono-prosthomeric. m, mouth; I, coelom of the first somite which carries the antennæ and is in front of the mouth; II, coelom of the second somite which carries the mandibles (hence deutero-gnathous); III and IV, coelom of the third and fourth somites; FP, rudimentary frontal processes perhaps representing the prostomial tentacles of Polychaeta; Ant, antenna or tactile tentacle; Ma, mandible; Op, oral papilla; P, protocerebrum or foremost cerebral mass belonging to the first somite; D, deuterocephalum, consisting of ganglion cells belonging to the second or mandibular somite. (After Goodrich.)

clasper. Three neuromeres—a proto-, deutero-, and tritocerebrum—corresponding to those three prosthomeres are sharply marked in the embryo. The fourth somite is that in which the mouth now opens, and which accordingly has its appendages converted into hemignathous mandibles. The Crustacea are tetartognathous.

The history of the development of the head has been carefully worked out in the Hexapod insects. As in Crustacea and Arachnida, a first prosthomere is indicated by the paired eyes and the protocerebrum; the second prosthomere has a well-marked coelomic cavity, carries the antennæ, and has the deutocerebrum for its neuromere. The third prosthomere is represented by a well-marked

FIG. 5.—Diagram of the head of a Crustacean. Tripriosthomerous. *FP*, frontal processes (observed in Cirriped nauplius-larvæ) probably representing the prostomial tentacles of Chætopoda; *e*, eye; *Ant¹*, first pair of antennæ; *Ant²*, second pair of antennæ; *md*, mandible; *ma¹*, *ma²*, first and second pairs of maxillæ; *m*, mouth; *I*, *II*, and *III*, the three prosthomeres; *IV*, *V*, *VI*, the three somites following the mouth; *P*, protocerebrum; *D*, deutocerebrum; *T*, tritocerebrum. (After Goodrich.)

FIG. 6.—Diagram of the head of a Hexapod insect. *e*, eye; *ant*, antenna; *md*, mandible; *ma¹*, first maxilla; *ma²*, second maxilla; *m*, mouth; *I*, region of the first or eye-bearing prosthomere; *II*, coelom of the second antenna-bearing prosthomere; *III*, coelom of the third prosthomere devoid of appendages; *IV*, *V*, and *VI*, coelom of the fourth, fifth, and sixth somites; *P*, protocerebrum belonging to the first prosthomere; *D*, deutocerebrum belonging to the second prosthomere; *T*, tritocerebrum belonging to the third prosthomere. (After Goodrich.)

pair of coelomic cavities and the tritocerebrum (*III*, Fig. 6), but has no appendages. They appear to have aborted. The existence of this third prosthomere corresponding to the third prosthomere of the Crustacea is a strong argument for the derivation of the Hexapoda, and with them the Chilopoda, from some offshoot of the Crustacean stem or class. The buccal somite, with its mandibles, is in Hexapoda, as in Crustacea, the fourth: they are tetartognathous.

The adhesion of a greater or less number of somites to the buccal somite posteriorly (opisthomeres) is a matter of importance, but of minor importance, in the theory and history of the Arthropod head. In *Peripatus* no such adhesion or fusion occurs. In *Diplopoda* two opisthomeres—that is to say, one in addition to the buccal somite—are united by a fusion of their terga with the terga of the prosthomeres. Their appendages are respectively the mandibles and the gnathochilarium.

In *Arachnida* the highest forms exhibit a fusion of the tergites of five postoral somites to form one continuous carapace united with the terga of the two prosthomeres. The five pairs of appendages of the postoral somites of the head or prosoma thus constituted all primitively carry gnathobasic projections on their coxal joints, which act as hemignaths: in the more specialized forms the mandibular gnathobases cease to develop.

In Crustacea the fourth or mandibular somite never has less than the two following somites associated with it by the adaptation of their appendages as jaws, and the ankylosis of their terga with that of the prosthomeres. But in higher Crustacea the cephalic "tagma" is extended, and more somites are added to the fusion, and their appendages adapted as jaws of a kind.

The Hexapoda are not known to us in their earlier or more primitive manifestations; we only know them as

possessed of a definite number of somites arranged in definite numbers in three great tagmata. The head shows two jaw-bearing somites besides the mandibular somite (*V*, *VI*, in Fig. 6)—thus six in all (as in some Crustacea), including prosthomeres, all ankylosed by their terga to form a cephalic shield. There is, however, good embryological evidence in some Hexapods of the existence of a seventh somite, the supra-lingual, occurring between the somite of the mandibles and the somite of the first maxillæ (4). This segment is indicated embryologically by its paired coelomic cavities. It is practically an exalted somite, having no existence in the adult. It is probably not a mere coincidence that the Hexapod, with its two rudimentary somites devoid of appendages, is thus found to possess twenty-one somites, including that which carries the anus, and that this is also the number present in the Malacostracous Crustacea.

The Segmental Lateral Appendages or Limbs of Arthropoda.—It has taken some time to obtain any general acceptance of the view that the parapodia of the Chætopoda and the limbs of Arthropoda are genetically identical structures; yet if we compare the parapodium of *Tomopteris* or of *Phyllodoce* with one of the foliaceous limbs of *Branchipus* or *Apus*, the correspondences of the two are striking. An erroneous view of the fundamental morphology of the Crustacean limb, and consequently of that of other Arthropoda, came into favour owing to the acceptance of the highly modified limbs of *Astacus* as typical. Protopodite, endopodite, exopodite, and epipodite were considered to be the morphological units of the crustacean limb. Lankester (5) has shown (and his views have been accepted by Professors Korschelt and Heider in their treatise on *Embryology*) that the limb of the lowest Crustacea, such as *Apus*, consists of a corm or axis which may be jointed, and gives rise to outgrowths, either leaf-like or filiform, on its inner and outer margins (endites and exites). Such a corm (see Figs. 9 and 10), with its outgrowths, may be compared to the simple parapodia of Chætopoda with cirrhi and branchial lobe (Fig. 7). It is by the specialization of two

FIG. 7.—Diagram of the somite-appendage or parapodium of a Polychæt Chætopod. The chætae are omitted. *Ax*, the axis; *nr.c*, neuropodial cirrus; *nr.l*, *nr.l'*, neuropodial lobes or endites; *nt.c*, notopodial cirrus; *nt.l*, *nt.l'*, notopodial lobes or exites. The parapodium is represented with its neural or ventral surface uppermost. Original.

"endites" that the endopodite and exopodite of higher Crustacea are formed, whilst a flabelliform exite is the homogen or genetic equivalent of the epipodite (see Lankester, "Observations and Reflections on *Apus Cancriformis*," *Q. J. Micr. Sci.*). The reduction of the growth-bearing "corm" of the parapodium of either a Chætopod or an Arthropod to a simple cylindrical stump, devoid of outgrowths, is brought about when mechanical conditions favour such a shape. We see it in certain

Chætopods (e.g., *Hesione*) and in the Arthropod *Peripatus* (Fig. 8). The conversion of the Arthropod's limb into a jaw, as a rule, is effected by the development of an endite near its base into a hard, chitinized, and often toothed gnathobase (see Figs. 9 and 10, *en*¹). It is not true that all the biting processes of the Arthropod limb are thus produced—for instance, the jaws of *Peripatus* are formed by the axis or corm itself, whilst the poison-jaws of Chilopods, as also their maxillæ, appear to be formed rather by the apex or terminal region of the ramus of the limb; but the opposing jaws (=hemignaths) of Crustacea, Arachnida, and Hexapoda are gnathobases, and not the axis or corm. The endopodite (corresponding to the fifth endite of the limb of *Apus*, see Fig. 9) becomes in Crustacea the "walking leg" of the mid-region of the body; it becomes the palp or jointed process of anterior segments. A second ramus, the "exopodite," often is also retained in the form of a palp or feeler. In *Apus*, as the figure shows, there are four of these "antenna-like" palps or filaments on the first thoracic limb. A common modification of the chief ramus of the Arthropod parapodium is the chela or nipper formed by the elongation of the penultimate joint of the ramus, so that the last joint works on it—as, for instance, in the lobster's claw. Such chelate rami or limb-branches are independently developed in Crustacea and in Arachnida, and are carried by somites of the body which do not correspond in position in the two groups. The range of modification of which the rami or limb-branches of the limbs of Arthropoda are capable is very large, and in allied orders or even families or genera we often find what is certainly the palp of the same appendage (as determined by numerical position of the segments)—in one case antenniform, in another chelate, in another pediform, and in another

FIG. 8.—Three somite-appendages or parapodia of *Peripatus*. A, a walking leg; *p*¹ to *p*⁴, the characteristic "pads"; *f*, the foot; *cp*¹, *cp*², the two claws. B, an oral papilla, one of the second pair of post-oral appendages. C, one of the first post-oral pair of appendages or mandibles; *cp*¹, *cp*², the greatly enlarged claws. (Compare A.) The appendages are represented with the neural or ventral surface uppermost. Original.

reduced to a mere stump or absent altogether. Very probably the power which the appendage of a given segment has of assuming the perfected form and proportions previously attained by the appendage of another segment

must be classed as an instance of "homœosis," not only where such a change is obviously due to abnormal development or injury, but also where it constitutes a difference permanently established between allied orders or smaller groups, or between the two sexes.

The most extreme disguise assumed by the Arthropod parapodium or appendage is that of becoming a mere

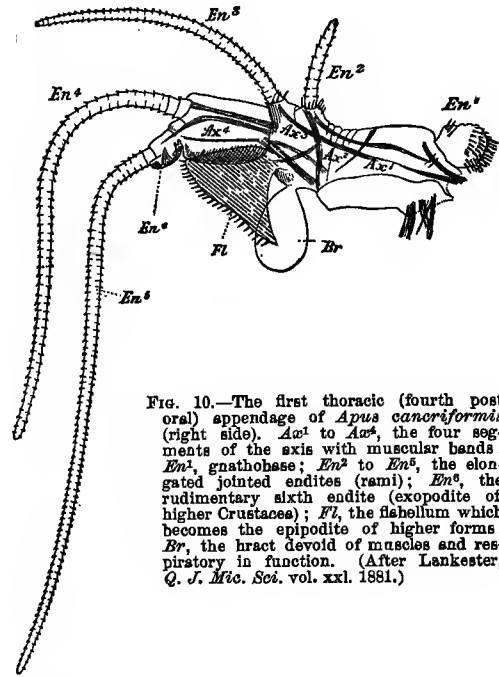

FIG. 10.—The first thoracic (fourth post-oral) appendage of *Apus canoriformis* (right side). *Ax*¹ to *Ax*⁶, the four segments of the axis with muscular bands; *En*¹, gnathobase; *En*² to *En*⁵, the elongated jointed endites (rami); *En*⁶, the rudimentary sixth endite (exopodite of higher Crustacea); *Fl*, the flabellum which becomes the epipodite of higher forms; *Br*, the bract devoid of muscles and respiratory in function. (After Lankester, *Q. J. Mic. Sci.* vol. xxi. 1881.)

stalk supporting an eye—a fact which did not obtain general credence until the experiments of Herbst in 1895, who found, on cutting off the eye-stalk of *Palæmon*, that a jointed antenna-like appendage was regenerated in its place. Since the eye-stalks of Podophthalmate Crustacea represent appendages, we are forced to the conclusion that the sessile eyes of other Crustacea and of other Arthropoda generally, indicate the position of appendages which have atrophied.¹

From what has been said, it is apparent that we cannot, in attempting to discover the affinities and divergences of the various forms of Arthropoda, attach a very high phylogenetic value to the coincidence or divergence in form of the appendages belonging to the somites compared with one another.

The principal forms assumed by the Arthropod parapodium and its rami may be thus enumerated:—

- (1) Axial corm well developed, unsegmented or with two to four segments; lateral endites and exites (rami) numerous and of various lengths (certain limbs of lower Crustacea).
- (2) Corm, with short unsegmented rami, forming a flattened foliaceous appendage, adapted to swimming and respiration (trunklimbs of Phyllopods).
- (3) Corm alone developed; with no endites or exites, but provided with terminal chitinous claws (ordinary leg of *Peripatus*), with terminal jaw teeth (jaw of *Peripatus*), or with blunt extremity (oral papilla of same) (see Fig. 8).
- (4) Three of the rami of the primitive limb (endites 5 and 6, and exite 1) specially developed as endopodite, exopodite, and epipodite—the first two often as firm and strongly chitinized, segmented, leg-like structures; the original axis or corm reduced to a basal piece, with or without a distinct gnathobase (endite 1)—typical tri-ramose limb of higher Crustacea.

FIG. 9.—The second thoracic (fifth post-oral) appendage of the left side of *Apus canoriformis*, placed with its ventral or neural surface uppermost to compare with Figs. 7 and 8. 1, 2, The two segments of the axis; *en*¹, the gnathobase; *en*² to *en*⁵, the five following "endites"; *fl*, the flabellum or anterior exite; *br*, the bract or posterior exite. (After Lankester, *Q. J. Mic. Sci.* vol. xxi. 1881.)

¹ H. Milne-Edwards, who was followed by Huxley, long ago formulated the conclusion that the eye-stalks of Crustacea are modified appendages, basing his argument on a specimen of *Palinurus* (figured in Bateson's hook (1), in which the eye-stalk of one side is replaced by an antenniform palp. Hofer (6) in 1894 described a similar case in *Astacus*.

(5) One ramus (the endopodite) alone developed—the original axis or corm serving as its basal joint with or without gnathobase. This is the usual uni-ramose limb found in the various classes of Arthropoda. It varies as to the presence or absence of the jaw-process and as to the stoutness of the segments of the ramus, their number (frequently six, plus the basal corm), and the modification of the free end. This may be filiform or brush-like or lamellate when it is an antenna or palp; a simple spike (walking leg of Crustacea, of other aquatic forms, and of Chilopods and Diplopods); the terminal joint flattened (swimming leg of Crustacea and Gigantostaca); the terminal joint provided with two or with three recurved claws (walking leg of many terrestrial forms—e.g., Hexapoda and Arachnida); the penultimate joint with a process equal in length to the last joint, so as to form a nipping organ (chela of Crustaceans and Arachnids); the last joint reflected and movable on the penultimate, as the blade of a clasp-knife on its handle (the retrovert, toothed so as to act as a biting jaw in the Hexapod *Mantis*, the Crustacean *Squilla*, and others; with the last joint produced into a needle-like stabbing process in spiders).

(6) Two rami developed (usually, but perhaps not always, the equivalents of the endopodite and exopodite) supported on the somewhat elongated corm (basal segment). This is the typical "biramose limb" often found in Crustacea. The rami may be flattened for swimming, when it is "a biramose swimmeret," or both or only one may be filiform and finely annulate; this is the form often presented by the antennae of Crustacea, and rarely by præ-oral appendages in other Arthropods.

(7) The endopoditic ramus is greatly enlarged and flattened, without or with only one jointing, the corm (basal segment) is evanescent; often the plate-like endopodites of a pair of such appendages unite in the middle line with one another or by the intermediary of a sternal up-growth and form a single broad plate. (These are the plate-like swimmerets and opercula of Gigantostaca and *Limulus* among Arachnids and of Isopod Crustaceans. They may have rudimentary exopodites, and may or may not have branchial filaments or lamellæ developed on their posterior faces. The simplest form to which they may be reduced is seen in the genital operculum of the Scorpion.)

(8) The gnathobase becomes greatly enlarged and not separated by a joint from the corm; it acts as a hemignath or half-jaw working against its fellow of the opposite side. The endopodite may be retained as a small segmented palp at the side of the gnathobase or disappear (mandible of Crustacea, Chilopoda, and Hexapoda).

(9) The corm becomes the seat of a development of a special visual organ, the Arthropod eye (as opposed to the Chætopod eye). Its jointing (segmentation) may be retained, but its rami disappear (Podophtalmous Crustacea). Usually it becomes atrophied, leaving the eye as a sessile organ upon the præ-oral region of the body. (The eye-stalk and sessile lateral eyes of Arthropoda generally, exclusive of *Peripatus*.)

(10) The forms assumed by special modification of the elements of the parapodium in the maxillæ, labium, &c., of Hexapods, Chilopods, Diplopods, and of various Crustacea, deserve special enumeration, but cannot be dealt with without ample space and illustration.

It may be pointed out that the most radical difference presented in this list is that between appendages consisting of the corm alone without rami (Onychophora) and those with more or less developed rami (the rest of the Arthropoda). In the latter class we should distinguish three phases: (a) those with numerous and comparatively undeveloped rami; (b) those with three, or two highly developed rami, or with only one—the corm being reduced to the dimensions of a mere basal segment; (c) those reduced to a secondary simplicity (degeneration) by overwhelming development of one segment (e.g., the isolated gnathobase often seen as "mandible" and the genital operculum).

There is no reason to suppose that any of the forms of limb observed in Arthropoda may not have been independently developed in two or more separate diverging lines of descent.

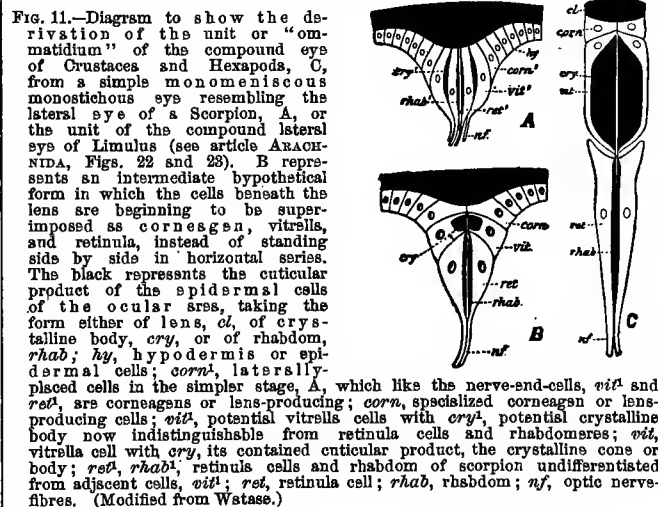

Branchia.—In connexion with the discussion of the limbs of Arthropods, a few words should be devoted to the gill-processes. It seems probable that there are branchial plumes or filaments in some Arthropoda (some Crustacea) which can be identified with the distinct branchial organs of Chætopoda, which lie dorsad of the parapodia and are not part of the parapodium. On the other hand, we cannot refuse to admit that any of the processes of an Arthropod parapodium may become modified as branchial organs, and that, as a rule, branchial out-growths are easily developed, *de novo*, in all the higher groups of animals. Therefore, it seems to be, with our present knowledge, a hopeless task to analyse the branchial organs of Arthropoda and to identify them genetically in groups.

A brief notice must suffice of the structure and history of the *Eyes*, the *Tracheæ*, and the so-called *Malpighian*

tubes of Arthropoda, though special importance attaches to each in regard to the determination of the affinities of the various animals included in this great sub-phylum.

The Eyes.—The Arthropod eye appears to be an organ of special character developed in the common ancestor of the Euarthropoda, and distinct from the Chætopod eye, which is found only in the Onychophora where the true Arthropod eye is absent. The essential difference between these two kinds of eye appears to be that the Chætopod eye (in its higher developments) is a vesicle enclosing the lens, whereas the Arthropod eye is a pit or series of pits into which the heavy chitinous cuticle dips and enlarges knob-wise as a lens. Two distinct forms of the Arthropod eye are observed—the monomeniscous (simple) and the polymeniscous (compound). The nerve-end-cells, which lie below the lens, are part of the general epidermis. They show in the monomeniscous eye (see article ARACHNIDA, Fig. 26) a tendency to group themselves into "retinulæ," consisting of five to twelve cells united by vertical deposits of chitin (rhabdoms). In the case of the polymeniscous eye (Fig. 23, article ARACHNIDA) a single retinula or group of nerve-end-cells is grouped beneath each associated lens. A further complication occurs in each of these two classes of eye. The monomeniscous eye is rarely provided with a single layer of cells beneath its lens; when it is so, it is called monostichous (simple lateral eye of Scorpion, Fig. 22, article ARACHNIDA). More usually, by an infolding of the layer of cells in development, we get three layers under the lens; the front layer is the corneagen layer, and is separated by a membrane from the other two which, more or less, fuse and contain the nerve-end-cells (retinal layer). These eyes are called diplostichous, and occur in Arachnida and Hexapoda (Fig. 24, in article ARACHNIDA).

On the other hand, the polymeniscous eye undergoes special elaboration on its lines. The retinulæ become elongated as deep and very narrow pits (Fig. 11 and

explanation), and develop additional cells near the mouth of the narrow pit. Those nearest to the lens are the corneagen cells of this more elaborated eye, and those between the original retinula cells and the corneagen cells become firm and transparent. They are the crystalline cells or vitrella (see Wstase, 7). Each such complex of cells underlying the lenticle of a compound eye is called an "ommatidium"; the entire mass of cells underlying a monomeniscous eye is an "ommatæum." The ommatæum, as already stated, tends to segregate into retinulæ which correspond potentially each to an ommatidium of the compound eye. The ommatidium is from the first segregate and consists of few cells. The compound eye

of the King-Crab (*Limulus*) is the only recognized instance of ommatidia in their simplest state. Each can be readily compared with the single-layered lateral eye of the Scorpion. In Crustacea and Hexapoda of all grades we find compound eyes with the more complicated ommatidia described above. We do not find them in any Arachnida.

It is difficult in the absence of more detailed knowledge as to the eyes of Chilopoda and Diplopoda to give full value to these facts in tracing the affinities of the various classes of Arthropods. But they seem to point to a community of origin of Hexapods and Crustacea in regard to the complicated ommatidia of the compound eye, and to a certain isolation of the Arachnida, which are, however, traceable, so far as the eyes are concerned, to a distant common origin with Crustacea and Hexapoda through the very simple compound eyes (monostichous, polymeniscous) of *Limulus*.

The Tracheæ.—In regard to tracheæ the very natural tendency of zoologists has been until lately to consider them as having once developed and once only, and therefore to hold that a group of "Tracheata" should be recognized, including all tracheate Arthropods. We are driven by the conclusions arrived at as to the derivation of the Arachnida from branchiate ancestors, independently of the other tracheate Arthropods (see article ARACHNIDA), to formulate the conclusion that tracheæ have been independently developed in the Arachnid class. We are also, by the isolation of *Peripatus* and the impossibility of tracing to it all other tracheate Arthropoda, or of regarding it as a degenerate offset from some one of the tracheate classes, forced to the conclusion that the tracheæ of the Onychophora have been independently acquired. Having accepted these two conclusions, we formulate the generalization that tracheæ can be independently acquired by various branches of Arthropod descent in adaptation to a terrestrial as opposed to an aquatic mode of life. A great point of interest therefore exists in the knowledge of the structure and embryology of tracheæ in the different groups. It must be confessed that we have not such full knowledge on this head as could be wished for. Tracheæ are essentially tubes like blood-vessels—apparently formed from the same tissue elements as blood-vessels—which contain air in place of blood, and usually communicate by definite orifices, the tracheal stigmata, with the atmosphere. They are lined internally by a cuticular deposit of chitin. In *Peripatus* and the Diplopods they consist of bunches of fine tubes which do not branch but diverge from one another; the chitinous lining is smooth. In the Hexapods and Chilopods, and the Arachnids (usually), they form tree-like branching structures, and their finest branches are finer than any blood-capillary, actually in some cases penetrating a single cell and supplying it with gaseous oxygen. In these forms the chitinous lining of the tubes is thickened by a close-set spiral ridge similar to the spiral thickening of the cellulose wall of the spiral vessels of plants. It is a noteworthy fact that other tubes in these same terrestrial Arthropoda—namely, the ducts of glands—are similarly strengthened by a chitinous cuticle, and that a spiral or annular thickening of the cuticle is developed in them also. Chitin is *not* exclusively an ectodermal product, but occurs also in cartilaginous skeletal plates of mesoblastic origin (connective tissue). The immediate cavities or pits into which the tracheal stigmata open appear to be in many cases ectodermic in sinkings, but there seems to be no reason (based on embryological observation) for regarding the tracheæ as an ingrowth of the ectoderm. They appear, in fact, to be an air-holding modification of the vasifactive connective tissue. Tracheæ are abundant just in proportion as blood-vessels become suppressed.

They are reciprocally exclusive. It seems not improbable that they are two modifications of the same tissue-elements. In *Peripatus* the stigmatic pits at which the tracheæ communicate with the atmosphere are scattered and not definite in their position. In other cases the stigmata are definitely paired and placed in a few segments or in several. It seems that we have to suppose that the vasifactive tissue of Arthropoda can readily take the form of air-holding instead of blood-holding tubes, and that this somewhat startling change in its character has taken place independently in several instances—viz., in the Onychophora, in more than one group of Arachnida, in Diplopoda, and, again, in the Hexapoda and Chilopoda.

The Malpighian Tubes.—This name is applied to the numerous fine cæcal tubes of noticeable length developed from the proctodæal invert of ectodermal origin in Hexapods. These tubes are shown to excrete nitrogenous waste products similar to uric acid. Tubes of renal excretory function in a like position occur in most terrestrial Arthropoda—viz., in Chilopoda, Diplopoda, and Arachnida. They are also found in some of the semi-terrestrial and purely aquatic Amphipod Crustaceans. But the conclusion that all such tubes are identical in essential character seems to be without foundation. The Malpighian tubes of Hexapods are outgrowths of the proctodæum, but those of Scorpion and the Amphipod Crustacea are part of the metenteron or endodermal gut, though originating near its junction with the proctodæum. Hence the presence or absence of such tubes cannot be used as an argument as to affinity without some discrimination. The Scorpion's so-called Malpighian tubes are *not* the same organs as those so named in the other Tracheata. Such renal cæcal tubes seem to be readily evolved from either metenteron or proctodæum when the conditions of the out-wash of nitrogenous waste-products are changed by the transference from aquatic to terrestrial life. The absence of such renal cæca in *Limulus* and their presence in the terrestrial Arachnida is precisely on a parallel with their absence in aquatic Crustacea and their presence in the feebly branchiate Amphipoda.

We shall now pass the groups of the Arthropoda in review, attempting to characterize them in such a way as will indicate their probable affinities and genetic history.

SUB-PHYLUM ARTHROPODA.—The characters of the sub-phylum and those of the associated sub-phyla Chætopoda and Rotifera, have been given above, as well as the general characters of the phylum Appendiculata which comprises these great sub-phyla.

Grade A.—Hyparthropoda.

Hypothetical forms.

Grade B.—Protarthropoda.

(a) The integument is covered by a delicate soft cuticle (not firm or plated) which allows the body and its appendages great range of extension and contraction.

(b) The paired claws on the ends of the parapodia and the fang-like modifications of these on the first post-oral appendages (mandibles) are the only hard chitinous portions of the integument.

(c) The head is deuterognathous—that is to say, there is only one prosthomere, and accordingly the first and only pair of hemignaths is developed by adaptation of the appendages of the second somite.

(d) The appendages of the third somite (second post-oral) are clawless oral papillæ.

(e) The rest of the somites carry equi-formal simple appendages, consisting of a corm or axis tipped with two chitinous claws and devoid of rami.

(f) The segmentation of the body is anomomeristic, there being no fixed number of somites characterizing all the forms included.

(g) The pair of eyes situated on the prosthomere are not of the Euarthropod type, but resemble those of Chætopods (hence Nereidophthalmous).

(h) The muscles of the body-wall and gut do not consist of transversely-stripped muscular fibre, but of the unstripped tissue observed also in Chætopoda.

(i) A pair of coelomducts is developed in every somite including the prosthomere, in which alone it atrophies in later development.

(j) The ventral nerve-cords are widely separated—in fact, lateral in position.

(k) There are no masses of nerve-cells forming a ganglion (neuro-mere) in each somite. (In this respect the Protarthropoda are at a lower stage than most of the existing Chætopoda.)

(l) The genital ducts are formed by the enlargement of the coelomducts of the penultimate somite.

Class (Unica).—ONYCHOPHORA.

With the characters of the grade: add the presence within the body of fine unbranched tracheal tubes, devoid of spiral thickening, opening to the exterior by numerous irregularly scattered tracheal pits.

Genera—Eoperipatus, Peripatopsis, Opisthopatus, &c.

Grade C (of the Arthropoda).—Euarthropoda.

(a) Integument heavily plated with firm chitinous cuticle, allowing no expansion and retraction of regions of the body nor change of dimensions, except, in some cases, a dorso-ventral bellows movement. The separation of the heavier plates of chitin by grooves of delicate cuticle results in the hinging or jointing of the body and its appendages, and the consequent flexing and extending of the jointed pieces.

(b) Claws and fangs are developed on the branches or rami of the parapodia, not on the end of the axis or corm.

(c) The head is either deutero-gnathous, tritognathous, or tetartognathous.

(d) Rarely only one, and usually at least two, of the somites following the mandibular somite carry appendages modified as jaws (with exceptions of a secondary origin).

(e) The rest of the somites may all carry appendages, or only a limited number may carry appendages. In all cases the appendages primarily develop rami or branches which form the limbs, the primitive axis or corm being reduced and of insignificant size. In the most primitive stock all the post-oral appendages had gnathobasic outgrowths.

(f) The segmentation of the body is anomomeristic in the more archaic members of each class, nomomeristic in the higher members.

(g) The two eyes of Chætopod structure have disappeared, and are replaced by the Euarthropod eyes.

(h) The muscles in all parts of the body consist of striped muscular fibre, never of unstriped muscular tissue.

(i) The coelomducts are suppressed in most somites, and retained only as the single pair of genital ducts (very rarely more numerous) and in some also as the excretory glands (one or two pairs).

(j) The ventral nerve-cords approach one another in the mid-ventral line behind the mouth.

(k) The nerve-cells of the ventral nerve-cords are segregated as paired ganglia in each somite, often united by meristic dislocation into composite ganglia.

(l) The genital ducts may be the coelomducts of the penultimate or antepenultimate or adjacent somite, or of a somite placed near the middle of the series, or of a somite far forward in the series.

Class 1 (of the Euarthropoda).—DIPLOPODA.

The head has but one prosthomere (monoprosthomerous), and is accordingly deutero-gnathous. This carries short-jointed antennæ (in one case biramous) and eyes, the structure and development of which require further elucidation. Only one somite following the first post-oral or mandibular segment has its appendages modified as jaws.

The somites of the body, except in Pauropus, either fuse after early development and form double somites with two pairs of appendages (Julus, &c.), or present legless and leg-bearing somites alternating.

Somites, anomomeristic, from 12 to 150 in the post-cephalic series. The genital ducts open in the fourth, or between the fourth and fifth post-oral somite.

Terrestrial forms with small-jointed legs formed by adaptation of a single ramus of the appendage. Tracheæ are present.

Note.—The Diplopoda include the Juliformia, the Symphyla (Scolopendrella), and Pauropoda (Pauropus). They were until recently classified with the Chilopoda (Centipedes), with which they have no close affinity, but only a superficial resemblance. (Compare the definition of the class Chilopoda.)

The movement of the legs in Diplopoda is like that of those of Peripatus, of the Phyllopod Crustacea, and of the parapodia of Chætopoda, symmetrical and identical on the two sides of the body. The legs of Chilopoda move in alternating groups on the two sides of the body. This implies a very much higher development of nerves and muscles in the latter.

Class 2 (of the Euarthropoda).—ARACHNIDA.

Head tritognathous and diprosthomerous—that is to say, with two prosthomeres, the first bearing typical eyes, the second a pair

of appendages reduced to a single ramus, which is in more primitive forms antenniform, in higher forms chelate or retrovert. The ancestral stock was panto-gnathobasic—i.e., had a gnathobase or jaw process on every parapodium. As many as six pairs of appendages following the mouth may have an enlarged gnathobase actually functional as a jaw or hemignath, but a ramus is well developed on each of these appendages, either as a simple walking leg, a palp, or a chela. In the more primitive forms the appendage of every post-oral somite has a gnathobase and two rami; in higher specialized forms the gnathobases may be atrophied in every appendage, even in the first post-oral.

The more primitive forms are anomomeristic; the higher forms nomomeristic, showing typically three groups or tagmata of six somites each.

The genital apertures are placed on the first somite of the second tagma or mesosoma. Their position is unknown in the more primitive forms. The more primitive forms have branchial respiratory processes developed on a ramus of each of the post-oral appendages. In higher specialized forms these branchial processes become first of all limited to five segments of the mesosoma, then sunk beneath the surface as pulmonary organs, and finally atrophied, their place being taken by a well-developed tracheal system.

A character of great diagnostic value in the more primitive Arachnida is the tendency of the chitinous investment of the tergal surface of the telson to unite during growth with that of the free somites in front of it, so as to form a pygidial shield or posterior carapace, often comprising as many as fifteen somites (Trilobites, Limulus).

A pair of central monomeric diplostichous eyes is often present on the head. Lateral eyes also are often present which are monostichous with aggregated lenses (*Limulus*) or with isolated lenses (*Scorpio*), or are diplostichous with simple lens (*Pedipalpi*, *Aranæa*, &c.).

Class 3 (of the Euarthropoda).—CRUSTACEA.

Head tetartognathous and triprosthomerous—that is to say, with three prosthomeres: the first bearing typical eyes, the second a pair of antenniform appendages (often biramous), the third a pair of appendages usually antenniform, sometimes claw-like. The ancestral stock was (as in the Arachnida) pantognathobasic, that is to say, had a gnathobase or jaw-process on the base of every post-oral appendage.

Besides the first post-oral or mandibular pair, at least two succeeding pairs of appendages are modified as jaws. These have small and insignificant rami, or none at all, a feature in which the Arachnida differ from them. The appendages of four or more additional following somites may be turned upwards towards the mouth and assist in the taking of food.

The more primitive forms (Entomostraca) are anomomeristic, presenting great variety as to number of somites, form of appendages, and tagmatic grouping; the higher forms (Malacostraca) are nomomeristic, showing in front of the telson twenty somites, of which the six hinder carry swimmerets and the five next in front ambulatory limbs. The genital apertures are neither far forward nor far backward in the series of somites, e.g., on the fourteenth post-oral in Apus, on the ninth post-oral in female *Astacus* and in *Cyclops*.

With rare exceptions, branchial plates are developed either by modification of a ramus of the limbs, or as processes on a ramus, or upon the sides of the body. No tracheate Crustacea are known, but some terrestrial Isopoda develop pulmonary in-sinkings of the integument. A characteristic, comparable in value to that presented by the pygidial shield of Arachnida, is the frequent development of a pair of long appendages by the penultimate somite, which with the telson form a trifold, or, when that is small, a bifid termination to the body.

The lateral eyes of Crustacea are polymeniscous, with highly specialized retinulae like those of Hexapoda, and unlike the simpler compound lateral eyes of lower Arachnida. Monomeniscous eyes are rarely present, and when present, single, minute, and central in position.

Note.—The Crustacea exhibit a longer and more complete series of forms than any other class of Arthropoda, and may be regarded as preserving the most completely represented line of descent.

Class 4.—CHILOPODA.

Head triprosthomerous¹ and tetartognathous. The two somites following the mandibular or first post-oral or buccal somite carry

¹ Embryological evidence of this is still wanting. In the other classes of Arthropoda we have more or less complete embryological evidence on the subject. It appears from observation of the embryo that whilst the first prosthomere of Centipedes has its appendages reduced and represented only by eye-patches (as in Arachnida, Crustacea, and Hexapoda), the second has a rudimentary antenna, which disappears, whilst the third carries the permanent antennæ, which accordingly correspond to the second antennæ of Crustacea, and are absent in Hexapoda.

appendages modified as maxillæ. The fourth post-oral somite has its appendages converted into very large and powerful hemignaths, which are provided with poison-glands. The remaining somites carry single-clawed walking legs, a single pair to each somite. The body is anomomeristic, showing in different genera from 17 (inclusive of the anal and genital) to 175 somites behind that which bears the poison-jaws. No tagmata are developed. The genital ducts open on the penultimate somite.

Tracheæ are developed which are dendriform and with spiral thickening of their lining. Their trunks open at paired stigmata placed laterally in each somite of the trunk or in alternate somites. Usually the tracheæ open by paired stigmata placed upon the sides of a greater or less number of the somites, but never quite regularly on alternating somites. At most they are present on all the pedigerous somites excepting the first and the last. In *Scutigera* there are seven unpaired dorsal stigmata, each leading into a sac whence a number of air-holding tubes project into the pericardial blood-sinus.

Renal cæcal tubes (Malpighian tubes) open into the proctodæum.

Class 5.—HEXAPODA.

Head shown by its early development to be triprosthomerous and consequently tetartognathous. The first prosthomere has its appendages represented by the compound eyes and a protocerebrum, the second has the antennæ for its appendages and a deutocerebral neuromere, the third has suffered suppression of its appendages (which corresponded to the second pair of antennæ of Crustacea), but has a tritocerebrum and cœlomic chamber. The mandibular somite bears a pair of gnathobasic hemignaths without rami or palps, and is followed by two jaw-bearing somites (maxillary and labial). This enumeration would give six somites in all to the head—three prosthomerous and three opisthomerous. Recent investigations (Folsom, 4) show the existence in the embryo of a pre-maxillary or supra-lingual somite which is suppressed during development. This gives seven somites to the Hexapod's head, the tergites of which are fused to form a cephalic carapace or box. The number is significant, since it agrees with that found in Edriophthalmous Crustacea, and assigns the labium of the Hexapod to the same somite numerically as that which carries the labium-like maxillipedes of those Crustacea.

The somites following the head are strictly nomomeristic and nomotagmic. The first three form the thorax, the appendages of which are the walking legs, tipped with paired claws or ungues (compare the homoplastic claws of *Scorpio* and *Peripatus*). Eleven somites follow these, forming the abdominal "tagma," giving thus twenty-one somites in all (as in the higher Crustacea). The somites of the abdomen all may carry rudimentary appendages in the embryo, and some of the hinder somites may retain their appendages in a modified form in adult life. Terminal telescoping of the abdominal somites and excalation may occur in the adult, reducing the obvious abdominal somites to as few as eight. The genital apertures are median and placed far back in the series of somites, viz., the female on the seventh abdominal (seventeenth of the whole series) and the male on the ninth or ante-penultimate abdominal (nineteenth of the whole series). The appendages of the eighth and tenth abdominal somites are modified as gonapophyses. The eleventh abdominal segment is the telson, usually small and soft; it carries the anus.

The Hexapoda are not only all confined to a very definite disposition of the somites, appendages, and apertures, as thus indicated, but in other characters also they present the specialization of a narrowly-limited highly-developed order of such a class as the Crustacea rather than a range from lower more generalized to higher more specialized forms such as that group and also the Arachnida present. It seems to be a legitimate conclusion that the most primitive Hexapoda were provided with wings, and that the term *Pterygota* might be used as a synonym of Hexapoda. Many Hexapoda have lost either one pair or both pairs of wings; cases are common, of wingless genera allied to ordinary *Pterygota* genera. Some Hexapods which are very primitive in other respects happen to be also *Apterous*, but this cannot be held to prove that the possession of wings is not a primitive character of Hexapods (compare the case of the *Struthious* Birds). The wings of Hexapoda are lateral expansions of the terga of the second and third thoracic somites. They appear to be serial equivalents (homogenous meromes) of the tracheal gills, which develop in a like position on the abdominal segments of some aquatic Hexapods.

The Hexapoda are all provided with a highly developed tracheal system, which presents considerable variation in regard to its stigmata or orifices of communication with the exterior. In some a serial arrangement of stigmata comparable to that observed in Chilopoda is found. In other cases (some larvæ) stigmata are absent; in other cases again a single stigma is developed, as in the smaller Arachnida and Chilopoda, in the median dorsal line or other unexpected position. When the facile tendency of Arthropoda to develop tracheal air-tubes is admitted, it becomes

probable that the tracheæ of Hexapods do not all belong to one original system, but may be accounted for by new developments within the group. Whether the primitive tracheal system of Hexapoda was a closed one or open by serial stigmata in every somite remains at present doubtful, but the intimate relation of the system to the wings and tracheal gills cannot be overlooked.

The lateral eyes of Hexapoda, like those of Crustacea, belong to the most specialized type of "compound eye," found only in these two classes. Simple monomeric eyes are also present in many Hexapods.

Renal excretory cæca (Malpighian tubes) are developed from the proctodæum (not from Mesenteron as in *Scorpion* and *Amphipoda*).

Concluding Remarks on the Relationships to one another of the Classes of the Arthropoda.—Our general conclusion from a survey of the Arthropoda amounts to this, that whilst *Peripatus*, the *Diplopoda*, and the *Arachnida* represent *terrestrial* offshoots from successive lower grades of primitive *aquatic* Arthropoda which are extinct, the Crustacea alone present a fairly full series of representatives leading upwards from unspecialized forms. The latter were not very far removed from the aquatic ancestors (*Trilobites*) of the Arachnida, but differed essentially from them by the higher specialization of the head. We can gather no indication of the forefathers of the Hexapoda or of the Chilopoda less specialized than they are, whilst possessing the essential characteristics of these classes. Neither embryology nor palæontology assists us in this direction. On the other hand, the facts that the Hexapoda and the Chilopoda have triprosthomerous heads, that the Hexapoda have the same total number of somites as the nomomeristic Crustacea, and the same number of opisthomerous in the head as the more terrestrial Crustacea, together with the same adaptation of the form of important appendages in corresponding somites, and that the compound eyes of both Crustacea and Hexapoda are extremely specialized and elaborate in structure and identical in that structure, all lead to the suggestion that the Hexapoda, and with them, at no distant point, the Chilopoda, have branched off from the Crustacean main stem as specialized terrestrial lines of descent. And it seems probable that in the case of the Hexapoda, at any rate, the point of departure was subsequent to the attainment of the nomomeristic character presented by the higher grade of Crustacea. It is on the whole desirable to recognize such affinities in our schemes of classification. We may tabulate the facts as to head-structure in *Chaetopoda* and *Arthropoda* as follows:—

Grade α (below the Arthropoda).—AGNATHA, APROSTHOMERA.

Without parapodial jaws; without the addition of originally post-oral somites to the præ-oral region, which is a simple prostomial lobe of the first somite; the first somite is perforated by the mouth and its parapodia are not modified as jaws.

= CHÆTOPODA.

Grade 1 (of the Arthropoda).—MONOGNATHA, MONOPROSTHOMERA.

With a single pair of parapodial jaws carried by the somite which is perforated by the mouth; this is not the first somite, but the second. The first somite has become a prosthomere, and carries a pair of extensile antennæ.

= ONYCHOPHORA (*Peripatus*, &c.).

Grade 2 (of the Arthropoda).—DIGNATHA, MONOPROSTHOMERA.

The third somite as well as the second develops a pair of parapodial jaws; the first somite is a prosthomere carrying jointed antennæ.

= DIPLOPODA.

Grade 3 (of the Arthropoda).—PANTOGNATHA, DIPROSTHOMERA.

A gnathobase is developed (in the primitive stock) on every pair of post-oral appendages; two prosthomerous present, the second somite as well as the first having passed in front of the mouth, but only the second has appendages.

= ARACHNIDA.

Grade 4 (of the Arthropoda).—PANTOGNATHA, TRIPROSTHOMERA.

The original stock, like that of the last grade, has a gnathobase on every post-oral appendage, but three prosthomerous are now present, in consequence of the movement of the oral aperture from the third to the fourth somite. The lateral eyes are polymeniscous,

with specialized vitrellæ and retinulæ of a definite type peculiar to this grade.

=CRUSTACEA, CHILOPODA,¹ HEXAPODA.

According to older views the increase of the number of somites in front of the mouth would have been regarded as a case of intercalation by new somite-budding of new præ-oral somites in the series. We are prohibited by a general consideration of metamerism in the Arthropoda (see a previous section of this article) from adopting the hypothesis of intercalation of somites. However strange it may seem, we have to suppose that one by one in the course of long historical evolution somites have passed forwards and the mouth has passed backwards. In fact, we have to suppose that the actual somite which in grades 1 and 2 bore the mandibles lost those mandibles, developed their rami as tactile organs, and came to occupy a position in front of the mouth, whilst its previous jaw-bearing function was taken up by the next somite in order, into which the oral aperture had passed. A similar history must have been slowly brought about when this second mandibulate somite in its turn became agnathous and passed in front of the mouth. The mandibular parapodia may be supposed during the successive stages of this history to have had, from the first, well-developed rami (one or two) of a palp-like form, so that the change required when the mouth passed away from them would merely consist in the suppression of the gnathobase. The solid palpless mandible such as we now see in some Arthropoda is, necessarily, a late specialization. Moreover, it appears probable that the first somite never had its parapodia modified as jaws, but became a prosthomere with tactile appendages before parapodial jaws were developed at all, or rather *pari passu* with their development on the second somite.

It is worth while bearing in mind a second possibility as to the history of the prosthomeres, viz., that the buccal gnathobasic parapodia (the mandibles) were in each of the three grades of prosthomerism only developed after the recession of the mouth and the addition of one, of two, or of three post-oral somites to the præ-oral region had taken place. In fact, we may imagine that the characteristic adaptation of one or more pairs of post-oral parapodia to the purposes of the mouth as jaws did not occur until after ancestral forms with one, with two, and with three prosthomeres had come into existence. On the whole the facts seem to be against this supposition, though we need not suppose that the gnathobase was very large or the rami undeveloped in the buccal parapodia which were destined to lose their mandibular features and pass in front of the mouth.

Arthur, Chester Alan (1830-1886), twenty-first president of the United States, was born in Fairfield, Vt., 5th October 1830. His father, William Arthur, when eighteen years of age, emigrated from County Antrim, Ireland, and, after teaching in various places in Vermont and Lower Canada, became a Baptist minister. William Arthur had married Malvina Stone, an American girl who lived at the time of the marriage in Canada, and the numerous changes of the family residence afforded a basis for allegations in 1880 that the son Chester was born not in Vermont, but in Canada, and was therefore ineligible for the presidency. Chester entered Union College as a sophomore, and graduated with honour in 1848. He then became a schoolmaster, at the same time studying law. In 1853 he entered a law office in New York City, and in the following year was admitted to the bar. In politics he was actively associated from the outset with the Republican party. When the Civil War began he held the position of engineer-in-chief on Governor Morgan's staff, and afterwards became acting quartermaster-general of the state troops, in which capacity he showed much administrative efficiency. At the close of Governor Morgan's term, 31st December 1862, General Arthur resumed the practice of his profession, remaining active, however, in party politics in New York City. In November 1871 he was appointed collector of customs for the port of New York. The custom-house had long been conspicuous for the most flagrant abuses of the "spoils system"; and though General Arthur admitted that the evils existed and that they rendered efficient administration

impossible, he made no extensive reforms. In 1877 President Hayes began the reform of the civil service with the New York custom-house. A non-partisan commission appointed by Secretary Sherman recommended sweeping changes. The president demanded the resignations of Arthur and his two principal subordinates. General Arthur refused, on the ground that to retire "under fire" would be to acknowledge wrong-doing, and claimed that as the abuses were inherent in a widespread system he should not be made to bear the responsibility alone. His cause was espoused by Senator Conkling, for a time successfully; but on 11th July 1878, during a recess of the Senate, the collector was removed, and in January 1879, after another severe struggle, this action received the approval of the Senate. In 1880 General Arthur was a delegate at large from New York to the Republican National Convention. In common with the rest of the "Stalwarts" he worked hard for the nomination of Grant. Upon the triumph of Garfield, the necessity of conciliating the defeated faction led to the hasty acceptance of Arthur for the second place on the ticket. His nomination was coldly received by the public; and when, after his election and accession, he actively engaged on behalf of Conkling in the great conflict with Garfield over the New York patronage, the impression was widespread that he was unworthy of his position. Upon the death of President Garfield, 19th September 1881, Arthur took the oath as his successor. Contrary to the general expectation, his appointments were as a rule unexceptionable, and he earnestly promoted the Pendleton law for the reform of the civil service. His use of the veto in the cases of a Chinese Immigration Bill and a River and Harbour Bill in 1882 confirmed the favourable impression which had been made. His

¹ The eyes of Chilopoda are not thoroughly understood, and may or may not be capable of interpretation as fitting in with those of Crustacea and Hexapoda.

administration was lacking in political situations of a dramatic character, but on all questions that arose his policy was sane and dignified. In 1884 he allowed his name to be presented for renomination in the Republican Convention, but he was easily defeated by the friends of Mr Blaine. At the expiration of his term he resumed his residence in New York City, where he died on 18th November 1886.

(W. A. D.)

Artillery.—Originally this word was applicable not only to missiles in general, but to the instruments or machines from which they were discharged—slings, bows and arrows, *tormenta*, &c. In the following article, however, we shall confine ourselves to the introduction of modern artillery and the progress of the bodies of men attached to its service.

The earliest recipe we possess for gunpowder is that of Dr John Anderne, who began to practise before 1350, and in his old age was appointed surgeon to Henry IV. It was recovered from his MSS. (now among the Sloane papers) by Mr Albert Way, and given in his edition of the *Promptorium Parvulorum*, an English-Latin vocabulary of the year 1440, in a note under "Gunne." This recipe is:—Saltpetre, 66·6 parts; charcoal, 22·2 parts; sulphur, 17·7 parts. The remarkable point about this recipe is, that it is identical with that given for rocket composition in the MS. of Marcus Græcus, who lived long before Friar Roger Bacon; and rocket composition will not project a round shot. The difficulty is easily explained. The fizzing rocket composition prepared with the Greek's impure ingredients became an explosive when prepared with the comparatively pure ingredients of a later age in the same proportions. If Bacon could refine nitre—a matter that hardly admits of a doubt—there may be a substratum of truth in the legend of the destruction of his Brazen Head. He and Friar Bungey, having mixed the pure ingredients in the old proportions, lay down to sleep. Their servant, Miles, from idle curiosity, applied fire to it, and produced an unexpected explosion which broke some of the chemical apparatus and terrified all three of them. If this view of the case be accepted gunpowder was invented by accident. It is not known who invented cannon, and we must fall back on the tradition that assigns the invention to a German monk, one Berthold Schwartz. There is good evidence to show that the Germans used guns at the siege of Cividade in Italy, 1331, and England had guns, both of iron and brass, in her navy in 1338. She was the first nation to bring guns into the open fields (at Cressy). Froissart calls these guns in one place *kanons*, in another *bombardiaux*; but Anderne expressly says they were called *gonnes* (in England), and Chaucer and Langland apply to them this word which had previously been used to denote the ancient *tormenta*.

For some three and a half centuries after the introduction of cannon artillerymen in all countries were civilians. Matters came to such a pass in England in the middle of the 16th century, that Henry VIII. had to employ Dutch gunners to instruct the men. In the time of Elizabeth the ages of some of the Tower gunners ranged from 64 to 92 years. The first to attempt any organization of the arm was Gustavus Adolphus. This great man clearly saw that the fundamental principle of all artillery organization is a twofold division, the gunners who follow an army into the field, and those who do not—field artillery and garrison artillery, and he reorganized his artillery accordingly; but he does not appear to have taken any step towards making them a military body. When the Great Rebellion broke out, loud were the complaints about the scarcity and inefficiency of the gunners. In 1638, Wemyss, master gunner of England, reported that there were "few good gunners in the kingdom . . . who understand the several ranges of ordnance or use of the mortar"; Norton refers in 1643 to "the penury of expert gunners"; and Eldred denounces "the idle laziness of the gunners," for which he had little or no power to punish them. Things became at length so intolerable that a warrant, dated 22nd August 1682, put the gunners under military discipline. Strange to say, the master gunners were shown as part of the "civil" establishment as late as 24th January 1783, in the establishment warrant of the ordnance. The ordnance officials had now some power over the gunners, yet their position was still so doubtful that a clause had to be inserted in their commissions in 1694 to place it beyond all doubt. These events were followed by the establishment of two permanent companies of artillery, 26th May 1716, and the formation of the (present) Royal Regiment of Artillery, 1st April 1722. Notwithstanding these improvements, Colonel Forbes Macbean, F.R.S., R.A., declares that the English artillery did not begin to assume a military appearance until the Flanders campaigns of 1748-49.

The officers of the French artillery before Louis XIV.'s time were only officers in the sense that they held an office. They were without rank in the army, and had no troops under their command. Only when war broke out were these officials united and supplied with the necessary *matériel*. At length Vauban protested against their position as helpless civilians, and they received military rank when Vallière reorganized the artillery in 1732.

"When Frederick the Great assumed the crown he found the army in a very good condition, excepting the corps of artillery and engineers, which consisted chiefly of mechanics and artisans, scarcely looked on by the rest of the army and the officers without commissions. His Majesty immediately drafted all the illiterate officers into the garrison regiments, supplying their places with gentlemen of examined capacity; gave them all commissions, rank with the officers of the guards, and an extraordinary pay."¹ It is strange that Capt. Smith, who was inspector of the Royal Military Academy, Woolwich, should have made no reference to the Prussian horse artillery. In 1773 the king formed a depot at Potsdam for the horse artillery (first formed 21st April 1759), consisting of 1 captain, 1 lieutenant, 10 non-commissioned officers, and 60 gunners. It is almost certain His Majesty had no intention of making it a *corps d'élite*.

Owing to the great progress made during the 18th century by those arts and sciences on which the efficiency of artillery essentially depends, it increased rapidly in numbers, and colleges were everywhere founded for the instruction of officers and others. The Royal Military Academy at Woolwich was opened in 1741. With regard to numbers, the four companies England possessed in the early years of the century were represented in Capt. Smith's time by four battalions; and these 3000 to 4000 men had swollen to 42,000 officers and men in 1899. Other artilleries increased in similar proportions.

The organization of the artilleries of the Great Powers is described under "Armies." A few remarks may be offered on the fundamental principles on which all these organizations are more or less based. Before the 18th century only one man can be named, the great Gustavus Adolphus, who clearly understood the first principle of all artillery organization—the separation of the personnel into two distinct bodies: (a) those who follow the army into the field, and (b) those who do not. This primary division of the artillery has long been practically acknowledged on the Continent and has been partially adopted in England. British garrison artillery consists of two branches: (a) the garrison artillery proper, or the gunners who defend a besieged fortress; and (b) the siege artillery, or the gunners who attack an enemy's fortress. Occasionally in a battle in the field guns of the 40-pr. type are used, taking up a fixed position which they occupy during the day. Whether these guns of position should be manned by garrison or field artillery is purely an academic question. The various subdivisions of the field artillery arise naturally from the nature of the duties they have to perform; while the nature of the ordnance with which they are severally armed is determined by the axiom, that the proper gun for any duty is the heaviest gun by which it can be carried out. The main body of the field artillery, the field batteries, are intended to support the infantry; and, in order to do so they must be capable of moving at a trot (and occasionally a gallop), the gunners being carried on the gun-carriages and limber, or the off-horses of the gun-team. Experience shows that guns of the 15-pr. type, drawn by six horses, are the most suitable for this branch. Similarly, guns of the 7-pr. type, carried on mules, are the best adapted for mountain artillery. For years there was much difficulty in organizing a body of field artillery to support cavalry. At length Frederick the Great solved the question by the creation of horse artillery, so called, not because the guns are drawn by horses, but because the gunners accompanying their gun are mounted on horses of their own distinct from the gun-team. At present the British equipment consists of guns of the 12-pr. type, each drawn by six horses.

For some five centuries the word "Artillery" in England meant simply garrison artillery; the field artillery only existed in time of war. When war broke out a train of artillery was organized, consisting of a certain number of field (or siege) guns, manned by garrison gunners; and when peace was proclaimed the train was disbanded, the *matériel* being returned into store, and the gunners reverting to some fort or stronghold. The first permanent body of field artillery in England were A and B troops of the royal horse artillery raised in 1793, the drivers of which (as well as the gunners) were enlisted under the military oath. In the early years of the nineteenth century a separate driver corps, under its own officers, was formed for the field batteries, but it was with good reason disbanded after Waterloo. The first permanent force of field batteries may be dated from the camp at Cobham, 1853. It is impossible to say on what principles the reorganization in 1899 of the artillery was based. This arm

¹ *Universal Military Dictionary*. Capt. G. Smith, R.A. London, 1779.

now consists of two large separate branches: (a) the royal horse artillery and the field batteries, and (b) the siege artillery, heavy field batteries, garrison artillery proper, and mountain artillery. There are 28 service batteries of horse artillery, armed with 12-pr. B.L. guns; 100 service field batteries armed with 15-pr. B.L. guns; and 12 service field batteries armed with 5-in. B.L. rifled howitzers—in all cases 6 pieces per battery. The formation of the latter was necessitated by the comparative flatness of the 12-pr. and 15-pr. trajectories, and the want of a shell, with a large angle of descent, to act upon troops under cover of earthworks, &c. The officers for each rank of the horse artillery are selected from the field batteries, to which they return on promotion to the next higher rank,* a system which gives rise to a constant interchange of officers. The garrison artillery consists of 104 service companies, of 199 officers and men each, on war strength, of which 7 companies are attached to siege train batteries, and 4 to heavy field batteries for Indian service.

A siege train battery for India consists of four 5-in. B.L. guns and two 6-in. B.L. howitzers. For service in South Africa, four 7-in. B.L. guns have been substituted for 6-in. B.L. guns. An Indian heavy field battery is armed with four 30-pr. B.L. guns and two 5·4-in. B.L. howitzers. A mountain battery is armed with six 2·5-in. screw R.M.L. guns, the projectile of which weighs 7 lb. A 10-pr. gun is under consideration. In addition to the foregoing there are in India 10 mountain batteries armed with 2·5-in. R.M.L. guns, 11 manned by natives, and 4 field batteries of the Haidarabad contingent armed with two 6-pr. S.B. guns and two 12-pr. S.B. howitzers. Finally, there are 13 companies of local artillery; at Kohat, 1 company; at Hong-Kong, 4; at Singapore, 1; in Ceylon, 2; in Mauritius, 2; at Sierra Leone, 1; at Jamaica, 1; and at St Lucia, 1. (H. W. L. H.)

Arts and Crafts.—The arts of decorative design and handicraft are comprehended under this title—all those arts and crafts, it may be said, which, in association with the mother-craft of building (or architecture) go to the making of the house beautiful. Arts and crafts are also associated with the movement generally understood as the English revival of decorative art, which has characterized the years since about 1875. The title itself only came into general use when the Arts and Crafts Exhibition Society was founded, and held its first exhibition at the New Gallery, London, in the autumn of 1888, since which time arts and crafts exhibitions have been common all over Great Britain. The idea of forming a society for the purpose of showing contemporary work in design and handicraft really arose out of a movement of revolt or protest against the exclusive view of art encouraged by the Royal Academy exhibitions, in which oil paintings in gilt frames claimed almost exclusive attention—sculpture, architecture, and the arts of decorative design, being relegated to quite subordinate positions. In 1886, out of a feeling of discontent among artists as to the inadequacy of the Royal Academy exhibitions, considered as representing the art of Great Britain, a demand arose for a national exhibition to include all the arts of design. One of the points of this demand was for the annual election of the hanging committee by the whole body of artists. After many meetings the group representing the arts and crafts (who belonged to a larger body of artists and craftsmen called the Art-workers' Guild, founded in 1884),¹ perceiving that the painters, especially the leading group of a school not hitherto well represented in the Academy exhibitions, only cherished the hope of forcing certain reforms on the Academy, and were by no means prepared to lose their chances of admission to its privileges, still less to run any risk in the establishment of a really comprehensive national exhibition of art, decided to organize an exhibition themselves in which artists and craftsmen might show their productions, so that contemporary work in decorative art should be displayed to the public on the same footing, and with the same advantages as had hitherto been monopolized by pictorial art. For many

years previously there had been great activity in the study and revival in the practice of many of the neglected decorative handicrafts. Amateur societies and classes were in existence, like the Home Arts and Industries Association, which had established village classes in wood-carving, metal-work, spinning and weaving, needle-work, pottery, and basket-work, and the public interest was steadily growing in handicraft. The machine production of an industrial century had laid its iron hands upon what had formerly been the exclusive province of the handicraftsman, who only lingered on in a few obscure trades and in forgotten corners of England for the most part. The ideal of mechanical perfection dominated British workmen, and the factory system, first by extreme division of labour, and then by the further specialization of the workman under machine production, left no room for individual artistic feeling among craftsmen trained and working under such conditions. The demand of the world-market ruled the character and quality of production, and to the few who would seek some humanity, simplicity of construction, or artistic feeling in their domestic decorations and furniture the only choice was that of the tradesman or salesman, or a plunge into costly and doubtful experiments in original design. From the 'forties onward there had been much research and study of mediæval art in England; there had been many able designers, architects, and antiquaries, such as the Pugins and Henry Shaw, and later William Burges, Butterfield, and G. E. Street and others. The school of præ-Raphaelite painters, by their careful and thorough methods, and their sympathy with mediæval design, were among the first to turn attention to beauty of design, colour, and significance in the accessories of daily life, and artists like D. G. Rossetti, Ford Madox Brown, and W. Holman Hunt themselves designed and painted furniture. The most successful and most practical effort indeed towards the revival of sounder ideas of construction and workmanship may be said to have arisen out of the work of this group of artists, and may be traced to the workshop of William Morris and his associates in Queen Square, London. William Morris, whose name covers so large a field of artistic as well as literary and social work, came well equipped to his task of raising the arts of design and handicraft, of changing the taste of his countrymen from the corrupt and vulgar ostentation of the Second Empire, and its cheap imitations, which prevailed in the 'fifties and 'sixties, and of winning them back, for a time at least, to the massive simplicity of plain oak furniture, or the delicate beauty of inlays of choice woods, or the charm of painted work, the richness and frank colour of formal floral and heraldic pattern in silk textiles and wall-hangings and carpets, the gaiety and freshness of printed cotton, or the romantic splendour of arras tapestry. Both William Morris and his artistic comrade and life-long friend, Edward Burne-Jones, were no doubt much influenced at the outset by the imaginative insight, the passionate artistic feeling, and the love of mediæval romance and colour of Dante Gabriel Rossetti, who remains so remarkable a figure in the great artistic and poetic revival of the latter half of the 19th century. To William Morris himself, in his artistic career, it was no small advantage to gain the ear of the English public first by his poetry. His verse-craft helped his handicraft, but both lived side by side. The secret of Morris's great influence in the revival was no doubt to be attributed to his way of personally mastering the working details and handling of each craft he took up in turn, as well as to his power of inspiring his helpers and followers. He was painter, designer, scribe, illuminator, wood-engraver, dyer, weaver, and finally printer and paper-maker, and having mastered these crafts, he could effectively direct and criticize the work of others.

¹ Whose members, comprehending as they do the principal living designers, architects, painters, and craftsmen of all kinds, have played no inconsiderable part in the aforesaid English revival.

His own work and that of Burne-Jones were well known to the public, and in high favour long before the Arts and Crafts Exhibition Society was formed, and though largely helped and inspired by the work of these two artists, the aims and objects of the society rather represented those of a younger generation, and were in some measure a fresh development both of the social and the artistic ideas which were represented by Ruskin, Rossetti, and Morris, though the society includes men of different schools. Other sources of influence might be named, such as the work of Norman Shaw and Philip Webb in architecture and decoration, of Lewis Day in surface pattern, and William de Morgan in pottery. The demand for the acknowledgment of the personality of each responsible craftsman in a co-operative work was new, and it had direct bearing upon the social and economic conditions of artistic production. The principle, too, of regarding the material, object, method, and purpose of a work as essential conditions of its artistic expression, the form and character of which must always be controlled by such conditions, had never before been so emphatically stated, though it practically endorsed the somewhat vague aspirations current for the unity of beauty with utility. Again, a very notable return to extreme simplicity of design in furniture and surface decoration may be remarked; and certain reserve in the use of colour and ornament, and a love of abstract forms in decoration generally, which are characteristic of later taste. Not less remarkable has been the new development in the design and workmanship of jewellery, gold- and silver-smiths' work, and enamels, with which the names of Alexander Fisher, Henry Wilson, Nelson Dawson, and C. R. Ashbee are associated. Among the arts and crafts of design which have blossomed into new life in recent years—and there is hardly one which has not been touched by the new spirit—book-binding must be named as having attained a fresh and tasteful development through the work of Mr Cobden-Sanderson and his pupils. The art and craft of the needle also must not be forgotten, and its progress is a good criterion of taste in design, choice of colour, and treatment. The work of Mrs Morris, of Miss Burden (sometime instructress at the Royal School of Art Needlework, which has carried on its work from 1875), of Miss May Morris, of Miss Una Taylor, of Miss Buckle, of Mrs Walter Crane, of Mrs Newbery, besides many other skilled needlewomen, has been frequently exhibited. Good work is often seen in the national competition works of the students of the English art schools, shown at South Kensington in July. The increase of late years in these exhibitions of designs worked out in the actual material for which they were intended is very remarkable, and is an evidence of the spread of the arts and crafts movement (fostered no doubt by the increase of technical schools, especially of the type of the Central School of Arts and Crafts under the Technical Education Board of the London County Council), of which it may be said that if it has not turned all British craftsmen into artists or all British artists into craftsmen, it has done not a little to expand and socialize the idea of art, and (perhaps it is not too much to say) has made the tasteful English house with its furniture and decorations a model for the civilized world. (w. c.)

Aru (Dutch *Aroe*) Islands, a group in the Dutch residency of Amboyna, S. of New Guinea, in 5° 18' to 7° 5' S. and 134° 8' to 134° 56' E. The larger islands (Wokan, Kobrur, Maikor, and Trangan) and certain of the lesser ones are regarded by the Malays as one land mass which they call *tana besar* ("great land"). Their area is 2442 square miles, not densely populated by about 13,000 inhabitants, of whom 581 are Christians

and 409 Mahomedans. The chief town, Dobbo, is visited by steamers of the Royal Steam Packet Company. The natives are governed by rajas (*orang kajas*), the Dutch Government being represented by a *posthouder*.

Aruwimi, R. See CONGO.

Arzamas, a district town of Russia, government and 81 miles S.W. of Nijni Novgorod, on the Tesha river. It is an important centre of trade, and has fifteen tanneries, twenty oil-works, flour-mills, and tallow-melting houses, and knitting is an important domestic industry. Population, 10,591.

Asbjørnsen, Peter Christen (1812-1885), and **Moe, Jørgen Engebretsen** (1813-1882), the eminent collectors of Norwegian folklore, were so closely united in their life's work that it is unusual to name them apart. Asbjørnsen was born in Christiania on the 15th January 1812; he belonged to an ancient family of the Gudbrandsdal, which is believed to have died with him. He became a student at the university in 1833, but as early as 1832, in his twentieth year, he had begun to collect and write down all the fairy stories and legends which he could meet with. Later he began to wander on foot through the length and breadth of Norway, adding to his stores. Moe, who was born at Mo i Hole parsonage, in Ringerike, on the 22nd April 1813, met Asbjørnsen first when he was fourteen years of age. A close friendship began between them, and lasted to the end of their lives. In 1834 Asbjørnsen discovered that Moe had started independently on a search for the relics of national folklore; the friends eagerly compared results, and determined for the future to work in concert. By this time, Asbjørnsen had become by profession a zoologist, and with the aid of the university made a series of investigating voyages along the coasts of Norway, particularly in the Hardanger fjord. Moe, meanwhile, had devoted himself to the study of theology, and was making a living as a tutor in Christiania. In his holidays he wandered through the mountains, in the most remote districts, collecting stories. In 1842-43 appeared the first instalment of the great work of the two friends, under the title of *Norwegian Popular Stories*, which was received at once all over Europe as a most valuable contribution to science as well as literature. A second volume was published in 1844, and a new collection in 1871. In 1845 Asbjørnsen published, without help from Moe, a collection of Norwegian fairy tales (*huldreeventyr og folkesagn*). In 1856 the attention of Asbjørnsen was called to the deforestation of Norway, and he induced the Government to take up this important question. He was appointed forest-master, and was sent by Norway to examine in various countries of the north of Europe the methods observed for the preservation of timber. From these duties, in 1876, he withdrew with a pension; he died in Christiania on the 6th January 1885. From 1841 to 1852 Moe travelled almost every summer through the southern parts of Norway, collecting traditions in the mountains. He had, however, long intended to take holy orders, and in 1853 he did so, becoming for ten years a chaplain in Sigdal, and then (1863) parish priest of Bragernes. He was moved in 1870 to the parish of Vestre Aker, near Christiania, and in 1875 he was appointed bishop of Christianssand. In January 1882 he resigned his diocese on account of failing health, and died on the following 27th March. Moe has a special claim on critical attention in regard to his lyrical poems, of which a small collection appeared in 1850. He wrote little original verse, but in his slender volume are to be found many pieces of exquisite delicacy and freshness. Asbjørnsen and Moe had the advantage of an admirable style in narrative prose. It was usually said that the

vigour of it came from Asbjørnsen and the charm from Moe, but the fact seems to be that from the long habit of writing in unison they had come to adopt almost precisely identical modes of literary expression. (E. G.)

Ascension, an island situated in the Atlantic Ocean, 800 miles north-west of St Helena. It is described in the Reports of the *Challenger* as "a series of extinct volcano cones." Ascension was compared by Darwin "to a huge ship kept in first-rate order." It is under the jurisdiction of the Admiralty, is garrisoned by marines, and is rated as a ship of war. The bare hills have been covered with plants and shrubs, a road has been constructed for six miles from the landing-place, and a good water supply secured. The average rainfall is slight, March and April being the rainy months. Population, about 160 sailors, marines, and Krumen from the Liberian coast. Fish, turtle, and edible birds' eggs are the chief products.

Asch, a manufacturing town of Bohemia, in the government district of Eger, near the Saxon and Bavarian frontiers, and a station on the Bavarian State Railway. Population in 1890, 15,556; in 1900, 19,146 (all German—70 per cent. Protestant, 30 per cent. Roman Catholic). It is the seat of a Protestant superintendent, whose jurisdiction extends over fourteen villages, of which six are in Bavaria. It contains monuments to Luther and to the Germanizing and liberal Austrian emperor, Joseph II. Important textile industry employs 11,000 hands, and there are manufactures of knitted goods (23,000 hands), leather, machinery, bleaching, dyeing, brewing, &c.

Aschaffenburg, a town of Bavaria, Germany, district Lower Franconia, on the right bank of the Main, 26 miles S.E. from Frankfurt by rail. The parish church of Our Lady and the church of St Agatha have been lately restored. There is an archæological museum. Ready-made clothing, paper, cellulose, tobacco, lime, and liqueurs are manufactured. Population (1900), 18,091. In March and July 1901 two suburbs were incorporated, raising the total population to 22,181.

Aschersleben, a town of Prussia, province of Saxony, 36 miles by rail N.W. from Halle. There are iron, zinc, and chemical manufactures, and the cultivation of agricultural seeds. Here are brine springs and baths. Population (1885), 21,519; (1900), 27,245.

Ascoli Piceno, a town and bishop's see of Italy (the Marches), capital of the province of Ascoli, situated on the E. side of the Apennines, 57 miles by rail S. from Ancona. The cathedral was restored in 1888, and is adorned with modern frescoes. There are an antiquarian museum, an agricultural school, and a training school for female teachers. The industries of Ascoli include silk-worm breeding, flour-mills, brickworks, limekilns, potteries, and factories for furniture and vehicles. Population, commune (1881), 23,225, (1901), 28,882; province (1881), 209,185, (1901), 245,883.

Ashanti. See GOLD COAST.

Ashby-de-la-Zouch, a market-town and railway station, in the Bosworth parliamentary division of Leicestershire, England, 16 miles N.W. by W. of Leicester. The old church of St Helen has been restored and enlarged, a Queen Eleanor cross erected to the Countess of Loudoun, a grammar school built, the charity Bluecoat and Greencoat schools have been enlarged, and a cottage hospital has been opened. Area of urban district (co-extensive with parish), 6061 acres; population (1901), 4722.

Asheville, a city of North Carolina, U.S.A., and capital of Buncombe county. It is situated in the western, mountainous part of the state, in 35° 35' N. lat. and

82° 33' W. long., on a terrace above the French Broad, on the north bank, at the mouth of the Swananoa, and at an altitude of 2000 feet. The site is uneven and the plan is irregular. It is noted as a winter health resort, particularly for Northern people. It is entered by the Southern railway, by which it has connexions eastward and westward. It is the seat of Asheville Female College. Near it is Mr G. W. Vanderbilt's estate, Biltmore, of 100,000 acres, mainly forest land, on which tree culture has been conducted on a large scale. Population (1900), 14,694.

Ashford, a market-town and railway station in the Ashford parliamentary division of Kent, England, on the Esshe, a branch of the Stour, 14 miles S.W. of Canterbury. Ashford has agricultural implement works, breweries, and locomotive and carriage works. Area of urban district, 2850 acres; population (1891), 10,728; (1901), 12,808.

Ashland, a city of Boyd county, Kentucky, U.S.A., situated in the north-eastern part of the state, on the south bank of the Ohio and on the Chesapeake and Ohio railway, at an altitude of 537 feet. It has important iron manufactures and considerable commerce, especially by river. Population (1900), 6800.

Ashland, a borough of Schuylkill county, in eastern Pennsylvania, U.S.A., situated in the anthracite coal region, at an altitude of 856 feet; a coal-mining place on the Lehigh Valley and the Philadelphia and Reading railways. Population (1900), 6438.

Ashland, a city of Wisconsin, U.S.A., and capital of Ashland county, situated in the northern part of the state, at the head of Chaquamegon Bay, an arm of Lake Superior. It is in 46° 35' N. lat. and 90° 58' W. long., at an altitude of 678 feet. It was founded in 1885 by the discovery of the Gogebic Range iron mines, 40 miles south-east. Its plan is regular. The Northern Pacific, the Wisconsin Central, the Chicago, St Paul, Minneapolis, and Omaha, and the Chicago and North-Western railways serve it; and it has also an extensive lake commerce, principally in lumber and iron ore. Population (1890), 9956; (1895), 12,310; (1900), 13,074.

Ashtabula, a city of Ashtabula county, Ohio, U.S.A., in the north-eastern part of the state, near the shore of Lake Erie; altitude, 647 feet. It is an important railway centre, being traversed by two great trunk lines and the terminus of a third. Having a fine harbour, it is a considerable lake port, shipping vast quantities of iron ore, in transport from the iron ranges of Lake Superior to Pittsburg for smelting. Population (1900), 12,949.

Ashton-in-Makerfield, a township in the Newton parliamentary division of Lancashire, England, 7 miles N. by W. of Warrington. The district is rich in minerals and has large collieries, and a colliery company's institute; iron goods are manufactured. Area of urban district, 6250 acres. Population (1901), 18,687.

Ashton-under-Lyne, a municipal and parliamentary borough (one member) of Lancashire, England, on the Tame, 6½ miles E. of Manchester by rail. Modern structures are a church, a Congregational chapel (£50,000), a theatre, a technical school, a school of art and free library, a children's hospital, and a new post-office. The market-place and town hall have been enlarged. There is a public park of 64 acres. Population of municipal borough in 1881, 37,040; in 1891, 40,463; in 1901, 43,890. In November 1898, a portion of the urban district of Dukinfield in Cheshire was added to the borough of Ashton-under-Lyne, and part of the borough was transferred to Dukinfield. As rearranged, the municipal borough has an area of 1396 acres.

ASIA.

NEXT to Africa, we shall probably find in Asia, oldest of the Old World continents, a greater store of new facts presented to us, or, it may be, of old facts with new features revealed by the light of modern scientific research, than in any other quarter of the globe. It is in the realm of physical geography, and its collateral branches of science, that we have chiefly to mark important accessions of knowledge; and the knowledge thus acquired is, throughout the continent, given to us rather in the form of more exact information than as absolutely new discovery which might lead to any large correction of preconceived ideas.

Recent changes in continental physio-graphy.

General Expansion of Exact Surveys.

The progress of geodetic surveys in Russia had long ago extended across the European half of the great empire, Petersburg being connected with Tiflis on the southern slopes of the Caucasus by a direct system of triangulation carried out with the highest scientific precision. Petersburg, again, is connected with Greenwich by European systems of triangulation; and the Greenwich meridian has been adopted by Russia as the zero for all her longitude values. But beyond the eastern shores of the Caspian no system of direct geodetic measurement by first-class triangulation has as yet been possible, and the surveys of Asiatic Russia are separated from those of Europe by the width of that inland sea. The arid nature of the trans-Caspian deserts has so far proved an insuperable obstacle to those rigorous methods of geodetic survey which distinguish Russian methods in Europe, so that Russian geography in Central Asia is dependent on other means than that of direct measurement for the co-ordinate values in latitude and longitude for any given point. The astronomical observatory at Tashkent is adopted for the initial starting-point of the trans-Caspian triangulation of Russia; the triangulation ranks as second class only, and now extends to the Pamir frontier beyond Osh. The longitude of the Tashkent observatory has been determined by telegraph differentially with Pulkova as follows:—

	H.	M.	S.
In 1875 <i>visâ</i> Ekaterinburg and Omsk	2	35	52-151
„ 1891 „ Saratow „ Orenburg	2	35	52-228
„ 1895 „ Kiew „ Baku	2	35	51-997

With these three independent values, all falling within a range of 0°25, it is improbable that the mean value has an error as large as 0°10.

Exact surveys in Russia, based upon triangulation, extend as far east as Chinese Turkestan in longitude about 75° E. of Greenwich. In India geodetic triangulation furnishes the basis for exact surveys as far east as the eastern boundaries of Burma in longitude about 100° E.

Extent of exact surveys in Asia.

The years since 1875 have witnessed the forging of the final links in the great geodetic triangulation of India, so far as the peninsula is concerned. Further geodetic connexion with the European systems still remains to be accomplished. Since 1890 further and more rigorous application of the telegraphic method of determining longitudes differentially with Greenwich has resulted in a slight correction (amounting to about 2" of arc) to the previous determination by the same method through Suez. This last determination was effected through four arcs as follows:—

- I. Greenwich—Potsdam.
- II. Potsdam—Teheran.
- III. Teheran—Bushire.
- IV. Bushire—Karachi.

Each arc was measured with every precaution and a multitude of observations. The only element of uncertainty was caused by the retardation of the current, which between Potsdam and Teheran (3000 miles) took 0°20 to travel; but it is probable that the final value can be accepted as correct to within 0°05.

The final result of this latest determination is to place the Madras observatory 2' 27" to the west of the position adopted for it on the strength of absolute astronomical determinations.

But whilst we have yet to wait for that expansion of first-class geodetic triangulation which will bring Asia into connexion with Europe by the direct process of earth measurement, we have already effected a topographical connexion between Russian and Indian surveys which sufficiently proves that the deductive methods employed by both countries for the determination of the co-ordinate values of fixed points so far agree that, for all practical purposes of future Asiatic cartography, no difficulty in adjustment between Indian and Russian mapping need be apprehended. This connexion was effected near Lake Victoria during the Pamir Boundary Commission of 1895. The final values determined in longitude for the initial pillar of the boundary by the Russian and English surveyors respectively differed by about 1·0" only, a difference which will never lead to serious difficulties in mutual map adjustment. In connexion with the Indian triangulation minor extensions carried out on systems involving more or less irregularity have been pushed outwards on all sides. They reach through Afghanistan and Baluchistan to the eastern districts of Persia, and along the coast of Makrán to that of Arabia. They have long ago included the farther mountain peaks of Nepal, and they now branch outwards towards Western China and into Siam. These far extensions furnish the basis for a vast amount of exploratory survey of a strictly geographical character, and they have contributed largely towards raising the standard of accuracy in Asiatic geographical surveys to a level which was deemed unattainable fifty years ago. There is yet a vast field open in Asia for this class of surveys. Whilst at the close of the 19th century Western Asia (exclusive of Arabia) may be said to be freed from all geographical perplexity, China, Mongolia, and Eastern Siberia still include enormous areas of which our geographical knowledge is in a primitive stage of nebulous uncertainty.

Connexion between Russian and Indian Surveys.

Extension of geographical surveys.

Of scientific geographical exploration in Asia (beyond the limits of actual surveys) the period since 1870 has been so prolific that it is only possible to refer in barest outline to some of the principal expeditions, most of which have been directed either to the great elevated tableland of Tibet, or to the central depression which exists to the north of it. In Southern Tibet the trans-Himalayan explorations of the native surveyors attached to the Indian survey, notably pundits Nain Sing and Kishen Sing, have added largely to our knowledge of the great plateau. Nain Sing explored the sources of the Indus and of the Upper Brahmaputra in the years 1865-67; and in 1874-75 he followed a line from the eastern frontiers of Kashmir to the Tengri Nor lake and thence to Lhasa, in which city he remained for some months. Kishen Sing's remarkable journey in 1879-82 extended from Lhasa northwards through Tsaidam to Sachu, or Saitu, in Mongolia. He subsequently passed through Eastern Tibet to

Explorations.

Indian explorers.

the town of Darchendo, or Ta Chien Lu, on the high road between Lhasa and Peking, and on the borders of China. Failing to reach India through Upper Assam he returned to the neighbourhood of Lhasa, and crossed the Himalayas by a more westerly route. Both these explorers visited Lhasa.

In 1871-73 the great Russian explorer, Prjevalski, crossed the Gobi desert from the north to Kansu in Western China. He first defined the geography of Tsaidam, and mapped the hydrography of that remarkable region,

from which emanate the great rivers of China, Siam, and Burma. He penetrated southwards to within a month's march of Lhasa. In 1876 he visited the Lob Nor and discovered the Altyn Tagh range. In 1879 he followed up the Urangi river to the Altai mountains, and demonstrated to the world the extraordinary physical changes which have passed over the heart of the Asiatic continent since Chenghiz Khan massed his vast armies in those provinces. He crossed, and named, the Dzungarian extension of the Gobi desert,

Russian explorers.

SKETCH MAP OF ASIA.

London, Stanford's Geog. Catalogue

and then traversed the Gobi itself from Hami to Sachu, which became a point of junction between his journeys and those of Kishen Sing. He visited the sources of the Hoang-ho (Yellow river) and the Salween, and then returned to Russia. His fourth journey in 1883-85 was to Sining (the great trade centre of the Chinese borderland), and thence through Northern Tibet (crossing the Altyn Tagh to Lob Nor), and by the Cherchen-Kiria trade route to Khotan. From Khotan he followed the Tarim to Aksu.

Following Prjevalski the Russian explorers, Pevtsoff and Roborovski, in 1889-90 (and again in 1894) have added

greatly to our knowledge of the topography of Western Chinese Turkestan and the northern borders of Tibet; all these Russian expeditions being conducted on scientific principles and yielding results of the highest value.

Although the establishment of a lucrative trade between India and Central Asia had been the dream of many successive Indian viceroys, and much had been done towards improving the approaches to Simla from the north, very little was really known of the highlands of the Pamirs, or of the regions of the great central depression, before the mission of Sir Douglas Forsyth to Yarkand in 1870. Shaw and Hay-

Other explorations in Central Asia.

ward were the European pioneers of geography into the central dominion of Kashgar, arriving at Yarkand within a few weeks of each other in 1868. Shaw subsequently accompanied Forsyth's mission in 1870, when Trotter made the first maps of Chinese Turkestan. The next great accession to our knowledge of Central Asiatic geography was gained with the Russo-Afghan Boundary Commission of 1884-86, when Afghan Turkestan and the Oxus regions were mapped by surveyors under Holdich; and when Ney Elias crossed from China through the Pamirs and Badakshan to the camp of the commission, identifying the great "Dragon Lake," Rangkul, on his way. About the same time a mission, under Lockhart, crossed the Hindu Kush into Wakhan, and returned to India by the Bashgol valley of Kafirstan. This was Woodthorpe's opportunity, and he was then enabled to verify the results of M'Nair's previous explorations, and to determine the conformation of the Hindu Kush. In 1885 Carey and Dalgleish, following more or less the tracks of Prjevalski, contributed much that was new to the map of Asia; and in 1886 Younghusband completed a most adventurous journey across the heart of the continent by crossing the Muztagh, the great mountain barrier between China and Kashmir.

It was in 1886-87 that Bonvalot, accompanied by Prince Henri d'Orléans, crossed the Tibetan plateau from north to south, but failed to enter Lhasa. In 1889-91 the American traveller, Rockhill, commenced his Tibetan journeys, and also attempted to reach Lhasa, without success. By his writings, as much as by his explorations, Rockhill has made his name great in the annals of Asiatic research. In 1891 Bower made his famous journey from Leh to Peking. He, too, failed to penetrate the jealously guarded portals of Lhasa; but he secured (with the assistance of a native surveyor) a splendid addition to our previous Tibetan mapping. In 1891-92-93 the gallant French explorer, De Rhins, was in the field of Tibet, where he finally sacrificed his life to his work; and the same years saw Curzon in the Pamirs, and Littledale on his first great Tibetan journey, accompanied by his wife. Littledale's first journey ended at Peking; his second, in 1894-95, took him almost within sight of the sacred walls of Lhasa, but he failed to pass inside. Greatest amongst recent Asiatic explorers (if we except Prjevalski) is the brave Swede, Sven Hedin, whose travels through the deserts of Takhla Makan and Tibet, and whose investigations in the glacial regions of the Sarikol mountains, occupied him from 1894 to 1896. His is a truly monumental record. From 1896 to 1898 we find two British cavalry officers taking the front position in the list of Tibetan travellers—Wellby of the 18th Hussars, and Deasy of the 16th Lancers, each striking out a new line, and each rendering most valuable service to geography. The latter continued the Pamir triangulation, which had been carried across the Hindu Kush by Holdich and Wahab during the Pamir Boundary Commission of 1895, into the plains of Kashgar and to the sources of the Zarafshan.

Meanwhile, in the farther east so rapid has been the progress of geographical research since the first beginnings of investigation into the route connexion between Burma and China in 1874 (when the brave Margary lost his life), that a gradually increasing tide of exploration, setting from east to west, and back again, has culminated in a flood of inquiring experts intent on economic and commercial development in China, essaying to unlock those doors to trade which are hereafter to be propped open for the benefit of humanity. Gill, of the Indian survey, first made his way across China to Eastern Tibet and Burma, and subsequently delighted the world with his story of the *River of Golden Sand*. Then followed another charming writer,

Baber, who, in 1877-78, unravelled the geographic mysteries of the western provinces of the Celestial empire. Mark Bell crossed the continent in 1887, and illustrated its ancient trade routes, following the steps of Colquhoun, who wandered from Peking to Talifu in 1881. Meanwhile, the acquisition of Burma and the demarcation of boundaries had opened the way to the extension of geographical surveys in directions hitherto untraversed. Woodthorpe was followed into Burmese fields by many others; and amongst the earliest travellers to those mysterious mountains which hide the sources of the Irrawaddy, the Salween, and the Mekong, was Prince Henri d'Orléans. Burma was rapidly brought under survey; Siam was already in the map-making hands of M'Carthy, whilst Curzon and Warrington Smyth added much to our knowledge of its picturesque coast districts.

Turning our attention westwards, no advance in the progress of scientific geography is more remarkable than that recorded on the northern and north-western frontiers of India. Here there is little matter of exploration. It has rather been a wide extension of scientific geographical mapping. The Afghan war of 1878-80; the Russo-Afghan Boundary Commission of 1884-85; the occupation of Gilgit and Chitral; the extension of boundaries east and north of Afghanistan, and again, between Baluchistan and Persia—these, added to the opportunities afforded by the systematic survey of Baluchistan which has been steadily progressing since 1880—have combined to produce a series of geographical maps which extend from the Oxus to the Indus, and from the Indus to the Euphrates.

In these professional labours the Indian surveyors have been assisted by such scientific geographers as Houtoum Schindler, Vaughan, and Sykes in Persia, and by Robertson and Cockerill in Kafirstan and the Hindu Kush.

In still more western fields of research much additional light has been thrown since 1875 on the physiography of the great deserts and oases of Arabia. The labours of Doughty and Blunt in Northern Arabia in 1877-78 were followed by those of Schweinfurth and Glaser in the south-west about ten years later. In 1884-85 Mills made his adventurous journey through Oman, whilst Bent threw searchlights backwards into ancient Semitic history by his investigations in the Bahrein Islands in 1888, and in Hadramut in 1894-95.

In Northern Asia it is impossible to follow in detail the results of the organized Russian surveys. The vast steppes and forest-clad mountain regions of Siberia have assumed a new geographical aspect in the light of these revelations, and already promise a new world of economic resources to Russian enterprise in the near future. A remarkable expedition by Baron Toll in 1892 through the regions watered by the Lena, resulted in the collection of material which will greatly help to elucidate some of the problems which beset the geological history of the world, proving *inter alia* the primeval existence of a boreal zone of the Jurassic Sea round the North Pole. The distinguished scientist, Richtshofen, has enriched the world by the results of his investigations into the physiography of the North-East in China, Korea, and Japan.

It is not possible further to follow the footsteps of that great company of geographers of all nations who have searched for new material for the illustration of Asiatic geography, geology, and history. In no period of the world's history, of equal length of time, has so much scientific enterprise been directed towards the field of Asiatic inquiry as during the last quarter of the 19th century.

General Physiography of the Asiatic Continent.

Asia is divided laterally along the parallel of 40° N. lat. by a depression which, commencing on the east of the desert of Gobi, extends westwards through Mongolia to Chinese Turkestan. To the west of Kashgar the central depression is limited by the meridional range of Sarikol and the great elevation of the Pamirs, of which the Sarikol is the eastern face. The level of this depression (once a vast inland sea) between the mountains which enclose the sources of the Hoang-ho and the Sarikol range probably never exceeds 2000 feet above sea, and modern researches tend to prove that in the central portions of the Gobi (about Lob Nor) it may be actually below sea-level. A vast proportion of the continent north of this central line is but a few hundred feet in altitude. Shelving gradually upward from the low flats of Siberia the general continental level rises to a great central water-parting, or divide, which stretches from the Black Sea through the Elburz and the Hindu Kush to the Tian Shan mountains in the Pamir region, and hence to Bering Strait on the extreme north-east. This great divide is not always marked by well-defined ranges facing steeply either to the north or south. There are considerable spaces where the strike, or axis, of the main ranges is transverse to the water-parting, which is then represented by intermediate highlands forming lacustrine regions with an indefinite watershed. Only a part of this great continental divide (including such ranges as the Hindu Kush, Tian Shan, Altai, or Khangai) rises to any great height, a considerable portion of it being below 5000 feet in altitude. South of the divide the level at once drops to the central depression of Gobi, which forms a vast interior, almost waterless, space, where the local drainage is lost in deserts or swamps. South of this enclosed depression is a second great hydrographic barrier which parts it from the low plains of the Amur, of China, Siam, and India, sinking into the shallows of the Yellow Sea and the shoals which enclose the islands of Japan and Formosa, all of them once an integral part of the continent. This second barrier is one of the most mighty upheavals in the world, both by reason of its extent and its altitude. Starting from the Amur river and reaching along the eastern margin of the Gobi desert towards the sources of the Hoang-ho, it merges into the Altyn Tagh and the Kuen Lun, forming the northern face of the vast Tibetan highlands which are bounded on the south by the Himalaya. This great lacustrine plateau averages 15,000 feet above sea-level. The Pamir highlands between the base of the Tian Shan mountains and the eastern buttresses of the Hindu Kush unite these two great divides, enclosing the Gobi depression on the west; and they would again be united on the east but for the transverse valley of the Amur, which parts the Kinghan mountains from the Yablonoi system to the east of Lake Baikal.

If we consider the whole continent to be divided into three sections, viz., a northern section with an average altitude of less than 5000 feet above sea, where all the main rivers flow northward to the Mediterranean, the Arctic Sea, or the Caspian; a central section of depression, where the drainage is lost in swamps or "hamúns," and of which the average level probably does not approach 2000 feet above sea; and a southern section divided between highly elevated tablelands from 15,000 to 16,000 feet in altitude, and lowlands of the Arabian, Indian, Siamese, and Chinese peninsulas, with an ocean outlet for its drainage, we find that there is only one direct connexion between northern and southern sections which involves no mountain passes, and no formidable barrier of altitudes. That one is afforded by the narrow valley of the Hari Rud to the west of Herat. From the Caspian to Karachi it is

possible to pass without encountering any orographic obstacle greater than the divide which separates the valley of the Hari Rud from the Helmund "hamún" basin, which may be represented by an altitude of about 4000 feet above sea-level. This fact possesses great significance in connexion with the development of Asiatic railways.

Hydrography.—If we examine the hydrographic basins of the three divisions of Asia thus indicated we find that the northern division, which includes the drainage falling into the Arctic Sea, the Aralo-Caspian depression, or the Mediterranean, embraces an area of about 6,394,500 square miles, as follows:—

Area of Arctic river basins	Sq. miles.
" Aralo-Caspian basin	4,367,000
" Mediterranean	1,759,000
	268,500
Total	6,394,500

The southern division is nearly equal in extent—

Pacific drainage	Sq. miles.
Indian Ocean	3,641,000
	2,873,000
Total	6,514,000

The interior or inland basins, including the lacustrine regions south of the Arctic watershed, the Gobi depression, Tibetan plateau, the Iranian (or Perso-Afghan) uplands, the Syro-Arabian inland basin, and that of Asia Minor, amount to 3,141,500 sq. miles, or about half the extent of the other two.

By far the largest Asiatic river basin is that of the Ob, which exceeds 1,000,000 sq. miles in extent. On the east and south the Amur embraces no less than 776,000 sq. miles, the Yang-tse-kiang including 685,000, the Ganges 409,500, and the Indus 370,000 sq. miles.

The lakes of Asia are innumerable, and vary in size from an inland sea (such as Lakes Baikal and Balkash) to a highland loch, or the indefinitely extended swamps of Persia. Many of them are at high elevations (Lake Victoria, 13,400 feet, being probably the most elevated), and are undoubted vestiges of an ancient period of glaciation. Such lakes, as a rule, show indications of a gradual decrease in size. Others are relics of an earlier geological period, when land areas recently emerged from the sea were spread at low levels with alternate inundations of salt and fresh water. Of these Lob Nor and the Helmund "hamúns" are typical. Such lakes (in common with all the plateau "hamúns" of S. W. Baluchistan and Persia) change their form and extent from season to season, and many of them are impregnated with saline deposits from the underlying strata. The "kavirs," or salt depressions, of the Persian desert are more frequently widespread deposits of mud and salt than water-covered areas.

Geology.—Over a great part of Asia, including the Caspian depression, the Central Asian Khanates, Turkestan, Tibet, China, Siberia, and India, geological research has been closely, and, in many regions, scientifically pursued. The results of such investigations are at present too disconnected and fragmentary to afford material for the construction of a continuous geological history of the formation of the whole continent. They have mainly been directed to those regions whose economic development seems possible, and whose resources of mineral wealth may be expected to enrich the world.

The great Caspian depression and its extension to the Aral Sea has been examined by Russian scientists, and the old theory of the former Oxus contribution to the Caspian finally dismissed. Whilst the extent and nature of these beds of an ancient western ocean have been under investigation, the Central Sea to the east of the Pamirs, represented by the Gobi Sands, the Tarim desert, and by the shallow lakes and swamps of Lob Nor, has also received much attention; but it has not yet been exhaustively explored, and we await the results of Sven Hedin's expedition to decide the position and extent of its possible survival in the existing lake system. Geological researches in Siberia have proved the existence

of almost boundless sources of mineral wealth in the north. Explorations in China have opened up new and vast fields for mining industry in the east; and the plains of India and Burma appear in a new light under the display of economic possibilities which the systematic labours of the Geological Survey of India have revealed. Never perhaps in the world's history has the importance of investigating old fields by the newest lights of science been so fully illustrated as in Asia during the last quarter of the 19th century. Changes in the configuration of the continent, due to slow processes of upheaval and subsidence, have been

Physical changes in the earth's crust.

proved not only to have taken place in the past, and thereby modified climatic conditions, and to have sensibly affected the history of the human race in Asia, but their continued action can be traced in the present, and in one instance at least (in Turkestan) the actual measurement of the progress in upheaval has been found possible.

One of the most remarkable discoveries of the last decade of the 19th century is the continuation westwards through Baluchistan to the Persian border of that line of volcanic activity

Volcanoes.

which, commencing in Kamchatka, and following the eastern coast-line of Asia to the Malay archipelago, there turns westward to the Sea of Bengal and is arrested in Arakan. No trace of it is to be found in the line of depression formed by the Indo-Gangetic alluvial plain across the width of the Indian peninsula, but it is again manifest in the active mud volcanoes of the Makran coast, and continues trending slightly north of west to the Persian frontier, where in (approximate) lat. 28° 30' N. and long. 61' E. it culminates in a giant inland volcano called the Koh-i-Taftan, or "burning" mountain. The highest peak of this mountain is 13,480 feet above sea-level, and from it there issues a perpetual pillar of smoke, which hangs heavily above the snow-clad summit. This volcano (which has been ascended by Captain Sykes) is, so far as is known at present, the only inland volcano in Asia. Its position has been well fixed from the Baluchistan survey bases.

In India geological science has shaped the historical outline for the evolution of geography from the early ages, when a land connexion existed between India and Africa, to the gradual and slow process of Himalayan upheaval, and the formation of the Himalayan valleys, by erosion, in the form in which we now see them. The entire peninsular area, including the north-west borderlands and Burma, are shown to have been submerged when the greater part of the peninsula (including the Gangetic basin) existed in the form of dry land, and the fascinating theory of a continuous sea which united the basins of the Indus and Ganges has to be given up. Many of the shifting changes which have occurred in the channels of great rivers are matters of history, as are some of the alterations in the coast-line, which can be readily traced on the Makran seaboard and between Bombay and Karachi.

Geological history of India.

Climate.—Although the general nature of those influences which govern the phenomena of climate over the broad area of the Asiatic continent have been fairly well established, yet the improvements in the methods of meteorological science and the establishment of centres for the record of observed phenomena over a very wide extent of Southern and Western Asia have much improved our knowledge of local cause and effect, and have especially assisted in supplying those data which enable meteorologists to determine the probable course and duration of disturbances, or, in other words, to make "weather forecasts." Improved means of telegraphic communication have added greatly to the facilities with which such prevision is rendered possible. For instance, the atmospheric conditions prevailing in early summer in the neighbourhood of the Seychelles Islands indicate the probable force and fulness of the monsoon on which the prospects of Indian agriculturists so largely depend; and much loss of life and property is undoubtedly averted by the comparative facility with which the probable course of hurricanes and cyclones can be foreseen and the necessary precautions signalled. In the field of investigation into climatic influence on the conditions of life, and ultimately of human existence, considerable advance has been made of late years, with results that will be more beneficial than they are at present when the theories which support them become more fully confirmed and recognized. The proposition that malarial fever is directly propagated by a special breed of mosquito is one of the theories which is new to science at present, and can now be said to be fully accepted. It is one of several which emanate from closer research into the intimate relations between atmospheric and biological conditions.

Tides.—Collaterally with investigation into the movements of great air-currents special study has been directed to tidal phenomena along the coasts of Western Asia. Tidal stations have been established on the coasts of India, at Aden and Suez, where a graphic form of registration supplies those data from which tidal elements can be calculated and curves representing momentary variation in the height of sea-level during any period can be

constructed. In connexion with these tidal observations extensive levelling operations in India have been carried out to ascertain whether there is any appreciable difference in mean sea-level at various points. The immediate practical benefit of these tidal determinations to the science of navigation is obvious. One of the ultimate results of them will be to supply a more assured basis than exists at present for the determination of altitudes over the land surface of Southern Asia.

Recent Investigations.—The first great result of recent geographical research has been to modify pre-existing ideas of the orography of the vast central region represented by Tibet and Mongolia. The great highland plateau which stretches from the Himalaya northwards to Chinese Turkestan, and from the frontier of Kashmir eastwards to China, has now been defined with comparative geographical exactness. The position of Sachu (or Saitu) in Mongolia may be taken as an obligatory point in modern map construction. The longitude value now adopted is 94° 54' E. of Greenwich, which is the revised value given by Prjevalski in the map accompanying the account of his fourth exploration into Central Asia. Other values are as follows:—

Prjevalski, by his second and third explorations	94° 26'
Krishna	94° 23'
Carey and Dagleish	94° 48'
Littledale	94° 49'
Kreitner (with Szecheny's expedition)	94° 58'

The longitude of Darchendo, or Ta Chien Lu, on the extreme east, may be accepted as another obligatory point. The adopted value by the Royal Geographical Society is 102° 12''.

Krishna gives	102° 15''
Kreitner	102° 5''
Baber	102° 18''

South and west the bounding territories are well fixed in geographical position by the Indian survey determinations of the value of Himalayan peaks. On the north the Chinese Turkestan explorations are now being brought into survey connexion with Kashmir and India.

No longer do we regard the Kuen Lun mountains, which extend from the frontiers of Kashmir, north of Leh, almost due east to the Chinese province of Kansu, as the southern limit of the Gobi or Turkestan depression. This very remarkable longitudinal chain is undoubtedly the northern limit of the Chang Tang, the elevated highland steppes of Tibet; but from it there branches a minor system to the north-east from a point in about 83° E. longitude, which culminates in the Altyn Tagh, and extends eastwards in a continuous water-divide to the Nan Shan mountains, north of the Koko Nor basin. Thus between Tibet and the low-lying sands of Gobi we have, thrust in, a system of elevated valleys (Tsaidam), 8000 to 9000 feet about sea-level, forming an intermediate steppe between the highest regions and the lowest, east of Lob Nor. All this is comparatively new geography, and it goes far to explain why the great trade routes from Peking to the west were pushed so far to the north.

On the western edge of the Kashgar plains, the political boundary between Russia and China is now defined by the meridional range of Sarikol. This range (known to the ancients as Taurus, and in mediæval times as Bolor), like many others of the most important great natural mountain divisions of the world, consists of two parallel chains, of which the western is the water-divide of the Pamirs, and the eastern (which has been known as the Kashgar or Kandar range) is split at intervals by lateral gorges to allow of the passage of the main drainage from the eastern Pamir slopes. It is on this eastern ridge that the highest peaks at present known north of the Himalaya have been fixed. Here is the Muztagh Ata of Sven Hedin (not to be confounded with the Muztagh range on the Kashmir frontier), whose height has been determined to be 24,000 feet above sea-level; and there are other peaks on this eastern ridge which may possibly be found to approach this value closely, when their altitude has been scientifically determined.

The Sarikol range marks the position of the great water-divide between the Aralo-Caspian basin and the central system of hydrography terminating in the Lob Nor depression. Immediately between the Sarikol and the Kashgar (or Kandar) are the lowlands of the Sarikol valley, of which the Taghdumbash Pamir forms a southern extension. The tri-junction of the boundaries of three great empires—Russia, China, and British India—is not inappropriately situated near the tri-junction of three great Asiatic mountain systems where the Sarikol range, reaching southwards to a junction with the Hindu Kush and the Muztagh ranges, defines the head of the Taghdumbash Pamir.

From this point the Hindu Kush trends westwards and south-westwards, overlooking the narrow valley of the Panja (one of the main Oxus affluents on the north) till it merges beyond Kabul into the mountains which separate Afghanistan from Afghan Turkestan.

Russo-Chinese boundary.

The central continental water-divide.

From the same point the Muztagh mountains stretch eastwards and southwards, separating the sources of the Zarafshan, or river of Yarkand, from the gigantic glacier region of Northern Kashmir. Much has been done towards elucidating the exact configuration of both of these important ranges. The Hindu Kush has been crossed at several points, and it is only where it passes through the unexplored wilderness of Kafiristan that the position of the main water-divide is at all doubtful. The Muztagh has been crossed once (by Younghusband) at a point where its passage may be considered to be ordinarily impracticable, not far from the gigantic peak Godwin Austen, which ranks as second only to Everest in the scale of Himalayan altitudes. Much practical gain (political and military) has been derived from a better appreciation of the physical characteristics of the mass of mountainous country which intervenes between the north of India and the southern borders of Asiatic Russia; and much has been attained in the more western regions, which include Northern Afghanistan and Persia.

Hindu Kush and Muztagh ranges.

In Western Asia we have learned the exact value of the mountain barrier which lies between Merv and Herat, and have mapped its connexion with the Elburz of Persia. We can now fully appreciate the factor in practical politics which that definite but somewhat irregular mountain system represents which connects the water-divide north of Herat with the southern abutment of the Hindu Kush, near Bamian. Every pass of importance is known and recorded; every route of significance has been explored and mapped; Afghanistan has assumed a new political entity by the demarcation of a boundary; the value of Herat and of the Pamirs as bases of aggression has been assessed, and the whole intervening space of mountain and plain thoroughly examined.

Although within the limits of Western Asiatic states, still under Asiatic government and beyond the active influence of European interests, the material progress of the Eastern world has appeared to remain stationary, yet large accessions to geographical knowledge have at least been made, and in some instances a deeper knowledge of the surface of the country and modern conditions of life has led to the straightening of many crooked paths in history, and a better appreciation of the slow processes of advancing civilization. The steady advance of scientific inquiry into every corner of Persia, backed by the unceasing efforts of a new school of geographical explorers, has left nothing unexamined that can be subjected to superficial observation. The geographical map of the country is fairly complete, and with it much detailed information is now accessible regarding the coast and harbours of the Persian Gulf, the routes and passes of the interior, and the possibilities of commercial development by the construction of trade roads uniting the Caspian, the Karun, the Persian Gulf, and India, *viâ* Sistan. Persia has assumed a comprehensible position as a factor in future Eastern politics. (See PERSIA.)

In Arabia progress has been slower. Little more is known of the wide spaces of interior desert than has already been given to the world in the works of Burton, Palgrave, and Pelly amongst Englishmen, and Niebuhr, Burckhardt, Visconte, Halévy and others, amongst foreign travellers. Doughty and Blunt have visited and illustrated the district of Nejd, and described the waning glories of the Wahabi empire. But extended geographical knowledge does not point to any great practical issue. Commercial relations with Arabia remain much as they were in 1875. (See ARABIA.)

In Asia Minor, Syria, and Mesopotamia there is little to record of progress in material development beyond the promises held out by the Euphrates Valley railway concession to a German company. The exact information obtained by the researches of English surveyors in Palestine and beyond Jordan, or by the efforts of explorers in the regions that lie between the Mediterranean and the Caspian, have so far led rather to the elucidation of history than to fresh commercial enterprise or the possible increase of material wealth.

Asiatic Russia, especially Eastern Siberia and Mongolia, have been brought within the sphere of Russian exploration, with results so surprising as to form an epoch in the history of Asia. Here there has been a development of the resources of the Old World which parallels the best records of the New. Further references to the results of recent Russian enterprise will be made when considering the general question of Asiatic progress.

The great central depression of the continent which reaches from the foot of the Pamir plateau on the west through the Tarim desert to Lob Nor and the Gobi is still under examination. This vast area of low elevation centres about Lob Nor, where we find, in a lake system (the full details of which are not yet fully known, although much has been recorded of them by Prjevalski and Sven Hedin), the last surviving evidences of a great inland sea. The depression westward of the Caspian and Aral basins, and the original con-

Chinese Turkestan and Oxus basin.

nexion of these seas, has also come under the close investigation of Russian scientists, with the result that the theory of an ancient connexion between the Oxus and the Caspian has been displaced by the more recent hypothesis of an extension of the Caspian Sea eastwards into trans-Caspian territory within the post-Pleocene age. The discovery of shells (now living in the Caspian) at a distance of about 100 miles inland, at an altitude of 140 to 280 feet above the present level of the Caspian, gives support to this hypothesis, which is further advanced by the ascertained nature of the Kara-kum sands, which appear to be a purely marine formation exhibiting no traces of fluvial deposits which might be considered as delta deposits of the Oxus.

In the discussion of this problem we find the names of Kaulbars, Anneukoff, Lessar, and Konshin prominent. Further matter of interest in connexion with the Oxus basin was elucidated by the researches of Griesbach in connexion with the Russo-Afghan Boundary Commission. He reported the gradual formation of an anticlinal, or ridge, extending longitudinally through the great Balkh plain of Afghan Turkestan, which effectually shuts off the northern affluents of that basin from actual junction with the river. This evidence of a gradual process of upheaval still in action may throw some light on the physical (especially the climatic) changes which must have passed over that part of Asia since Balkh was the "mother of cities," the great trade centre of Asia, and the plains of Balkh were green with cultivation. In the restoration of the outlines of ancient and mediæval geography in Asia Sven Hedin's discoveries of the actual remains of cities which have long been buried under the advancing waves of sand in the Takla Makan desert, cities which flourished in the comparatively recent period of Buddhist ascendancy in High Asia, is of the very highest interest, filling up a blank in the identification of sites mentioned by early geographers and illustrating more fully the course of old pilgrim routes.

With the completion of the surveys of Baluchistan and Makrán much light has also been thrown on the ancient connexion between east and west; and the final settlement of the southern boundaries of Afghanistan has led to the reopening of one at least of the old trade routes between Sistan and India. (See BALUCHISTAN.)

Farther east no part of Asia has been brought under more careful investigation than the hydrography of the strange mountain wilderness that divides Tibet and Burma from China. In this field the researches of travellers already mentioned, combined with the more exact reconnaissance of native surveyors and of those exploring parties which have recently been working in the interests of commercial projects, have left little to future inquiry. We know now for certain that the great Tsangpo of Tibet and the Brahmaputra are one and the same river; that north of the point where the great countermarch of that river from east to west is effected are to be found the sources of the Salween, the Mekong, the Yang-tse-kiang, and the Hoang-ho, or Yellow river, in order, from west to east; and that south of it, thrust in between the extreme eastern edge of the Brahmaputra basin and the Salween, rise the dual sources of the Irrawaddy. From the water-divide which separates the most eastern affluent of the Brahmaputra, eastwards to the deep gorges which enclose the most westerly branch of the upper Yang-tse-kiang (here running from north to south), is a short space of 100 miles; and within that space two mighty rivers, the Salween and the Mekong, send down their torrents to Burma and Siam. These three rivers flow parallel to each other for some 300 miles, deep hidden in narrow and precipitous troughs, amidst some of the grandest scenery of Asia; spreading apart where the Yang-tse takes its course eastwards, not far north of the parallel of 25°.

The comparatively restricted area which still remains for close investigation includes the most easterly sources of the Brahmaputra, the most northerly sources of the Irrawaddy, and some 300 miles of the course of the Upper Salween.

The comparatively restricted area which still remains for close investigation includes the most easterly sources of the Brahmaputra, the most northerly sources of the Irrawaddy, and some 300 miles of the course of the Upper Salween.

Ancient Trade Routes and Modern Railways.

No branch of knowledge gained by the results of recent Asiatic research is more instructive than the comparison of ancient means of trade communication with modern, the directions along which the wealth of East and West has been interchanged at various epochs in the world's history, and the means and methods of its propulsion. "The struggle for these trade routes forms a key to the policy and the wars of many nations"; and even if the command of them was "the expression rather than the cause of the aggrandizement of a nation," examples in which "the possession of Asiatic trade¹ has marked high water in the history of empire and its loss marked the ebb of the tide" are so frequent and so conspicuous in the world's great chronicle that no general consideration of the physiography of the continent of Asia can be regarded as complete without a reference to them. The two earliest civilized communities that created a demand for trade were, undoubtedly, Egypt on the

¹ Hunter, *Hist. of India*, vol. i.

west and China on the east; and thus from the earliest historical times there has not only existed a right-of-way to traders across the entire continent of Asia, but we can faintly trace the dawn of a sea-borne traffic in the records of Egyptian fleets in the Red Sea and of Chinese junks east of Ceylon. The great development of Asiatic trade has, however, been in hands that are neither Egyptian nor Mongolian, but which belonged to Semitic races—Jews, Phœnicians, or Sabæan Arabs; and clear history only begins with those early days when Arabs were masters of the Eastern seas, with settlements on the coast of India, in Ceylon, in the Straits, and China, as well as on the shores of Eastern Africa—if indeed they were not planted in the interior of that continent. Egypt, Assyria, Babylon, Persia, Macedonia, had each secured the right of trade to Eastern Asia in turn and each in turn had lost it when Rome appeared in the field, and for seven centuries (from 1st century B.C. to the 6th A.D.) held more or less complete command of the regions intervening between Eastern Asia and the Mediterranean. But Egyptians were busy with their ships whilst Rome held command on land. The Arabs gradually superseded the Egyptians on the high seas, and ere the days of Islam had already established themselves as the greatest nation of traders that the world had ever seen. The conquest of Sind (in the 8th century A.D.) led to the establishment of a land route through Makrân, north of the Arabian Sea, to the Indus valley.

Land route from Persia to India.

The port of Tiz, in the bay of Chabar, was the terminus of the voyage eastwards of the Arab merchantman, and from Tiz through Kiz, or Kej, to Bela and the Indus valley the journey was performed on land. From the far East the clumsy Chinese junk met the buggalow of the Arab at Ceylon. Here cargoes were exchanged, and thus for centuries the trade between East and West was maintained by sea till the Cape route was discovered by a Portuguese explorer and the whole traffic of the East diverted into new channels. From prehistoric days the land routes of Asia have remained much the same through the eastern parts of the continent. The geographical position of Kashgar, almost on the same parallel of latitude as Peking, with nearly 2000 miles of low-lying desert and steppe intervening, and forming a long narrow area of depression between the Tibetan plateau and the Tian-Shan mountains, a depression which, so far as we know, between Kashgar and the Upper Amur never rises above 2000 feet above sea-level and may sink to less than 500, renders it an almost obligatory point in any line of trade connecting China and the Caspian. All recent travellers have confirmed its importance, and we find several routes from the east gathering themselves at Kashgar before diverging again westwards. Only one route of any importance passes to the north of Kashgar, i.e., that which, following the modern track between Peking and Hami, strikes off from the latter place to Urumtsi and Kulja, instead of passing through Aksu, south of the Tian-Shan, to Kashgar. Another route which was much used by the silk traders from Central China passes through Sining-fu (east of Koko Nor), and skirts the northern foot of the Altyn Tagh and the southern edge of the Tarim desert. From Kashgar westwards over the elevated region of the Pamirs the most direct route follows the Kashgar river to its source, and, crossing the great continental water-divide by the passes which lead into the Altai valley, makes its way by the fertile banks of the Surkhob to the Oxus. But from the southern towns of Chinese Turkestan, which group themselves along the foot of the Kuen Lun and once spread into the plains of Lob Nor and the Takla Makan desert, the road to the Oxus lay through Tashkurghan (the "stone tower" of mediæval geography) and by the passes of the Sarikol to the great Pamirs and Lake Victoria. There can be little doubt that this was a much-traversed Khafila route during the middle centuries of our era. From Lake Victoria it passes to Ishkashim and across Badakshan to Afghan Turkestan and Herat or Mashad.

The route from India *viâ* Kandahar, Kirman, and Babylon was well enough known in Alexander's time, but it is only lately that the facilities of it have been fully demonstrated. In later years trade found its way from the Indus valley to the Oxus *viâ* Kabul and Balkh, and thence passed north of the Caspian into Russia, or else by Tabriz and Tiflis to the Black Sea and Constantinople. When the Arabs prevailed in Asia, and Baghdad became the capital of the Caliphs, the Euphrates valley and Syria again were filled with Eastern merchandise. Then the Saracens gave place to the Crusader, and the command of the greatest trade routes of Asia was in the hands of Christians. In 1258 Baghdad fell before the Mogul, and by the commencement of the 15th century Turks and Mongols had blocked the Syrian outlet. For 200 years previously Venetians and Genoese had developed the overland trade between India and Europe *viâ* the Black Sea, and rendered themselves supreme in the Mediterranean. Venetian influence may still be traced along the coast districts of Persia and Makrân to Western India. In Makrân Venetian gold coins were till quite recently recognized as the only gold currency.

It was the barrier set by the Mogul that started the Portuguese quest for a new sea route, and thus was initiated that line of sea

traffic round the Cape of Good Hope which revolutionized the whole system of Eastern trade. Now, once again has the Red Sea resumed its pre-eminence in the commercial geography of the world. The ships of Tarshish are replaced by the modern ocean liners. But no developments corresponding in space have distinguished the methods of land transport. For a vast part of Asia the slow-moving camel is still the mainstay of the merchant traveller; and there is as yet no land connexion between Europe and Eastern Asia that will compete with the facilitated sea route. But we are within a measurable distance of witnessing such an overland connexion, and we are meanwhile already in possession of such perfected systems of local communication in India as render her railway developments of the last quarter of the 19th century distinguished in the annals of the world's progress.

Sea routes.

The first great continental line of railway which will bring Western Europe into touch with Eastern Asia will be that of Siberia. The Russian system connects St Petersburg with the Asiatic frontier by a line which is rather more than 1700 miles in length, passing through Moscow.

Russian railways.

From the Asiatic frontier eastwards, the Western Siberia line now extends to beyond the 90th meridian of east longitude, linking up with the Central Siberian line, which will touch Lake Baikal at Irkutsk. So far the traffic returns have shown a steady increase as the various sections of the line have been opened, and so great an expanse of trade is anticipated that the line is now being adapted for the service of at least eight pairs of trains, instead of the three for which the original calculations were framed. From Irkutsk eastwards the trans-Baikal and Manchurian sections of this great continental line will extend to a junction with the Usuri railway of the Amur river basin, of which the terminal port is at Vladivostok, on the Pacific coast. A part of the Usuri line is already complete. It was initiated by the present emperor on the 19th May 1891. The Baltic and Pacific will thus be connected by a line which will be little short of 6000 miles in length, covering nearly a quarter of the circumference of the globe. A remarkable feature in this enterprise is that the railway traverses those vast steppes and wide uplands which have historically been regarded as the waste lands of Asia, passing far to the north of the teeming districts whose wealth has been the desire of the nations from time immemorial. Undoubtedly it will eventually be connected with Central China and Peking, but at present the tardily recognized resources of Siberia alone are held amply to justify the construction of this magnificent line. Farther south, the ports of the Caspian have been connected by rail with the Central Asian Khanates by a line which passes along the foot of the northern slopes of the Persian Elburz to Merv, Bokhara, and Samarkand. Here, again, the advent of the railway is marked by enormous commercial developments, and the province of Ferghana already reproduces the smiling landscapes of Central Asia ere the days of Mogul devastation.

Whilst Russia has been so busy, India (strictly within the limits of her own borders) has effected even more in actual length of railway extension. An extent of line which would nearly circle the globe (about 23,000 miles) represented the railway traffic capabilities of India at the close of the 19th century, and of this amount three-fourths at least have been brought into existence since 1875. The record of the many schemes which have resulted in so great an accession of trade arteries belongs to the annals of India. They can hardly be called continental, for as yet no definite proposal has taken practical shape which will end in linking India with Europe. Between India and China there is indeed a prospect of the evolution of a practical scheme of connexion. The extension of Burmese railways northwards to Mogaung, in the Upper Irrawaddy basin, and north-eastwards from Mandalay to the Kunlon ferry on the Salween, points the way to further extensions which will unite Dibrugarh, in Upper Assam, with Mogaung, and the Kunlon ferry with Talifu, in the Chinese province of Yun-nan. But at present, with all the wealth of interior railway development which has distinguished the close of the century, both within the peninsula of India and in Burma, the two still remain unconnected and, in a measure, isolated from the rest of the world.

Indian railways.

China.—In China we find perhaps the most noteworthy record of Asiatic national evolution that the history of the 19th century can show. It is not a long record, but it is a most surprising one. The old order has changed; the conservatism of her political principles is disappearing; the bulwark of national antipathy to foreign innovations has been broken through, and the sacred seclusion that hedged about the Imperial Court has been invaded. The birth of a new century will herald the birth of a new era for China—an era of railways and company projectors, and mining developments; the scattering of empire; the burial of prehistoric isolation and dignity. The record of China's late achievements in material progress so far is not a long one, but its promise is great, for it is a practical indication that the hostility of China to the introduction of railways has at last disappeared. The first railway from Shanghai to

Chinese railways.

Wusung (on the coast) was laid in 1876, and was eagerly utilized. The following year it was torn up by the authorities. The next temporary line (which tapped the Kaiping collieries and extended to the Taku forts) is now replaced by a permanent connexion between these (now demolished) forts and Tientsin, and extends north-eastwards into Manchuria. In 1897 a line was laid from Peking to Tientsin—73 miles—and it is already doubled. Another railway is under construction by a Belgian company which will ultimately connect Peking with Hankow on the Yang-tse-kiang, and a new line now links Shanghai with Wusung. These, with a few short industrial lines for the conveyance of material in the Yang-tse basin, are all that exist. The great extent of waterways in China undoubtedly reduces the prospective profits of railway undertakings, as they have formed the great natural trade arteries of the country from time immemorial. But considering the length of the great river channels and the volume of the river discharge, the length of the actual waterway is comparatively small. Explorations have only lately been carried into the basins of the Upper Yang-tse tributaries by the agents of European syndicates to determine their possible value as lines of internal trade communication either by rail or river, and the result will probably be a development of steam navigation in the Min and Kialing affluents of the Yang-tse, and a possible railway connexion between Burma and Central China. An extension from the Russian-Siberian system into Manchuria, and a connexion between the Central Siberian railway and Central China, are the chief continental projects now before the world.

Persia.—The development of roads in Persia has been slow, but not unimportant. Railways do not exist. The opening of the Karun river to navigation in 1889 was the first step towards an awakening of commercial speculative interest in Persia, which has not been altogether unproductive of benefit to the country. Hitherto this country, which includes more than half a million square miles of territory without navigable rivers (except about 200 miles of the Karun), and nine millions of intelligent and industrious inhabitants, has had to “carry on its foreign trade and local traffic along mule tracks, the like of which are hardly to be met with in any other part of the world, however backward.” In 1880 a cart road was constructed between Tehran (or *Teheran*, the latter being more popular but less correct) and Kasvin (96 miles); in 1883 Tehran was connected with Kum (97 miles); and in 1890 Mashad and Askabad, in Russian territory, were united by a more or less metalled road 150 miles in length. Concessions have been granted for the construction of roads between Tehran and Ahwaz, with a branch road to Ispahan from Burujird; between Tehran and Baghdad; Tabriz and Astara; Tabriz and Bayazid; Zinjan and Burujird; Kazvin and Hamadan; and Kazvin and Resht; but only the last, the concession for which was granted in 1893, has become a *fait accompli* so far. This road has been engineered by Russians, and has largely widened the circle of her Persian trade. It has also shortened the distance between Europe and Tehran, which place can now be reached from London, in case of urgency, within two weeks *viâ* Baku and Resht. The road from Tehran to Ahwaz (530 miles) has advanced as far as Kum, and the opening of a trade route between Shuster and Ispahan through the Bakhtiari country has been secured politically; but much remains to be done on both these lines. A new route from which great trade results are anticipated has been opened between Persia and India. This connects Mashad with Quetta on the Indian railway system by way of Sistan and Nushki, passing through the Helmund desert. On the north-west, Russian railways are rapidly approaching Persia; and the completion of the Tiflis, Alexandropol-Kars line, with a branch line from Alexandropol to Erivan, will greatly affect the current of Persian trade. The result of these railway developments on the north-west of Persia will be to increase the importance of Tehran as a trade centre, and to draw away traffic from the southern ports.

In *Asia Minor* and *Syria* progress in railway development has been slow, but the recent concession to an Anatolian company for the Euphrates valley line may reawaken commercial activity in this part of Asia. A line from the Bosphorus to Angora, and another from Smyrna to Konieh, represent the chief railway systems of *Asia Minor* at present. In *Syria* the Beirut-Damascus and Jaffa-Jerusalem lines exhibit little prospect of extension.

Economic Developments and Commercial Enterprise in Asia.

It will be found, as might naturally be expected, that increase of material wealth and of commercial importance amongst Asiatic countries has been coincident with the development of trade routes and railways. Although Asia is the oldest amongst the historically recognized continents of the world, and although it was in Asia that the “cradle of civilization” was rocked, it has remained for the later centuries of our era, and especially for the latter part of the 19th century, to witness a display of natural resources such as could never have been imagined by those who first grasped at the wealth of the East. Russia, India, China, Japan, and in a less degree Persia, have all developed hidden capabilities and economic

possibilities such as must inevitably affect the world’s commercial history. In this field the most surprising advance has undoubtedly been made by Russia.

In 1875 Russia was astride of the Caspian, but as yet only straining her eyes across the eastern Turkman deserts. In 1880 she was knocking at the gates of Merv. Five years later she was setting a limit to the northern borders of Afghanistan. **Russian prospects.** To-day she books her passengers from the Caspian to Samarkand by rail, and has completed two sections of a trans-Asiatic line which will link her capital of St Petersburg with Vladivostok, on the shores of the Pacific. Already one may cross Asia by steam. With these railways have arisen those local commercial developments which support them, and which were awaiting them. Ferghana is once again a garden in Asia, rich in cereals and fruit, and rapidly developing a most important cotton trade. Siberia and the lands of the Amur have been found to be rich beyond all previous conjecture. Here five millions of square miles are inhabited by four million inhabitants, but the tide of immigration has set in with a steady flow which promises soon to adjust the balance. In 1898 400,000 immigrants were numbered, and the numbers are increasing. It is said that “this vast territory, long looked on as a barren waste, is destined to be one of the world’s richest and most productive sections.” Here wheat ripens with phenomenal rapidity, and in the Irkutsk country the frost period only lasts for 100 days. Transbaikalia and the Usuri regions are essentially fitted for agricultural development, and the wheat production of the empire has already been sensibly increased since the opening of the Central Siberian railway. Rice is also now largely grown in Russia, its cultivation having commenced about the year 1880. In the Caucasus, Transbaikal, and Turkestan regions, rice is sown in the same way as wheat. The demand for it is increasing throughout European Russia. Rice grown in Asia is shipped uncleaned to the Caspian ports, and there sold to commission agents. In late years the annual export from Baku has amounted to nearly 50,000 tons.

The mineral resources of Western Siberia are boundless. Between Tomsk and Kooznesk lie 23,000 square miles of coal lands as yet untouched. In Eastern Siberia 400 places are known in which gold is to be found, and iron, graphite, and lapis-lazuli deposits are all awaiting development. **Mineral wealth.**

The industries of Siberia are growing rapidly. Chemicals, sugar, and paper mills are already paying well. Manchuria looks to Russia for the development of its natural wealth. **Industries.** The Ob and the Yenisei both carry their fleets of steamers, and Russian merchantmen are busy on the Pacific between the Usuri coast and Japan. A strange industry has arisen on the Arctic shores of Siberia, where mammoth ivory is found preserved in layers of underground ice. It is collected by the primitive Tangut inhabitants for the market. These people depend for their living on the migrations of animals. They come with the reindeer herds to the Arctic coast in summer, and return to the protection of the southern forests in winter.

Russian explorations in Manchuria in connexion with the Siberian railway project, no less than English explorations in the upper basin of the Yang-tse, have largely increased our knowledge of the resources of Eastern Asia. Manchuria has been called the Canada of China, and is found capable of increasing largely her capacities for the supply of food stuff and agricultural products in support of that increased population of the north-eastern provinces of China which will attend the development of the great northern coalfields in the province of Shansi, and the collateral industries which will arise therefrom. **Manchuria.**

Although the resources of China in silk, tea, and opium have long been known, and although much further material progress in agriculture is hardly to be expected from a country which has been highly cultivated by a swarming and industrious population throughout historical ages, it is only lately that these vast resources of mineral wealth have been exhibited which require the development of the many railway schemes which have been already floated to give them practical effect. Vast fields of as yet untouched coal and anthracite exist in the northern, western, and central provinces of China. Copper, iron, mercury, silver, lead, and tin are amongst her mineral products, and salt is found in the upper valleys of the Yang-tse-kiang, or Kinsha. **Mineral wealth of China.**

The modern history of Japan shows steady progress in scientific and philosophic culture. Her arts and industries have received a certain impetus since the conclusion of the war with China in 1894, but it is chiefly in the direction of that material advancement which now places Japan in the position of an important military and naval power that the end of the 19th century has to regard Japanese progress. Japan already possesses 3420 miles of railway and 562 miles of telephone. Her army includes 125,000 regulars and 407,000 reserves, and her navy 31 war-ships. (See JAPAN.) **Japan.**

India, Burma, and Ceylon.—No part of the Asiatic continent has been so prolific in contribution to the general wealth of the

world as India, and no countries have been so systematically and continuously drained of their wealth as the Eastern possessions of Great Britain. And yet it may be doubted if any century of their chequered history can show a more astonishing record of agricultural and industrial development than the 19th, and especially the concluding decades of it. It is a record which can only be referred to here in sufficient detail to illustrate the part played by India, Burma, and Ceylon in the economy of the Asiatic continent as a whole.

The main arteries of Indian railway communication connecting Bombay with Calcutta, Calcutta with Lahore in the extreme north-west, together with a part of the Madras system, were already in existence in 1870; but the great north-western network was as yet in its infancy, and the "battle of the gauges" had yet to be fought out ere a continuity of gauge measurement for all the main Indian lines was finally adopted. In 1899 the number of miles open for traffic and under construction was 22,500 and 3568 respectively.

The advancement of irrigation works has also been notable, especially on the Punjab, where for one million acres that were irrigated in 1868 no less than 5,200,000 were irrigated in 1899.

The result of the increase in the area of production has been a general increase in agricultural products, and a special development of the growth of wheat for exportation. Under the indirect influence of a depreciation of the silver currency of India, the wheat of the Punjab has been lately able to compete successfully with that of other countries in the English markets, and to undersell that of home production.

Tea has lately superseded coffee cultivation in Ceylon, and cocoa has superseded cinchona. Many districts in India have been found suitable for tea growth which in 1880 were still under forest. More than half a million of acres are now taken up with tea industry in India alone.

The conservation of forests has gradually expanded to the dimensions of a state department with most gratifying results. Out of the 960,000 square miles which constitute British India (apart from the native states) 114,000 square miles are now under the control of the Forest Department. The exports from India to foreign ports amount to over 64,000 tons of teak wood alone, and the forest revenue is yearly expanding. Many special woods from Burma have found their special application in England, and the forests of Burma (as yet undeveloped) promise to be a fruitful source of future revenue. (See INDIA AND BURMA.)

The recent researches of the Geological Survey of India have proved that country to be rich in mineral wealth. Vast areas known to be covered with rocks that are the matrix of gold, copper, lead, tin, iron, coal, salt, oil, &c., have been mapped out, and actual mining operations on many of these areas have proved that the geologists are not mistaken. Since 1890 the coal production of India has increased from a million and a half to four million tons per annum. Enormous tracts of country are auriferous; but of these all that is being worked is one small patch in Mysore, and yet from this patch gold to the value of 222 lakhs of rupees (a million and a half sterling) was mined in 1899. Petroleum to the extent of 19 million gallons was extracted in the same year, chiefly from the Burma oil wells. The salt mines of the Punjab yielded 66,000 tons of rock salt. Mica to the value of £85,000 was exported from the mines at Hazaribagh, and rubies worth £50,000 to £60,000 were removed from the gem-bearing strata of Mogok (Burma). The mining industry of India is still in its infancy, and yet it employs 263,000 persons, and turns out material to the value of three millions per year. This development of the mineral resources of India is of very recent date, and yet but a fractional part of the vast deposits of coal, gold, and other minerals has been touched. New industrial developments in many other directions remain to be recorded. (See INDIA.)

The Political Geography of Asia.

The period since 1875 has been an era of boundary-marking in Asia, of defining the politico-geographical limits of empire, and of determining the responsibilities of governments. Russia, Persia, Afghanistan, Baluchistan, India, and China have all revised their borders, and with the revision the political relations between these countries have acquired a new and more assured basis.

The advance of Russia to the Turkman deserts and the Oxus demanded a definite boundary between her trans-Caspian conquests and the kingdom of Afghanistan. This was determined on the north-west by the Russo-Afghan Boundary Commission of 1884-86. A boundary was then fixed between the Hari Rud (the river of Herat), and the Oxus, which is almost entirely artificial in its construction. Zulfikar, where the boundary leaves the Hari Rud, is

about 70 miles south of Sarakhs, and the most southerly point of the boundary (where it crosses the Kushk) is about 60 miles north of Herat. From the junction of the boundary with the Oxus at Khamiab, about 150 miles above the crossing-point of the Russian Trans-Caspian railway at Charjui, the main channel of the Oxus river becomes the northern boundary of Afghanistan, separating that country from Russia, and so continues to its source in Victoria Lake of the Great Pamir. Beyond this point the Anglo-Russian Commission of 1895 demarcated a line to the snowfields and glaciers which overlook the Chinese border. Between the Russian Pamirs and Chinese Turkestan the rugged line of the Sarikol range intervenes, the actual dividing line being still indefinite. Beyond Kashgar the southern boundary of Siberia follows an irregular course to the north-east, partly defined by the Tian-Shan and Alatau mountains, till it attains a northerly point in about 53° N. lat. marked by the Sayan range to the west of Irkutsk. It then deflects south-east till it touches the Kunlon affluent of the Amur river at a point which is shown in unofficial maps as in about 117° 30' E. long. and 49° 20' N. lat. From here it follows this affluent to its junction with the Amur river, and the Amur river to its junction with the Usuri. It follows the Usuri to its head (its direction now being a little west of south), and finally strikes the Pacific Coast on about 42° 30' N. lat. at the mouth of the Tumen river 100 miles south of the Amur bay, at the head of which lies the Russian port of Vladivostok. At two points the Russian boundary nearly approaches that of provinces which are directly under British suzerainty. Where the Oxus river takes its great bend to the north from Ishkashim, the breadth of Afghan territory intervening between that river and the main water-divide of the Hindu Kush is not more than 10 or 12 miles; and east of the Pamir extension of Afghanistan, where the Beyik Pass crosses the Sarikol range and drops into the Taghdumbash Pamir, there is but the narrow width of the Karachukar valley between the Sarikol and the Muztagh. Here, however, the boundary is again undefined. Eastwards of this the great Kashgar depression, which includes the Tarim desert, separates Russia from the vast sterile highlands of Tibet; and a continuous series of desert spaces of low elevation, marking the limits of a primeval inland sea from the Sarikol meridional watershed to the Khinghan mountains on the western borders of Manchuria, divide her from the northern provinces of China. From the Khinghan ranges to the Pacific, south of the Amur, stretch the rich districts of Manchuria, a province which connects Russia with the Korea by a series of valleys formed by the Sungari and its affluents—a land of hill and plain, forest and swamp, possessing a delightful climate, and vast undeveloped agricultural resources. Over this land of promise leading to the sea-girt peninsula of Korea, Russian influence is rapidly extending; as it is also over the western Chinese province of the new dominion, including Kashgar and Sarikol.

Coincident with the demarcation of Russian boundaries in Turkestan was that of Northern Afghanistan. From the Hari Rud on the west to the Sarikol mountains on the east her northern limits were set by the Boundary Commissions of 1884-86 and of 1895 respectively. Her southern and eastern boundaries have been further defined by a series of minor commissions, working on the basis of the Kabul agreement of 1893, which lasted for nearly 4 years, terminating with the Mohmand settlement at the close of an expedition in 1897.

The Pamir extension of Afghan territory to the north-east reaches to a point a little short of 75° E. long., from whence it follows the water-divide to the head of the Taghdumbash Pamir, and is thenceforward defined by the water-parting of the Hindu Kush. It leaves the Hindu Kush near the Dorah Pass at the head of one of the minor Chitral affluents, and passing south-west divides Kafirstan from Chitral and Bajor, separates the sections of the Mohmands who are within the respective spheres of Afghan and British sovereignty, and crosses the Peshawur-Kabul route at Landi-Khana. It thus places a broad width of independent territory between the boundaries of British India (which have remained practically, though not absolutely, untouched) and Afghanistan; and this independent belt includes Swat, Bajor, and a part of the Mohmand territory north of the Kabul river. (See AFGHANISTAN.) The same principle of maintaining an intervening width of neutral territory between the two countries is now definitely established throughout the eastern borders of Afghanistan, along the full length of which a definite boundary has been demarcated to the point where it touches the northern limits of Baluchistan on the Gomul river. From the Gomul Baluchistan itself becomes an intervening state between British India and Afghanistan, and the dividing line between Baluchistan and Afghanistan has been laid down with all the precision employed on the more northerly sections of the demarcation. (See BALUCHISTAN.)

Baluchistan can no longer be regarded as a distinct entity amongst Asiatic nations, such as Afghanistan undoubtedly is. Baluchistan independence demands qualification. There is British Baluchistan *par excellence*, and there is the rest of Baluchistan

Southern boundary of Russia in Asia.

Afghan political boundaries.

which exists in various degrees of independence, but which is everywhere subject to British control. British Baluchistan officially includes the districts of Peshin, Sibi, and of Tal-Chotiali. As these districts had originally been Afghan, they were transferred to British authority by the treaty of Gandamak in 1879, although nominally they had been handed over to Kalat forty years previously. Now they form an official province of British Baluchistan within the Baluchistan Agency; and the agency extends from the Gomul to the Arabian Sea and the Persian frontier. Within this agency there are districts as independent as any in Afghanistan, but the political status of the province as a whole is almost precisely that of the native states of the Indian peninsula. The agent to the governor-general of India, with a staff of political assistants, practically exercises supreme control.

The increase of Russian influence on the northern Persian border and its extension southwards towards Sistan have led to the appointment of a British consul at Kirman, the dominating town of Southern Khorassan, directly connected with Mashad on the north; and the acquisition of rights of administration of the Nushki district has secured to Great Britain the trade between Sistan and Quetta by the new Helmund desert route.

Whilst British India has so far avoided actual geographical contact with one great European power in Asia on the north and west she has touched another on the east. The Mekong river which limits British interests in Burma limits also those of France in Tongking. The eastern boundaries of Burma are not yet fully demarcated on the Chinese frontier. At a point level in latitude with Mogaung, near the northern termination of the Burmese railway system, this boundary is defined by the eastern watershed of the Nmaika, the eastern of the two great northern affluents of the Irrawaddy. Then it follows an irregular course southwards to a position south-east of Bhamo in lat. 24°. It next defines the northern edge of the Shan States, and finally strikes the Mekong river in lat. 21° 45' (approximately). From that point southwards the river becomes the boundary between the Shan States and Tongking for some 200 miles, the channel of the river defining the limits of occupation (though not entirely of interest) between French and British subjects. Approximately on the parallel of 20° N. lat. the Burmese boundary leaves the Mekong to run westwards towards the Salween, and thereafter following the eastern watershed of the Salween basin it divides the Lower Burma provinces from Siam.

More important, however, than the geographical relationship of Great Britain and France in the wilds of Eastern Burma is that of Great Britain and Russia still farther east. The occupation of Port Arthur by the Russians at the close of the war between China and Japan in 1894 placed Russia in a position favourable for further strategic developments. A line joining Vladivostok with Port Arthur shuts off Korea from the rest of Asia, dominating the peninsula to the south as effectually as it dominates Manchuria to the north. It further commands the entrance to the Gulf of Pe-cheli, and thus might serve to close the seaward gates of Peking. British occupation of Wei-hai-Wei on the opposite side of the strait connecting the Yellow Sea with the Pe-cheli Gulf ensures the due maintenance of British interests on that coast; but it not only places Great Britain in closer geographical proximity to Russia here than has ever occurred yet in Asiatic history, but this juxtaposition is effected at a point where all the engines of naval warfare might be brought into action at a day's notice.

The following table gives a list of the different political divisions of Asia, classified according as they are independent of European Powers or otherwise, with the approximate area and population:—

I. INDEPENDENT, OR NOMINALLY INDEPENDENT.

Name of Country.	Area in square miles.	Population.
Persia	628,000	9,000,000
Afghanistan	215,500	4,000,000
Arabia	960,000	2,000,000
China:		
(1) China Proper	1,336,850	386,000,000
(2) Manchuria	362,310	7,500,000
(3) Mongolia	1,288,000	2,000,000
(4) Tibet	652,000	6,000,000
(5) Dzungaria	147,950	600,000
(6) Turkestan	431,800	580,000
Total Chinese Territories	4,218,910	402,680,000
Japan	152,000	46,500,000
Siam	200,000	5,000,000
Total Independent Asia	6,374,410	469,180,000

II. DEPENDENT TERRITORIES.

Name of Country.	Area in square miles.	Population.
TURKISH SPHERE.

The total area of Continental Asia alone is 17,800,000 miles, and its roughly estimated population, 823,000,000.

The Ethnography of Asia.

Although no systematic inquiry into the ethnographical conditions of British Asia has been instituted of late years, collateral information has been acquired during the progress of late political missions and military campaigns which has assisted to illustrate some of the more complex of Asiatic race problems. Within the limits of the continent vast emigrations have taken place periodically, originated partly by the increase of populations in certain districts, and the diminution of food supply in others due to change of climatic conditions; and partly by the lust of conquest, resulting in the irruption of savage hordes into districts already brought under civilized conditions of existence. These irruptions occurred in days when war was not relegated to a portion of the population set apart as the military caste, but when entire nations joined the movement, and their tides swept east and west in fierce currents of swarming humanity for which we can find no parallel later. Combining with the peoples whom they swamped in their course, they have survived in communities all over Southern Asia in conditions so mixed that the problem of individual origin is involved in the greatest entanglement.

The result of trans-border surveys to the north and west of India has been to establish the important geographical fact that it is by two gateways only, one on the north-west and one on the west of India, that the Central Asiatic tides of immigration have flowed into the peninsula. The Kabul valley indicates the north-western entrance, and Makrán indicates that on the west. By the Kabul valley route, which includes at its head the group of passes across the Hindu Kush which extend from the Khawák to the Kaoshán, all those Central Asian hordes, be they Sacæ, Yuchi, Jats, Goths, or Huns, who were driven towards the rich plains of the south, entered the Punjab. Some of them migrated from districts which belong to Eastern Asia, but none of them penetrated into India by eastern passes. Such tides as set towards the Himalaya broke against their farther buttresses, leaving an interesting ethnographical fotsam in the northern valleys; but they never overflowed the Himalayan barrier. And more recently most of the historic invasions of India from Central Asia followed the route which leads directly from Kabul to Peshawur and Delhi.

By the western gates of Makrán prehistoric irruptions from Mesopotamia broke into the plains of Lower Sind, and either passed on towards the central provinces of India or were absorbed in the highlands south of Kalat. In later centuries the Arabs from the west reached the valley of the Indus by this western route, and there established a dynasty which lasted for 300 years. The identification of existing peoples with the various Scythic, Persian, and Arab races who have passed from High Asia into the Indian borderland, has opened up a vast field of ethnographical inquiry which has hardly yet found adequate workers for its investigation. To such-fields may be added the yet more complicated problems of those reflex waves which flowed backwards from India into the border highlands.

By far the greater part of the population of Asia is Mongolian. In the form of nomadic and comparatively peaceful communities they extend through the ice-bound steppes of Siberia and the sterile sands of the central deserts to the plains north of the Caspian, and through Eastern Asia, China, and Tibet to Burma and Northern India. We now know that to the Tibeto-Chinese modifications of the pure Mongolian type all the Eastern Burmese tribes—Chins, Kachins, Shans, &c.—belong (as indeed do the Burmese themselves), and that a cognate race occupies the Himalaya to the eastern limits of Kashmir.

Some new light has been thrown on the connexion between the Tibetan race and certain tribes of Central India, the Bhils and Kóls; and it seems more probable that these tribes are the remnants of a Mongolian race which first displaced a yet earlier Negroid population, and was then itself shouldered out by a Caucasian irruption, than that they entered India by any of the northern passages within historic times. Mongolian settlements have lately been found very much farther extended into the border countries of North-west India than has been hitherto recognized. The Mingals, who, conjointly with the Brahuís, occupy the hills south of Kalat to the limits of the Rajput province of Lus Bela, claim Mongolian descent, and traces of a Mongolian colony have been found in Makrán.

Considerable progress has been made in the classification of the various races which occupy the continent to the west of the great Mongolian region. The ancient Sacæ, or Scyths, are now recognized in the Aryan population, who may be found in great numbers and in their purest form in the more inaccessible mountains and glens of the central highlands. These Tajiks (as they are usually called) form the underlying population of Persia, Baluchistan, Afghanistan, and Badakshan, and their language (in the central districts of Asia) is found to contain words of Aryan or Sanskrit derivation which are not known in Persian. They have been for the most part dispossessed of their country by Turkish immigration and conquests, but they still retain their original intellectual superiority over the Turkish and other mixed tribes by which they are surrounded. Uzbeks and Kirghiz have but small affinity with the Mongol element of Asia. They are the representatives of those countless Turkish irruptions which have taken place through all history. Of the two divisions (Kara Kirghiz and Kassak Kirghiz) into which the Kirghiz tribes are divided by Russian authorities, the Kassak Kirghiz is the more closely allied to the Mongol type; the Kara Kirghiz, who are found principally in the valleys of the Tian-Shan and Altai mountains, being unmistakably Turkish. The Kipchaks are only a Kirghiz clan. The language of the Kirghiz is Turki and their religion that of Mahommed. As a nomadic people they have great contempt for the Sarts, who represent the town dwellers of the tribe. The Kalmuks are a Buddhist and Mongolian people who originated in a confederacy of tribes dwelling in Dzungaria, migrated to Siberia, and settled on the Lower Volga. From thence they returned late in the 18th century to the reoccupation of their old ground in Kuldja under the Chinese. The Turkman is the purest form of the Turk element, and his language is the purest form of the Turkish tongue, which is represented at Constantinople by a comparatively mongrel, or mixed, dialect. Recent ethnographers have traced a connexion between the Turkman of Central Asia and the Teutonic races of

Europe, based on a similarity of national customs and immemorial usage. Evidence of an original affinity between Turkman and Rajput has also been found in the mutual possession by these races of a ruddy skin, so that as ethnographical inquiry advances the Turk appears to recede from his Mongolian affinities and to approach the Caucasian. Turks and Mongols alike were doubtless included under the term Scyth by the ancients, and as Tatars by more modern writers, inasmuch that the Turkish dynasty at Delhi, founded by Babar, is usually termed the Mogul dynasty, although there can be no distinction traced between the terms Mogul and Mongol. The general results of recent inquiry into the ethnography of Afghanistan is to support the general correctness of Bellew's theories of the origin of Afghan races. The claim of the Durani Afghan to be a true Ben-Israel is certainly in no way weakened by any recent investigation. The influence of Greek culture in Northern India is now fully recognized, and the distribution of Greek colonies previous to Alexander's time is attested by recent practical knowledge of the districts they were said to occupy. The *habitat* of the Nysæans, and the identity of certain tribes of Kafiristan with the descendants of these pre-Alexandrian colonists from the west, are also well established. To this, day hymns are unwittingly sung to Bacchus in the dales and glens of Kafiristan. The ethnographical status of the mixed tribes of the mountains that lie between Chitral and the Peshawur plains has been fairly well fixed by Biddulph, and much patient inquiry in the vast fields of Baluchistan by Mockler, Tate, and others has resulted in quite a new appreciation of the tribal origin of the great conglomeration of Baluch peoples.

The recent bibliography of Asia, including the works of travellers and explorers since 1880, is voluminous. It is impossible to refer to all that has been written in the Survey Reports and Gazetteers of the Government of India, or in the records of the Royal Asiatic Society, or the Asiatic Society, Bengal; but amongst the more important popular works are the following:—

Asia, the first Roman province east of the Ægean, was formed 133 B.C. out of the kingdom left by the will of Attalus, king of Pergamos, to the Romans. It included Mysia, Lydia, Caria, and Phrygia. In 84 B.C., on the close of the Mithradatic war, Sulla reorganized the province, and it was then or later divided into *conventus*. In 27 B.C. it was made a senatorial province under a proconsul. By the reorganization of Diocletian, A.D. 297, Asia was broken up into several small provinces, and one of these, of which the capital was Ephesus, retained the name of the original province.

Asia Minor, the peninsula on the extreme west of Asia, bounded on the N. by the Black Sea, on the W. by the Ægean, and on the S. by the Mediterranean, and at its N.W. extremity is only parted from Europe by the narrow straits of the Bosphorus and Dardanelles. On the E. no natural boundary separates it from the Armenian plateau, but, for descriptive purposes, it will suffice to take a line drawn roughly from the Giaour Dag, east of the Gulf of Alexandretta, to the Black Sea, east of Trebizond. The term *Anatolia* is sometimes used by geographers as synonymous with Asia Minor; and the same country, excluding Cilicia, is locally called *Rûm*, a name which perpetuates the memory of Rome. The greater portion of Asia Minor consists of a plateau rising gradually from west to east, 2500 feet to 4500 feet, until, east of the Kizil Irmak, the ground rises more sharply to the highlands of Armenia (see ARMENIA). On the south the plateau is buttressed by the Taurus range, which stretches in a broken irregular line from the Ægean to the Persian frontier. On the north, it is supported by a range of varying altitude, which follows the southern coast of the Black Sea and has no distinctive name. On the west the edge of the plateau is broken by broad valleys, and the deeply-indented coast-line throws out long rocky promontories towards Europe. On the north, excepting the deltas formed by the Kizil and Yeshil Irmaks, there are no coast plains, no good harbours except Sinope, and no islands. On the west there are narrow coast plains of limited extent, deep gulfs, which offer facilities for trade and commerce, and a fringe of protecting islands. On the south are the plains of Pamphylia and Cilicia, the almost land-locked harbours of Marmarice and Makri, the broad bay of Adalia, the deep-seated gulf of Alexandretta or Iskanderûm, and the islands of Rhodes, Castelorízo, and Cyprus. The *geology* of Asia Minor is imperfectly known. The Taurus range is, for the most part, formed of Cretaceous limestones, and the Black Sea coast range of saccharine limestones, mica schists, and metamorphic rocks. The interior is partly occupied by a vast plain of Tertiary lacustrine formation;

igneous rocks are found in nearly every part of the peninsula. In the south-west, serpentine occurs; round Kûla and in the Phrygian monument country there are extensive volcanic deposits; and in the north-west there are granites and various forms of trachyte. In the south-east a remarkable series of volcanic mountains, apparently of the Tertiary period, stretches from Mount Argæus to Kara Dag, and around them are soft volcanic rocks in which dwelling-places have been cut from a remote period.

Mountains.—The Taurus range, perhaps the most important feature in Asia Minor, attains in Lycia altitudes of 9800 and 10,500 feet, and in the Bulgar Dag of 8000 and 9000 feet. East of the Bulgar Dag the continuity of the range is broken by the Sihûn and Jihûn, and their tributaries. The principal passes across the range are those over which Roman or Byzantine roads ran:—From Laodicea to Adalia; from Apamea or from Pisidian Antioch to Adalia; from Laranda to Germanicopolis, and thence to Anemourium or Kelenderis; from Laranda to Claudiopolis, and thence to Kelenderis or Seleuceia; from Iconium or Cæsarea-Mazaca through the Cilician Gates to Tarsus; from Cæsarea over Anti-Taurus to the valley of the Sarus, and thence to Flaviopolis on the Cilician Plain; from Cæsarea over Anti-Taurus to Kokusos, and thence to Germanicia. Large districts on the southern slopes of the Taurus chain are covered with forests of oak and fir, and there are numerous "yailas" or "alps," with abundant pasturage, to which villagers and nomads move with their flocks during the summer months. Anti-Taurus is the line of heights and mountain peaks which separates the waters running to the Black Sea and the Anatolian plateau from those falling to the Persian Gulf and the Mediterranean. It has its origin in the high land, near the source of the Kizil Irmak, and thence runs south-west to the volcanic district of Mount Argæus. Here it loses its distinctive character, but southwards it terminates in the lofty sharp-peaked ridge of Ala Dag. South of Sivas a line of bare hills connects Anti-Taurus with a range of high forest-clad mountains, which loses itself southwards in the main mass of Taurus. This range, held to be the true Anti-Taurus by some geographers, throws off, in the latitude of Kaisariéh, a third, the Binboa Dag, which separates the waters of the Sihûn from those of the Jihûn. The principal passes are those followed by the old roads:—From Sebasteia to Tephrike and the Euphrates; from Sebasteia to Melitene; and from Cæsarea to Arabissus. The range of Amanus (Giaour Dag) is sharply separated from the mass of Taurus by the deep gorge of the Jihûn, whence it runs S.S.W. to Rás el-Khanzir, forming the limit between Cilicia and Syria. It attains its greatest altitude in Kaya Duldul, 6500 feet, which

rises abruptly from the bed of the Jihún, and it is crossed by two celebrated passes—the Amanides Pylæ (Baghche Pass), through which ran the road from the Cilician Plain to Apamea-Zeugma, on the Euphrates; and the Pylæ Syriæ (Beilan Pass), through which passed the great Roman highway from Tarsus to Syria. On the western edge of the plateau several short ranges, running approximately east and west, rise above the general level:—Salbakus-Kadmus, 8000 feet; Messogis, 3600 feet; Tmolus, 4000 feet; Dindymus, 8200 feet; Ida, 5800 feet; and the Mysian Olympus, 7600 feet. The valleys of the Mæander and Hermus facilitate communication between the plateau and the Ægean, and the descent from Dorylæum to the Sea of Marmora presents no difficulties. The northern buttress of the plateau is formed by a succession of forest-clad mountain ranges, which have a general east and west direction, and rise progressively as they approach the interior until they culminate in the Galatian Olympus, 8200 feet. East of the Kizil Irmak, although the ground is in places over 7000 feet high, there is no distinct mountain chain. The best routes from the plateau to the Black Sea are those followed by the Roman roads from Tavium and Sebasteia to Amisus. Several minor ranges rise above the level

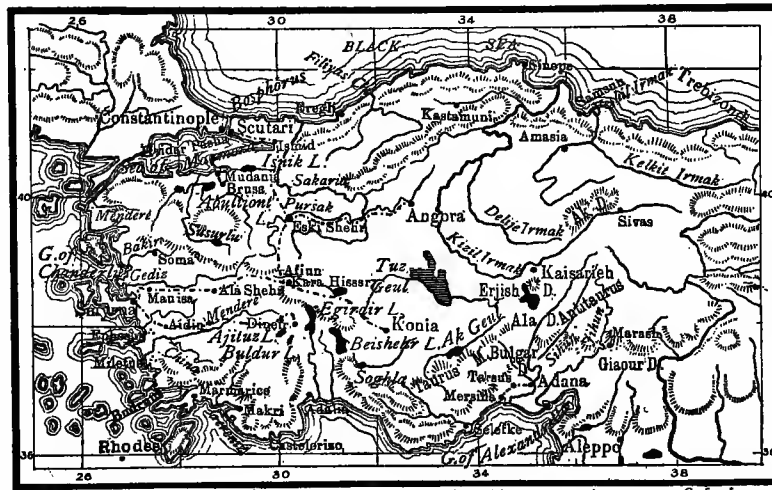

of the plateau, and in its south-east quarter groups of volcanic peaks and cones extend for about 150 miles from Kaisarieh to Karaman. The most important are M. Argæus, 13,100 feet; Ali Dagh, 6200 feet; Hassan Dagh, 8000 feet; Karaja Dagh; and Kara Dagh, 7500 feet. The centre of the plateau is occupied by a vast treeless plain, the Axylon of the Greeks, in which lies a large salt lake, Tuz Geul. The plain is fertile where cultivated, fairly supplied

with deep wells, and in many places covered with good pasture. Enclosed between the Taurus and Amanus ranges and the sea is the fertile plain of Cilicia, consisting in great part of a rich, stoneless loam, out of which rise rocky crags that are crowned with the ruins of Greco-Roman and Armenian strongholds.

Rivers.—The rivers of Asia Minor are of no great importance. Some do not flow directly to the sea; others find their way to the coast through deep rocky gorges, or are mere torrents; and a few only are navigable for boats for short distances from their mouths. The most important rivers which flow to the Black Sea are:—the Iris (Yeshil Irmak), with its tributaries the Lycus (Kelkit Irmak), which rises on the Armenian plateau, the Chekerek Irmak, which has its source near Yuzgat, and the Tersakan Su. The Halys (Kizil Irmak), the largest river in Asia Minor, with its tributaries the Delije Irmak, Cappadox, which flows through the eastern part of Galatia, and the Geuk Irmak, which has its sources in the mountains above Kastamûni. With the exception of Sivas, no town of importance lies in the valley of the Kizil Irmak throughout its course of over 600 miles. The Sangarius (Sakarîa) rises in the Phrygian mountains and, after many changes of direction, falls into the Black Sea, about 80 miles east

of the Bosphorus. Its tributaries are the Pursak Su (Tembris), which has its source in the Murad Dagh, and, after running north to Eski-shehr, flows almost due east to the Sakarîa, and the Enguri Su, which joins the Sakarîa a little below the junction of the Pursak. To the Black Sea, about 40 miles east of Eregli, also flows the Billæus (Filiyas Chai). Into the Sea of Marmora run the Rhyndacus (Edrenos Chai), and the Macesus (Susurlu Chai), which unite about 12 miles from the sea. The most celebrated streams of the Troad are the Granicus (Bigha Chai) and the Scamander (Mendere Su), both rising in Mount Ida (Kaz Dagh). The former flows to the Sea of Marmora; the latter to the Dardanelles. The most northerly of the rivers that flow to the Ægean is the Caicus (Bakir Chai), which runs past Soma, and near Pergamos, to the Gulf of Chandleri. The Hermus (Gediz Chai) has its principal sources in the Murad Dagh, and, receiving several streams on its way, runs through the volcanic district of Katakekau-mene to the broad fertile valley through which it flows past Manisa to the sea, near Lefke. So recently as about 1880 it discharged into the Gulf of Smyrna, but the shoals formed by its silt-laden waters were so obstructive to navigation that it was turned back into its old bed. Its

principal tributaries are—the Phrygius (Kûm Chai), which receives the waters of the Lycus (Geurduk Chai), and the Cogamus (Kuzu Chai), which in its upper course is separated from the valley of the Mæander by hills that were crossed by the Roman road from Pergamos to Laodicea. The Caystrus (Kuchuk Mendere) flows through a fertile valley between M. Tmolus and Messogis to the sea near Ephesus, where its silt has filled up the

SKETCH MAP OF ASIA MINOR.

port and advanced the coast-line between 2 and 3 miles. The Mæander (Mendere Chai) takes its rise in a celebrated group of springs near Dineir, and after a winding course enters the broad valley, through which it meanders to the sea. Its deposits have long since filled up the harbours of Miletus, and converted the islands which protected them into mounds in a swampy plain. Its principal tributaries are the Glaucus, the Senarus (Banaz Chai), and the Hippurius, on the right bank. And on the left bank are the Lycus (Churuk Su), which flows westwards by Colossæ through a broad open valley that affords the only natural approach to the elevated plateau; the Harpasus (Ak Chai), and the Marsyas (Chîna Chai). The rivers that flow to the Mediterranean, with two exceptions, rise in Mount Taurus, and have short courses, but in winter and spring they bring down large bodies of water. In Lycia are the Indus (Geremiz Chai), and the Xanthus (Eshen Chai). The Pamphylian plain is traversed by the Cestrus (Ak Su), the Eurymedon (Keupri Su), and the Melas (Menavgat Chai), which, where it enters the sea, is a broad, deep stream, navigable for about 6 miles. The Calycadnus (Geuk Su) flows south-east, near Mût, and enters the sea a deep rapid river about 12 miles below Selefke. West of Mût it is joined by a large stream which runs below Ermenek. The Cydnus (Tersus

Chai) is formed by the junction of three streams that rise in Mount Taurus, and one of these flows through the narrow gorge known as the Cilician Gates. After passing Tarsus, the river enters a marsh which occupies the site of the ancient harbour. The Cydnus is liable to floods, and its deposits have covered Roman Tarsus to a depth of 20 feet. The Sarus (Sihún) is formed by the junction of the Karmalas (Zamanti Su), which rises in the Uzún Yaila, and the Sarus (Saris), which has its sources in the hills to the south of the same plateau. The first, after entering Mount Taurus, flows through a deep chasm walled in by lofty precipices, and is joined in the heart of the range by the Saris. Before reaching the Cilician Plain the river receives the waters of the Kerkhun Su, which cuts through the Bulgar Dag, and opens a way for the roads from the Cilician Gates to Konia and Kaisaríeh. After passing Adana, to which point small craft ascend, the Sihún runs south-west to the sea. There are, however, indications that at one period it flowed south-east to the Pyramus. The Pyramus (Jihún) has its principal source in a group of large springs near Albistan; but before it enters Mount Taurus it is joined by the Sogutli Irmak, the Khurman Su, and the Geuk Su. The river emerges from Taurus, about 7 miles west of Marash, and here it is joined by the Ak Su, which rises in some small lakes south of Taurus. The Jihún now enters a remarkable defile which separates Taurus from the Giaour Dag, and reaches the Cilician Plain near Budrúm. From this point it flows west, and then south-west past Missis, until it makes a bend to discharge its waters south of Ayas Bay. The river is navigable as far as Missis. In the central and southern portions of the plateau the streams either flow into salt lakes, where their waters pass off by evaporation, or into fresh-water lakes, which have no visible outlets. In the latter cases the waters find their way beneath Taurus in subterranean channels, and reappear as the sources of rivers flowing to the coast. Thus the Ak Geul supplies the Cydnus, and the Beishehr, Egirdir, and Kestel lakes the rivers of the Pamphylian Plain.

Lakes.—The salt lakes are Tuz Geul, which lies in the great central plain, and is about 60 miles long and 10 to 30 miles broad; Buldur Geul, 2900 feet above sea-level; and Aji-tuz Geul, 2600 feet. The sweetwater lakes are Beishehr Geul, 3770 feet, a fine sheet of water 30 miles long, which discharges south-east to the Soghla Geul; Egirdir Geul, 2850 feet, which is 30 miles long, and noted for the abundance and variety of its fish. In the north-west portion of Asia Minor are Isnik Geul, Abulliont Geul, and Maniyas Geul.

Springs.—Asia Minor is remarkable for the number of its thermal and mineral springs. The most important are:—Yalova, in the Ismid sanjak; Brúsa, Chitli, Terje, and Eski-shehr, in the Brúsa; Tuzla, in the Karasi; Cheshme, Ilija, Hierapolis, and Ala-shehr, in the Aidin; Terzili Hammam, in the Angora; Boli and Iskelib, in the Kasta múni; and Khavsa, in the Sivas viláyet.

The *climate* is varied, but systematic observations are wanting. On the plateau the winter is cold, and in the northern districts there is much snow. The summer is very hot, but the nights are usually cool. On the north coast the winter is cold, and the winds, sweeping across the Black Sea from the steppes of Russia, are accompanied by torrents of rain and heavy falls of snow. East of Samsún, where the coast is partially protected by the Caucasus, the climate is more moderate. In summer the heat is damp and enervating, and, as Trebizond is approached, the vegetation becomes almost subtropical. On the south coast the winter is mild, with occasional frosts and heavy rain; the summer heat is very great. On the west coast the climate is moderate, but the influence of the cold

north winds is felt as far south as Smyrna, and the winter at that place is colder than in corresponding latitudes in Europe.

The mineral wealth of Asia Minor is very great, but few mines have yet been opened. The minerals known to exist are—alum, antimony, arsenic, asbestos, boracide, chrome, coal, copper, fuller's earth, gold, iron, kaolin, lead, lignite, magnetic iron, manganese, meerschau, nickel, rock-salt, silver, sulphur, and zinc. The vegetation varies with the climate, soil, and elevation. The mountains on the north coast are clothed with dense forests of pine, fir, cedar, oak, beech, &c. On the Taurus range the forests are smaller, and there is a larger proportion of pine. On the west coast the ilex, plane, oak, valonea oak, and pine predominate. On the plateau willows, poplars, and chestnut trees grow near the streams. On the south and west coasts the fig and olive are largely cultivated. The vine yields rich produce everywhere, except in the higher districts. The apple, pear, cherry, and plum thrive well in the north; the orange, lemon, citron, and sugar-cane in the south; styrax and mastic in the south-west; and the wheat lands of the Sivas viláyet can hardly be surpassed. The most important vegetable productions are—cereals, cotton, gum tragacanth, liquorice, olive oil, opium, rice, saffron, salep, tobacco, and yellow berries. Silk is produced in large quantities in the vicinity of Brúsa and Amasia. The wild animals include bear, boar, chamois, fallow, red and roe deer, gazelle, hyæna, ibex, jackal, lynx, moufflon, panther, wild sheep, and wolf. Amongst the domestic animals are the buffalo, the Syrian camel, and a mule camel, bred from a Bactrian sire and Syrian mother. Large numbers of sheep and Angora goats are reared on the plateau, and fair horses are bred on the Uzún Yaila; but no effort is made to improve the quality of the wool and mohair, or the breed of horses. Good mules can be obtained in several districts, and small hardy oxen are largely bred for ploughing and transport. The larger birds are the bittern, great and small bustard, eagle, francolin, goose; giant, grey, and red-legged partridge; pelican, pheasant, stork, and swan. The rivers and lakes are well supplied with fish, and the mountain streams abound with trout.

History.—Asia Minor owes the peculiar interest of its history to its geographical position. "Planted like a bridge between Asia and Europe," it has been from the earliest period a battle-ground between the east and the west. The central plateau, 2500 to 4500 feet above the sea, with no navigable river and few natural approaches, with its monotonous scenery and severe climate, is a continuation of Central Asia. The west coast, with its alternation of sea and promontory, of rugged mountains and fertile valleys, its bright and varied scenery, and its fine climate, is almost a part of Europe. These conditions are unfavourable to permanence, and the history of Asia Minor is that of the march of hostile armies, and the rise and fall of small states, rather than that of a united state under an independent sovereign. At a very early period Asia Minor appears to have been occupied by non-Aryan tribes or races which differed little from each other in religion, language, and social system. Since 1875 much light has been thrown upon one of these races—the "Hittites" or "Syro-Cappadocians," who, after their rule had passed away, were known to Herodotus as "White Syrians," and whose descendants can still be recognized in the villages of Cappadocia.¹ The centre of their power was Boghaz Keui (Pteria), east of the Halys, whence roads radiated to the harbours on the Ægean, to Sinope, to Northern Syria,

¹ The people, Moslem and Christian, are physically one and appear to be closely related to the modern Armenians. This relationship is noticeable in other districts, and the whole original population of Asia Minor has been characterized as Porto-Armenian or Armenoid.

and to the Cilician Plain. Their strange sculptures and inscriptions have been found at Boghaz Keui, Euyuk, Fraktin, Ivriz, and other places between Smyrna and the Euphrates (see HITTITES, in the ninth edition of this work). When the great Aryan immigration from Europe commenced is unknown, but it was dying out in the 11th and 10th centuries B.C. In Phrygia the Aryans founded a kingdom, of which traces remain in various rock tombs, forts, and towns, and in legends preserved by the Greeks. The Phrygian power was broken in the 9th or 8th century B.C. by the Cimmerians, who entered Asia Minor through Armenia; and on its decline rose the kingdom of Lydia, with its centre at Sardis. A second Cimmerian invasion almost destroyed the rising kingdom, but the invaders were expelled at last by Alyattes, 617 B.C. The last king, Croesus, 560-546 B.C., carried the boundaries of Lydia to the Halys, and subdued the Greek colonies on the coast. The date of the foundation of these colonies cannot be fixed; but at an early period they formed a chain of settlements from Trebizond to Rhodes, and by the 8th century B.C. some of them rivalled the splendour of Tyre and Sidon. Too jealous of each other to combine, and too demoralized by luxury to resist, they fell an easy prey to Lydia; and when the Lydian kingdom ended with the capture of Sardis by Cyrus, 546 B.C., they passed, almost without resistance, to Persia. Under Persian rule Asia Minor was divided into four satrapies, but the Greek cities were governed by Greeks, and several of the tribes in the interior retained their native princes and priest-dynasts. An attempt of the Greeks to regain their freedom was crushed 500 B.C., but later the tide turned and the cities were combined into a league for defence against the Persians. The weakness of Persian rule was disclosed by the expedition of Cyrus and the Ten Thousand Greeks, 402 B.C.; and in the following century Asia Minor was subdued by Alexander, 334 B.C.

The wars which followed the death of Alexander gave Asia Minor to Seleucus, but none of the Seleucid kings were able to establish their rule over the whole peninsula. Rhodes became a great maritime republic. An independent kingdom was founded at Pergamos, 283 B.C., which gave its name to a school of sculpture, and lasted until Attalus III., 133 B.C., made the Romans his heirs. Bithynia became an independent monarchy, and Cappadocia and Paphlagonia tributary provinces under native princes. In Southern Asia Minor the Seleucids founded Antioch, Apamea, Attaleia, Laodicea, Seleuceia, and other cities as centres of commerce, and some of them afterwards played an important part in the Hellenization of the country and in the spread of Christianity. During the 3rd century, 278-277 B.C., certain Gallic tribes crossed the Bosphorus and Hellespont, and established a Celtic power in Central Asia Minor. They were confined by the victories of Attalus I. of Pergamos, *circa* 232 B.C., to a district on the Sangarius and Halys to which the name Galatia was applied; and after their defeat by Manlius, 189 B.C., they were subjected to the suzerainty of Pergamos (see GALATIA).

The defeat of Antiochus the Great at Magnesia, 190 B.C., placed Asia Minor at the mercy of Rome; but it was not until 133 that the first Roman province, Asia, was formed. Errors in policy and in government facilitated the rise of Pontus into a formidable power under Mithradates, who was finally driven out of the country by Pompey, and died 63 B.C. Under the settlement of Asia Minor by Pompey, Bithynia-Pontus and Cilicia became provinces, whilst Galatia and Cappadocia were allowed to retain nominal independence under native kings. A long period of tranquillity followed, during which the Roman dominion grew, and all Asia Minor was divided into provinces. The boundaries were often changed; and about

A.D. 297, in Diocletian's reorganization of the empire, the power of the great military commands was broken, and the provinces were made smaller and united in groups called dioceses. A great change followed the introduction of Christianity, which spread first along the main roads that ran north and west from the Cilician Gates, and especially along the great trade route to Ephesus. In some districts it spread rapidly, in others slowly. With its advance the native languages and old religions gradually disappeared, and at last the whole country was thoroughly Hellenized, and the people united by identity of language and religion.

At the close of the 6th century Asia Minor had become wealthy and prosperous; but centuries of peace and over-centralization had affected the *morale* of the people and weakened the central Government. During the 7th century the provincial system broke down, and the country was divided into *themes* or military districts. From 616 to 626 Persian armies swept unimpeded over the land, and Chosroes II. pitched his camp on the shore of the Bosphorus. The victories of Heraclius forced Chosroes to retire; but the Persians were followed by the Arabs, who, advancing with equal ease, laid siege to Constantinople, A.D. 688. It almost appeared as if Asia Minor would be annexed to the dominion of the Caliph. But the tide of conquest was stemmed by the iconoclast emperors, and the Arab expeditions, excepting those of Harún er-Rashíd, 781 and 806, and of el-Motasem, 838, became simply predatory raids. In the 10th century the Arabs were expelled. They never held more than the districts along the main roads, and in the intervals of peace the country rapidly recovered itself. But a more dangerous enemy was soon to appear on the eastern border.

In 1067 the Seljúk Turks ravished Cappadocia and Cilicia; in 1071 they defeated and captured the Emperor Romanus, Diogenes; and in 1080 they took Nicæa. One branch of the Seljúks founded the empire of Rúm, with its capital first at Nicæa and then at Iconium. The empire, which at one time included nearly the whole of Asia Minor, with portions of Armenia and Syria, passed to the Mongols when they defeated the sultan of Rúm in 1243, and the sultans became vassals of the Great Khán. The Seljúk sultans were liberal patrons of art, literature, and science, and the remains of their public buildings and tombs are amongst the most beautiful and most interesting in the country. The march of the Crusaders across Asia Minor left no permanent impression. But the support given by the Latin princes to the Armenians in Cilicia facilitated the growth of the small warlike state of Lesser Armenia, which fell in 1375 with the defeat and capture of Leo VI. by the Memlík sultan of Egypt. The Mongols were too weak to govern the country they had conquered, and the vassalage of the last sultan of Rúm, who died in 1307, was only nominal. On his death the governors of his western provinces drove out the Mongols and asserted their independence. A contest for supremacy followed, which eventually ended in favour of the Osmanli Turks. In 1400 Sultan Bayezid I. held all Asia Minor west of the Euphrates; but in 1402 he was defeated and made prisoner by Timúr, who swept through the country to the shores of the Ægean. On the death of Timúr, Osmanli supremacy was re-established after a prolonged struggle, which ended with the annexation by Muhammad II. (1451-81) of Karamania and Trebizond, and the abandonment of the last of the Italian trading settlements which had studded the coast during the 13th and 14th centuries. The later history of Asia Minor is that of the Turkish empire. The most important event was the advance (1832-33) of an Egyptian army, under Ibrahim Pasha, through the Cilician Gates to Konia and Kutaya.

The defeat of the Emperor Romanus (1071) initiated a change in the condition of Asia Minor which was to be complete and lasting. A long succession of nomad Turkish tribes, pressing forward from Central Asia, wandered over the rich country in search of fresh pastures for their flocks and herds. They did not plunder or ill-treat the people, but they cared nothing for town life or for agricultural pursuits, and as they passed onward they left the country bare. Large districts passed out of cultivation and were abandoned to the nomads. The peasants either became nomads themselves or took refuge in the towns or the mountains. The Mongols, as they advanced, sacked towns and laid waste the agricultural lands. Timúr conducted his campaigns with a ruthless disregard of life and property. Entire Christian communities were massacred, flourishing towns were completely destroyed, and all Asia Minor was ravaged. From these disasters the country never recovered, and the last traces of Western civilization disappeared with the enforced use of the Turkish language and the wholesale conversions of Islám under the Osmanli sultans. The large increase of the Greek population in the western districts, the construction of railways, and the growing interests of Germany and Russia, seem, however, to indicate that the tide is again turning in favour of the West.

Population.—None of the conquering races that invaded Asia Minor, whether from the east or from the west, wholly expelled or exterminated the race in possession. The vanquished retired to the hills or absorbed the victors. In the course of ages race distinction has been almost obliterated by fusion of blood; by the complete Hellenization of the country, which followed the introduction of Christianity; by the later acceptance of Islám; and by migrations due to the occupation of cultivated lands by the nomads. It will be convenient here to adopt the modern division into Moslems, Christians, and Jews:—*(a) Moslems.* The Turks never established themselves in such numbers as to form the predominant element in the population. Where the land was unsuitable for nomad occupation the agricultural population remained, and it still retains some of its original characteristics. Thus in Cappadocia the facial type of the non-Aryan race is common, and in Galatia there are traces of Gallic blood. The Zeibeks of the west and south-west are apparently representatives of the Carians and Lycians; and the peasants of the Black Sea coast range, of the people of Bithynia, Paphlagonia, and Pontus. Wherever the people accepted Islám they called themselves Turks, and a majority of the so-called "Turks" belong by blood to the races that occupied Asia Minor before the Seljúk invasion. Turkish and Zaza-speaking Kúrds (see KURDISTAN) are found in the Angora and Sivas viláyets. There are many large colonies of Circassians and smaller ones of Noghai Tatars, Georgians, Lazis, Cossacks, Albanians, and Pomaks. East of Boghaz Keui there is a compact population of Kizilbash, who are partly descendants of Shíá Turks transplanted from Persia and partly of the indigenous race. In the Cilician Plain there are large settlements of Ansariéh who have migrated from the Syrian mountains (see SYRIA). The nomads and semi-nomads are, for the most part, representatives of the Turks, Mongols, and Tatars who poured into the country during the 350 years that followed the defeat of Romanus. Turkomans are found in the Angora and Adana viláyets; Avshars, a tribe of Turkish origin in the valleys of Anti-Taurus; and Tatars in the Angora and Brúsa viláyets; Yuruks are most numerous in the Konia viláyet. They speak Turkish and profess to be Moslems, but have no mosques or imáms. The Chepmi and Takhtaji, who live chiefly in the Aidin viláyet, appear to be derived from one of the early races. *(b) Chris-*

tians. The Greeks are in places the descendants of colonists from Greece; but most of them belong by blood to the indigenous races. These people became "Greeks" as being subjects of the Byzantine empire and members of the Eastern Church; and at the present day every Turkish subject who belongs to the Orthodox Church is officially a "Greek." On the west coast, in Cappadocia, in Pontus, and in the mining villages, the language is Romaic; on the south coast and in many inland villages it is either Turkish, which is written in Greek characters, or a Greco-Turkish jargon. In and near Smyrna there are large colonies of Hellenes. Armenians are most numerous in the eastern districts, where they have been settled since the great migration that preceded and followed the Seljúk invasion. In Central and Western Asia Minor they are the descendants of colonists from Persia and Armenia (see ARMENIA). *(c) The Jews* live chiefly on the Bosphorus; and in Smyrna, Brúsa, and other western towns. *Gypsies*—some Moslem, some Christian—are also numerous.

In the absence of trustworthy statistics, only the following rough estimate can be given:—Moslems, 6,800,000; Armenians, 560,000; Greeks, 780,000; other Christians, 45,000; Jews, gypsies, foreigners, &c., 150,000; total, 8,335,000. This does not include the population of the islands—Moslems, 27,500; Greeks, 342,000; other Christians, 3000; Jews and foreigners, 2000; total, 374,500.

Administration.—The modern division of the country and the present system of administration are treated elsewhere (see TURKEY). The modern towns rarely occupy the sites of the ancient cities, a point well brought out by Ramsay (*Hist. Geog.* pp. 82-88). All Turkish subjects who are not Moslems must belong to one of the recognized millets or religious communities—Armenian, Greek, Jewish, Latin, Protestant, &c. The most striking educational feature is the great influence for good exercised by the schools and colleges of the American Board of Missions. The Greeks and Armenians have good schools for both sexes.

The principal *manufactures* are:—Carpets, rugs, cotton, mohair and silk stuffs, soap, wine, and leather. The *exports* are:—Cereals, cotton, cotton seed, dried fruits, drugs, fruit, gall nuts, gum tragacanth, liquorice root, maize, nuts, olive oil, opium, rice, sesame, sponges, storax, timber, tobacco, valonea, walnut wood, wine, yellow berries, carpets, cotton yarn, cocoons, hides, leather, mohair, silk, silk stuffs, rugs, wax, wool, leeches, live stock, minerals, &c. The *imports* are:—Coffee, cotton cloths, cotton goods, crockery, dry salteries, fezzes, glass-ware, haberdashery, hardware, henna, iron-ware, jute, linen goods, manufactured goods, matches, petroleum, salt, sugar, woollen goods, yarús, &c.

Communications.—There are few metalled roads, but on the plateau light carts can pass nearly everywhere. The lines of railway now open are:—(1) From Haidar Pasha to Ismid, Eski-shehr, and Angora, to be extended to Kir-shehr and Kaisariéh. (2) From Mudánia to Brúsa. (3) From Eski-shehr to Afíun Kara-hissar and Konia. (4) From Smyrna to Manisa, Ala-shehr and Afíun Kara-hissar, with a branch line from Manisa to Soma. These lines are worked by the German *Gesellschaft der Anatolischen Eisenbahn*. (5) From Smyrna to Aidin and Dineir, constructed and worked by an English company. (6) Mersina to Tarsus and Adana. The German company has power to extend its system to Baghdad, but the route by which the line will cross the Taurus has not yet been decided. There are thus two competing routes—one running inland from Constantinople (Haidar Pasha), the other from Smyrna. The first is practically connected with the European railway system;

the second, with the great sea routes from Smyrna to Trieste, Marseilles, and Liverpool. The right to construct all railways in Armenia and north-eastern Asia Minor has been conceded to Russia.

AUTHORITIES.—Since 1870 Asia Minor has been visited by many travellers, who have brought back valuable information; excavations have been carried out at a few places; and special questions have been studied on the spot by qualified explorers. Valuable papers have been published by Anderson, Benndorf, Bent, Crowfoot, Foucart, Headlam, Hicks, Hogarth, Myres, Ramsay, Schuchhardt, Smith, Wilson, &c., in the *Proceedings R. Geog. Society, Journ. Hellenic Society*, in MASPERO'S *Recueil*, vols. xiv. xv., &c., in the *American Journ. of Archaeology, Journal of Philology, Mitt. des kais. d. arch. Inst. Athen. Abth., Bull. de Corr. Hellénique, Wiener Vorlegeblätter*, &c. Fuller works are:—CHANTRE, E. *Recherches archéologiques, Mission en Cappadoce*. Paris, 1898.—CLARKE, J. T. Askabad, or ASKHABAD, a town of Russian Central Asia, capital of the Transcaspian province, 345 miles by rail S.E. of Krasnovodsk and 602 from Samarcand, situated in a small oasis of the same name at the foot of the Kopetdagh range. In 1881 it consisted of merely 500 tents, but it has increased rapidly since it became the chief town of the province. It has three Russian churches, one Armenian church, three mosques, a public library, a progymnasium for boys and another for girls, a technical railway school, and several charitable institutions. It has also a daily newspaper, and strikes the traveller by its relatively good hotels and shops. There are several cotton-cleaning works, as also tanneries, brick-works, and "mineral waters" factory. The trade with Persia, Merv, and Khiva is valued at £250,000 a year. The population, 4000 in 1889, was 19,428 in 1897.

Asmara. See ERITREA.

Asnières, a town of France, department of Seine, arrondissement of St Denis, 4 miles S.W. of that town, on the railway to Havre and the river Seine. The town, which has grown rapidly in recent years, is a favourite boating-centre for the Parisians. The industries include the manufacture of bicycles, pianos, trellis-work, perfumery, and boat-building. Population (1881), 10,666; (1896), 23,931, (comm.) 23,931; (1901), 30,881.

Aspen, a city of Colorado, U.S.A., and capital of

Pitkin county, situated in the western, mountainous portion of the state, in 39° 12' N. lat. and 106° 49' W. long., in the valley of Roaring Fork, a branch of the Grand river. The site of the city is level and its plan is regular. It has two railways, the Denver and Rio Grande and the Colorado Midland. The altitude is 7853 feet. The surrounding country contains many mines, principally of silver, but owing to the depression in the price of this metal, the prosperity of the district has been seriously affected. Population (1890), 5108; (1900), 3303.

Aspinwall. See COLON.

Assab. See ERITREA.

Assam, a province of British India, under the administration of a chief commissioner, situated on the extreme north-east frontier, being almost surrounded on two sides by semi-independent tribes. The administrative headquarters are at the station of Shillong, in the Khasi Hills. Assam is naturally divided into three distinct tracts: first, the valley of the Brahmaputra, from where that river forces its way through the Himalayan range to where it debouches on the plain of Northern Bengal. To this tract alone is the name of Assam strictly applicable, being derived from the Ahom dynasty which

SKETCH MAP OF ASSAM.

formerly ruled here, and here alone is the Assamese language spoken. The second tract is the valley of the Surma or Barak, which is really an extension of the Bengal delta, enclosed by hills on three sides. Between these two valleys lies the third tract, consisting of a series of hill ranges, inhabited by a number of different tribes, entirely unconnected with either the Assamese or the Bengalis. There is still a border line along the north and the east, beyond which only vague political influence is exercised. The Southern Lushai Hills were added to the province in 1898. The numerous democratic chiefs of the Khasi Hills enjoy a certain measure of independence. The native state of Manipur, on the eastern border, is subordinate to Assam. Frontier troubles occasionally arise with the Akas, Dafias, Abors, and Mishmis along the northern border, arising out of raids into British territory. A military expedition had to be sent against the Mishmis in the winter of 1899-1900.

Population.—The following table gives the area and population of the several districts of Assam, according to the census of 1891:—

Area and Population of Assam, 1891.

Divisions.	Districts.	Area in Square Miles.	Number of Towns and Villages.	Population, Census of 1891.			Density of Population to Square Mile.
				Males.	Females.	Total.	
Surma Valley . .	Cachar Plains	2,472	639	104,373	173,169	367,542	149

	North Lushai (estimated)		25	20,667	20,923	41,590	
		20,249	3,215	250,135	254,881	505,016	25
Grand total		49,004	17,160	2,819,675	2,657,258	5,476,933	112

Since 1881 the population increased by 11 per cent., which cannot be considered a high rate when we take into consideration the large amount of waste land and also the continuous immigration of tea coolies. Classified according to religion, Hindus numbered 2,997,072, or 54.7 per cent. of the total population; Mahomedans numbered 1,483,974, or 27 per cent.; Christians numbered 16,844, or .31 per cent.; aboriginal tribes numbered 969,765, or 17.7 per cent.; Buddhists numbered 9065, or .16 per cent.; and "others," 122. The Mahomedans are mostly found in the two old Bengal districts of Sylhet and Goalpara; the Christians in the Khasi and Jaintia Hills, where the Welsh Calvinistic Mission has been most successful. Europeans numbered 1687 and Eurasians 392, leaving 14,765 for native converts.

The provisional figures for the census of 1901 returned the total population of Assam as 6,122,201, including 283,957 for Manipur and 82,344 for the Lushai Hills, neither of which was comprised in the census of 1891. Deducting this additional area, the rate of increase for the province is 6 per cent., compared with 11 per cent. for the previous decennial period. The increase is confined to the tea districts. The lower districts of the Brahmaputra valley, which have suffered severely from a fatal form of fever, show a heavy decrease.

Agriculture.—The greater part of the two districts of Sylhet and Goalpara were permanently settled, with the rest of Bengal. The Brahmaputra valley has a temporary settlement of its own known as *manzawari*, the average incidence of assessment being about Rs.2:8:0 per acre. Agricultural statistics are confined to the temporarily settled tract. In 1897-98, out of a total cultivated area of 2,472,734 acres, no less than 1,614,292 acres were under rice, which is everywhere the staple crop, 310,826 acres under tea, and 169,223 acres under mustard. Jute is grown to some extent in Sylhet and Goalpara. The Brahmaputra valley does not produce sufficient rice for its own consumption, large quantities being imported to feed the tea coolies.

Tea Plantations.—Tea is the staple industry of Assam, in both the Brahmaputra and the Surma valleys. The following table shows the progress of the industry at various years between 1883 and 1897:—

Statistics.

Year.	Area under Mature Plants.	Area under Immature Plants.	Area of Tea Gardens.	Number of Adult Labourers.	Number of Labourers per 100 Acres.
	Acrea.	Acrea.	Acrea.		
1883	161,707	27,746	923,664	153,739	81
1890	200,658	30,380	994,497	250,113	108
1895	234,909	41,105	995,787	334,298	121
1896	247,655	44,254	968,895	366,460	125
1897	263,313	47,337	1,014,017	402,205	129

The following table gives the statistics of the tea industry, according to districts, for 1897, which was not a very prosperous year:—

District.	Number of Tea Gardens.	Total Area of Gardens.	Area under Mature and Immature Plants.	Total Yield.	Out-turn per Acre.
		Acrea.	Acrea.	lb	lb
Cachar	191	282,583	61,190	22,031,593	406
Sylhet	137	150,614	70,200	26,153,168	474
Khasi Hills	1	100	30	4,000	133
Goalpara	3	852	410	140,798	371
Kamrup	31	18,785	5,873	753,228	132
Darrang	89	108,067	33,984	11,154,360	407
Nowgong	50	49,884	12,659	4,019,795	355
Sibsagar	171	231,475	70,644	24,021,294	391
Lakhimpur	149	171,657	55,560	18,988,096	399
Total	822	1,014,017	310,550	107,266,332	408

In 1897 the average price per lb was R.0:5:11 (say 6d.) in the Surma valley, and R.0:7:8 (say 7½d.) in the Brahmaputra valley. The labour required on the tea gardens is almost entirely imported, as the natives of the province are too prosperous to do such work. The importation of coolies is controlled by an elaborate system of legislation, which provides for the registration of contracts, the medical inspection of coolies during the journey, and supervision over rates of pay, &c., on the gardens. A revised Immigration Act for Assam was passed by the Viceroy's council in March 1901. In 1897 the mean annual strength of the labour force was 630,107, of whom 227,902 were children. The total number of adults at the end of the year was 399,975, of whom 195,267 were women. In 1897 the total immigration was 95,931, compared with 81,115 in the preceding year, and with 36,080 in 1890. This large increase is ascribed mainly to the famine in the recruiting tracts, but partly to the demand for additional labour on the tea gardens. The mortality among the coolies during the journey was high, owing to an outbreak of cholera; and the death-rate on the gardens was also high—41.4 per thousand, compared with 32 in the preceding year.

Minerals.—The mineral products of Assam include coal, petroleum, and limestone. The most valuable coal-mines are at the head of the Brahmaputra valley, in the neighbourhood of Makum, which is connected by railway with Dibrugarh on the river. The coal is the best found in India; it is largely used for local purposes, and is also exported to Bengal. In 1897 the output was 197,499 tons, yielding to the Government a revenue of Rs.33,065. In the same neighbourhood are oil-fields, yielding kerosene and paraffin. In 1897 the output was 222,077 gallons. Coal is also found in the Naga and the Khasi Hills. The limestone of the Khasi Hills is largely exported to Bengal. In 1896-97 the total output was 1,630,000 maunds, yielding to the Government a revenue of Rs.18,000.

Railways.—Assam is still unconnected with the general railway system of India, and the Brahmaputra valley entirely depends upon communications by steamer. The Assam-Bengal railway is intended to run from the seaport of Chittagong to the Surma

valley, and thence across the hills to Dibrugarh, at the head of the Brahmaputra valley, with a branch to Gauhati lower down the Brahmaputra. The hill section of this line has been found exceedingly difficult of construction, and extensive damage was done by the earthquake of 1897. This railway is financed by the Government, though worked by a company, and therefore ranks as a state line. Up to the end of 1898 the total length open for traffic was 379 miles; the gross earnings in that year were Rs.130,812, and the working expenses Rs.125,357. There are several short lines of light railway, or tramway, in the province. The most important is the Dibru-Sadiya railway, at the head of the Brahmaputra valley, with a branch to the coal-fields. Its length is 78 miles; in 1898 its gross earnings amounted to Rs.78,141, and the working expenses were Rs.49,894.

Trade.—The external trade of Assam is conducted partly by steamer, partly by native boat, and to a small extent by rail. In the Brahmaputra valley steamers carry as much as 86 per cent. of the exports, and 94 per cent. of the imports. In the Surma valley native boats carry about 43 per cent. of both. In 1897-98 (which was a bad year, owing to the earthquake and a poor tea crop) the total exports were valued at Rs.5,33,00,000, of which Rs.3,13,00,000 came from the Brahmaputra and Rs.2,20,00,000 from the Surma valley. The chief items were tea (Rs.3,52,76,000), rice in the husk, oil-seeds, tea-seed, timber, coal, and jute. The imports (excluding treasure) were valued at Rs.4,04,00,000, of which Rs.2,14,00,000 went to the Brahmaputra and Rs.1,90,00,000 to the Surma valley. The chief items were cotton piece-goods, rice not in the husk, sugar, grain and pulse, salt, iron and steel, tobacco, cotton twist and yarn, and brass and copper. No less than three-fourths of the total trade is conducted with Calcutta. The trans-frontier trade is insignificant; and most of it is conducted with the Bengal state of Hill Tipperah. In 1897-98 the total imports were valued at Rs.6,70,600, and the exports at Rs.3,03,236.

Government.—The administrative staff for the province of Assam consists of a chief commissioner, appointed by the governor-general, who is assisted by a secretary, an assistant-secretary, and a personal assistant; a district and sessions judge for Sylhet, who is also sessions judge for Cachar; a judge and commissioner for the Brahmaputra valley; a conservator of forests; a principal medical officer, who is also sanitary commissioner; a director of public instruction; a director-general of police and jails, who is also inspector-general of registration, commissioner of excise, and superintendent of stamps; a director of land records and agriculture, with an assistant; and thirteen deputy commissioners. The total number of civil and revenue courts is 68, and of criminal courts 102. The total strength of the police force consisted in 1897 of 2833 military police, 2263 civil police, and 6993 rural police. The proportion of civil police was one man to 19 square miles of area and to 2356 of population. The daily average number of prisoners in jail during 1897 was 1499. The total number of municipalities is 14, only one of which (Sylhet) has a population exceeding 10,000. In 1897-98 the aggregate municipal income was Rs.2,51,819, of which Rs.90,186 was derived from rates and taxes, and Rs.88,844 from Government contributions. There are 19 local boards, with an aggregate income of Rs.12,28,131, of which Rs.6,46,000 was derived from rates. Of the expenditure, 64 per cent. was devoted to public works, 18 per cent. to education, and 8 per cent. to medical. In 1897 the military force in Assam consisted of three battalions of Gurkhas, one of which was stationed in Manipur, and one regiment of Bengal infantry. In addition, there are three volunteer corps: the Shillong Rifles (60 strong), the Assam Valley Light Horse (373 strong), and the Surma Valley Light Horse (350 strong).

The net revenue and expenditure of Assam for 1897-98 in tens of rupees (Rx.), distributed under the three heads of imperial, provincial, and local, was as follows—net revenue: imperial, Rx.416,626; provincial, Rx.660,100; local, Rx.63,953; total Rx.1,140,679. Net expenditure: imperial, Rx.62,517; provincial, Rx.631,468; local, Rx.92,585; total, Rx.786,570. Surplus: imperial, Rx.354,109; provincial, Rx.28,632; local, Rx. -28,632; total, Rx.354,109. During the previous ten years, the gross land revenue increased from Rx.429,939 to Rx.596,123, excise from Rx.210,297 to Rx.276,791, and stamps from Rx.78,683 to Rx.87,051.

Education.—The following table gives the chief statistics of education in Assam for the three quinquennial years, 1886-87, 1891-92, and 1896-97. The figures show steady progress, the rate of increase being considerably higher than for India generally. If we compare the number of pupils with the estimated population of school-going age (15 per cent. of the total population), the increase has been from 9.5 to 12.7 per cent. Taking girls alone, the number at school increased from 5136 in 1891-92 to 8276 in 1896-97, or by no less than 61 per cent.; while the proportion to the female population of school-going age rose from 1.3 to 2.1 per cent. This improvement is mainly due to the Welsh missionaries in the Khasi Hills.

	1886-87.		1891-92.		1896-97.	
	Schools.	Pupils.	Schools.	Pupils.	Schools.	Pupils.
Colleges	1	27

Total	2,289	69,730	2,800	83,638	3,534	103,541

Earthquakes.—Assam is liable to earthquakes. By far the severest shock known is that which occurred on the evening of 12th June 1897. The area of this seismic disturbance extended over North-Eastern India, from Manipur to Sikkim; but the focus was undoubtedly in the Khasi and Garo Hills. In the station of Shillong every masonry building was levelled to the ground. Throughout the country bridges were shattered, roads were broken up like ploughed fields, and the beds of rivers were dislocated. In the hills there were terrible landslips, which wrecked the little Cherrapunji railway and caused 600 deaths. The total mortality recorded was 1542, including two Europeans at Shillong. The damage done to public property is estimated at Rs.50,00,000. On the Assam-Bengal railway alone the cost of repairs was Rs.13,84,000. (J. S. C.)

Assaying.—In its restricted sense the term assaying is applied to the determination of the amount of gold or silver in ores or alloys; but in this article it will be used in its wider signification, and will include a description of the methods for the quantitative determination of those elements in ores which affect their value in metallurgical operations. It would be impossible to give in detail here all the precautions necessary for the successful use of the methods, and the descriptions will therefore be confined to the principles involved and the general manner in which they are applied to secure the desired results.

Gold and Silver.—Ores containing gold or silver are almost invariably assayed in the dry way; that is, by fusion with appropriate fluxes and ultimate separation of the elements in the metallic form. One of the customs which has grown out of our peculiar system of weights is the form of statement of the results of such an assay. Instead of expressing the amounts of gold and silver in percentages of the weight of ore, they are expressed in ounces to the ton, the ounce being the Troy ounce and the ton that of 2000 avoirdupois pounds. To simplify calculation and to enable the assayer to use the metric system of weights employed in all chemical calculations, the "assay ton" ("A.T." = 29.166 grammes) has been devised, which bears the same relation to the ton of 2000lb avoirdupois that one milligram does to the Troy ounce; when one assay ton of ore is used, each milligram of gold or silver found represents one ounce to the ton.

The assay of an ore for gold or silver consists of two operations. In the first the gold or silver is made to combine or alloy with metallic lead, the other constituents of the ore being separated from the lead as slag. In the second, the lead button containing the gold or silver is cupelled and the resulting gold or silver button is weighed. The second operation has been fully described in the ninth edition of this work (vol. ii. p. 725) and need not be further considered. The first is conducted in one of two ways, known respectively as the crucible method and the scorification method. The crucible method is generally used for ores containing gold in small amounts and for certain classes of silver ores. The amount of ore taken for assay is generally one-half "A.T.," but in very low grade ores one, two, and sometimes even four "A.T.s" are used. In the scorification method one-tenth of an "A.T." is the amount commonly taken. While in both methods the same result is sought, the means employed are quite different. In the scorification method the ore is mixed in the scorifier (a shallow dish of burned clay) with from ten to twenty times its weight of granulated metallic lead (test lead) and a little borax glass, and heated in a muffle, the front of which is at first closed. When the lead melts and begins to oxidize, the lead oxide or litharge, as it is called, combines or dissolves the non-metallic and readily oxidizable constituents of the ore, while the gold and silver alloy with the lead. As the slag thus formed flows off to the sides of the scorifier, the assay clears and the melted metallic lead forms an "eye" in the middle. The door of the muffle is then opened and the current of air which is drawn over the scorifier rapidly oxidizes the lead, while the melted litharge gradually closes over the metal. When the "eye" has quite disappeared the door is closed and the temperature

raised to make the slag very liquid. The scorifier is taken from the muffle in a pair of tongs and the contents poured into a mould, the lead forming a button in the bottom while the slag floats on top. When cold, the contents of the mould are taken out and the lead button hammered into the form of a cube, the slag, which is glassy and brittle, separating readily from the metal, which is then ready for cupellation. In the crucible method the ore is mixed with from once to twice its weight of flux, which varies in composition, but of which the following may be taken as a type:—

Sodium bicarbonate	8 parts.
Potassium carbonate	3 "
Powdered borax	4 "
Flour	1 "
Litharge	9 "

The mixture is charged into a round clay crucible from 100 mm. to 125 mm. high, and heated either in a muffle or in a crucible furnace at a gradually increasing heat for forty or fifty minutes. At the expiration of this time, when the charge should be perfectly liquid and in a tranquil state of fusion, the crucible is removed from the furnace and the contents are poured into a mould. The resulting lead button hammered into shape and carefully cleansed from slag is ready for the cupel. If the button is too large for cupellation, or if it is hard, it may be scorified either alone or mixed with test lead before cupellation. The character and amount of the flux necessarily depend upon the character of the ore, the object being to concentrate in the lead button all the gold and silver while dissolving and carrying off in the slag the other constituents of the ore. Under the most favourable conditions there is a slight loss of gold and silver in the fusion, the scorification, and the cupellation, both by absorption in the slag and by actual volatilization and absorption in the cupel. In ores containing much copper, this metal is largely concentrated in the lead button, making it hard and necessitating repeated scorifications, and in some cases a preliminary removal of the copper by solution of the ore in nitric acid. This leaves the gold in the insoluble residue, which is filtered off, and the silver in the solution is thrown down by hydrochloric acid. The resulting precipitate of silver chloride is filtered, and the residue and the precipitate are scorified together. Ores containing much arsenic or sulphur are generally roasted at a low heat and the assay is made on the roasted material.

Lead.—The "dry" or fire assay for lead is largely used for the valuation of lead ores, although it is being gradually replaced by volumetric methods. One part of the ore is mixed with from three to five parts of a flux of the following composition:—

Potassium carbonate	40.6 per cent.
Sodium bicarbonate	31.3 "
Borax	15.6 "
Flour	12.5 "

The mixture is charged into a clay crucible and heated for twenty minutes at a good red heat. When the mixture has been in a tranquil state of fusion for a few minutes it is poured into a mould, and weighed. The proportion is calculated from the amount of ore used, and the result is expressed in parts in a hundred or percentage of the ore. Various impurities, such as copper, antimony, and sulphur, go into the lead button, so that the result is generally too high. The most accurate method for the determination of lead in ores is the gravimetric method, in which it is weighed as lead sulphate after the various impurities have been separated. Nearly all lead ores contain more or less sulphur; and as in the process of solution in nitric acid this is oxidized to sulphuric acid which unites with the lead to form the very insoluble lead sulphate, it is simpler to add sulphuric acid to convert all the lead into sulphate and then evaporate until the nitric acid is expelled. The salts of iron, copper, &c., are then dissolved in water and filtered from the insoluble silica, lead sulphate, and calcium sulphate, which are washed with dilute sulphuric acid. The insoluble matter is treated with a hot solution of alkaline ammonium acetate, which dissolves the lead sulphate, the other materials being separated by filtration. The lead sulphate, re-precipitated in the filtrate by an excess of sulphuric acid and alcohol, is then filtered on an asbestos felt in a Gooch crucible, washed with dilute sulphuric acid and alcohol, ignited, and weighed. Lead sulphate contains 68.30 per cent. of metallic lead.

There are several volumetric methods for assaying lead ores, but the best known is that based on the precipitation of lead by ammonium molybdate in an acetic acid solution. The lead sulphate, obtained as described above and dissolved in ammonium acetate, is acidulated with acetic acid diluted with hot water and heated to boiling-point. A standardized solution of ammonium molybdate is then added from a carefully-calibrated burette. As long as the solution contains lead, the addition of the molybdate solution causes a precipitation of white lead molybdate. An excess of the precipitant is shown by a drop of the solution imparting a yellow colour to a solution of tannin, prepared by dissolving one part of tannin in 300 of water; drops of this solution are placed on

a white porcelain plate, and as the precipitant is added to the lead solution a drop of the latter is removed from time to time on a glass stirring-rod and added to one of the drops on the porcelain plate. The appearance of a yellow colour shows that all the lead has been precipitated and that the solution contains an excess of molybdate. From the reading of the burette the lead is calculated. The molybdate solution should be of such a strength that 1 cc. will precipitate 0.01 gramme of lead. It is standardized by dissolving a weighed amount of lead sulphate in ammonium acetate and proceeding as described above.

Zinc.—Chemically the ores of zinc consist of the silicates, carbonates, oxides, and sulphides of zinc associated with other metals, some of which complicate the methods of assay. The most modern and the most generally accepted method is volumetric, and is based on the reaction between zinc chloride and potassium ferrocyanide, by which insoluble zinc ferrocyanide and soluble potassium chloride are formed; the presence of the slightest excess of potassium ferrocyanide is shown by a brownish tint being imparted by the solution to a drop of uranium nitrate. The ore (0.5 gramme) is digested with a mixture of potassium nitrate and nitric acid. A saturated solution of potassium chlorate in strong nitric acid is added, and the mass evaporated to dryness. It is then heated with a mixture of ammonium chloride and ammonia, filtered and washed with a hot dilute solution of the same mixture. The filtrate diluted to 200 cc. is carefully neutralized with hydrochloric acid, an excess of 6 cc. of the strong acid is added, and the solution saturated with hydrogen sulphide, which precipitates the copper and cadmium, metals which would otherwise interfere. Without filtering, the standard solution is added from a burette, and from time to time a drop of the solution is removed on the glass stirring-rod and added to a drop or two of a strong solution of uranium nitrate, previously placed on a white porcelain plate. The appearance of a brown tint in one of these tests shows the end of the reaction. When cadmium is not present the copper may be precipitated by boiling the acidulated ammoniacal solution with test lead and titrating, as before described, without removing the lead and copper from the solution. The ferrocyanide solution is standardized by dissolving 1 gramme of pure zinc in 6 cc. of hydrochloric acid, adding ammonium chloride and titrating as before. This method is modified in practice by the character of the ores, carbonates and silicates free from sulphides being decomposed by hydrochloric acid, with the addition of a little nitric acid.

Copper.—The fire assay for copper ores was abandoned years ago and the electrolytic method took its place; this in turn is now largely replaced by volumetric methods. In the electrolytic method from 0.5 to 5 grammes of ore are treated in a flask or beaker, with a mixture of 10 cc. of nitric and 10 cc. of sulphuric acid, until thoroughly decomposed. When this liquid is cold it is diluted with cold water, heated until all the soluble salts are dissolved, transferred to a tall, narrow beaker, and diluted to about 150 cc. The electrodes are attached to a frame connected with the battery and the beaker is placed on a stool, which can be raised so that the electrodes are immersed in the liquid and reach the bottom of the beaker. The electrodes consist of two cylinders of platinum (placed one inside the other) about 75 mm. high, the smaller of the two 37 mm., and the larger 50 mm. in diameter, both pierced with 10 to 12 holes 5 mm. in diameter, evenly distributed over the surfaces to facilitate diffusion of the liquids. The surfaces of the cylinders are roughened with a sand blast to increase the areas and make the deposited metals adhere more firmly. Each cylinder has a platinum wire fused to the upper circumference to connect with a clamp from which a wire leads to the proper pole of the battery. The smaller cylinder is generally the negative electrode on which the copper is deposited. The framework carrying the clamps is arranged so that a number of determinations may be made at one time, the wires from the clamps running from a rheostat, so arranged that currents of any strength may be used simultaneously. The cylinder, having been carefully weighed, is placed in position, the beaker containing the solution is adjusted, and the current passed until all the copper is precipitated. This generally requires from two to twelve hours. The cylinders are then removed from the solution and washed with distilled water, the one holding the deposited copper being washed with alcohol, dried, and weighed; the increase in weight represents the copper contents of the ore. The deposited copper should be firmly adherent and bright rosy red in colour. Silver, arsenic, and cadmium, if present, are precipitated with the copper and affect the accuracy of the results; they should be removed by special methods.

Volumetric methods are more expeditious and require less apparatus. The potassium cyanide method is based on the fact that, when potassium cyanide is added to an ammoniacal solution of a salt of copper, the insoluble copper cyanide is formed, the end of the reaction being indicated by the disappearance of the blue colour of the solution. One gramme of the ore is treated in a flask with a mixture of nitric and sulphuric acids and evaporated until all the nitric acid is expelled. After cooling a little, water is added,

and then a few grammes of aluminum foil free from copper. On this foil the copper in the solution is all precipitated by electrolytic action in a few minutes, and the aluminum is dissolved by the addition of an excess of sulphuric acid. Water is added, and as soon as the gangue and copper particles have settled the clear solution is decanted, and the residue washed several times in the same way. The copper is then dissolved in 5 cc. of nitric acid; if silver is present a drop or two of hydrochloric acid is added, the solution diluted to about 50 cc., and filtered. To the filtrate (or, if no silver is present, to the diluted nitric acid solution) 10 cc. of ammonia are added, and a standard solution of potassium cyanide is run in from a burette until the blue colour has nearly disappeared. The solution is filtered to get rid of the precipitate, and the titration is finished in the nearly clear filtrate, which should be always about 200 cc. in volume. The titration is complete when the blue colour is so faint that it is almost imperceptible after the flask has been vigorously shaken. The potassium cyanide solution is standardized by dissolving 0.5 gramme of pure copper in 5 cc. of nitric acid, diluting, adding 10 cc. of ammonia, and titrating exactly as described above.

When potassium iodide is added to a solution of cupric acetate, the reaction $\text{Cu}(\text{C}_2\text{H}_3\text{O}_2)_2 + 2\text{KI} = \text{CuI} + 2\text{K}(\text{C}_2\text{H}_3\text{O}_2) + \text{I}$ takes place; that is, for each molecule of copper one molecule of iodine is liberated. If a solution of sodium hyposulphite is added to this solution, hydriodic acid and sodium tetrathionate are formed; and if a little starch solution has been added, the end of the reaction is indicated by the disappearance of the blue colour, due to the iodide of starch. The amount of iodine liberated is therefore a measure of the copper in the solution, and when the sodium hyposulphite has been carefully standardized the method is extremely accurate. The ore is treated as described in the cyanide method until the copper precipitated by the aluminum foil has been washed and dissolved in 5 cc. of nitric acid; then 0.25 gramme of potassium chlorate is added, and the solution boiled nearly dry to oxidize any arsenic present to arsenic acid. The solution is cooled, 50 cc. water added, then 5 cc. ammonia, and the solution is boiled for five minutes. Next 5 cc. of glacial acetic acid are added, the solution cooled, and 5 cc. of a solution of potassium iodide (300 grammes to the litre) and the standard solution of sodium hyposulphite run in from a burette until the brown colour has nearly disappeared. A few drops of starch solution are then added, and when the blue colour has nearly vanished a drop or two of methyl orange makes the end reaction very sharp. The hyposulphite solution is standardized by dissolving 0.3 to 0.5 gramme of pure copper in 3 cc. of nitric acid, adding 50 cc. of water and 5 cc. of ammonia, and titrating as above after the addition of 5 cc. of glacial acetic acid and 5 cc. of the potassium iodide solution.

Iron.—The methods used in the assay for iron are volumetric, and are all based on the property possessed by certain reagents of oxidizing iron from the ferrous to the ferric state. Two salts are in common use for this purpose, potassium permanganate and potassium bichromate. It is necessary in the first place, after the ore is in solution, to reduce all the iron to the ferrous condition; then the carefully standardized solution of the oxidizing reagent is added until all the iron is in the ferric state, the volume of the standard solution used, being the measure of the iron contained in the ore. The end of the reaction when potassium permanganate is employed is known by the change in colour of the solution. As the solution of potassium permanganate, which is deep red in colour, is dropped into the colourless iron solution, it is quickly decolorized, while the iron solution gradually assumes a yellowish tinge, the first drop of the permanganate solution in excess giving it a pink tint. With potassium bichromate solution, which is yellow, the iron solution becomes green from the chromium chloride or sulphate formed, and the end of the reaction is determined by removing a drop of the solution on the stirring-rod and adding it to a drop of a dilute solution of potassium ferriocyanide on a white tile. So long as the solution contains a ferrous salt, the drop on the tile changes to blue; hence the absence of a blue coloration indicates the complete oxidation of all the ferrous salt and the end of the reaction. One gramme of ore is usually taken for assay and treated in a small flask or beaker with 10 cc. of hydrochloric acid. All the iron in the ore generally dissolves upon heating, and a white residue is left. Occasionally this residue contains a small amount of iron in a difficultly soluble form; in that case the solution is slightly diluted with water and filtered into a larger flask. The residue in the filter is ignited and fused with a little sodium carbonate and nitrate, or with sodium peroxide. The product is treated with water, filtered, and the residue dissolved in hydrochloric acid and added to the main solution. This solution, which should not exceed 50 cc. or 75 cc. in volume, contains the iron in the ferric state and is ready for reduction.

In the reduction by metallic zinc, about 3 grammes of granulated or foliated zinc are placed in the flask, which is closed with a small funnel; when the iron is reduced, add 10 cc. of sulphuric acid, and as soon as all the zinc is dissolved the solution is ready for

titration. In the reduction by stannous chloride the solution of the ore in the flask is heated to boiling, and a strong solution of stannous chloride is added until the solution is completely decolorized; then 60 cc. of a solution of mercuric chloride (50 grammes to the litre) are run in and the contents of the flask poured into a dish containing 600 cc. of water and 60 cc. of a solution containing 200 grammes of manganous sulphate, 1 litre of phosphoric acid (1.3 sp. gr.), 400 cc. of sulphuric acid, and 1600 cc. of water. The solution is then ready for titration with the standard permanganate solution.

The permanganate or bichromate solution is standardized by dissolving 0.5 of a gramme of pure iron wire in a flask in hydrochloric acid, oxidizing it with a little potassium chlorate, boiling off all traces of chlorine, deoxidizing by one of the methods described above, and titrating with the solution. As the wire always contains impurities, the absolute amount of iron in the wire must be determined and the correction made accordingly. Pure oxalic acid may also be used, which, in the presence of sulphuric acid, is oxidized by the standard solution according to the reaction:—

The reaction in case of ferrous sulphate is:—

that is, the same amount of potassium permanganate is required to oxidize 5 molecules of oxalic acid that is necessary to oxidize 10 molecules of iron in the form of ferrous sulphate to ferric sulphate, or 63 parts by weight of oxalic acid equal 56 parts by weight of metallic iron. Ammonium ferrous sulphate may also be used; it contains one-seventh of its weight of iron. (A. A. B.)

Assche, a town of Belgium, in the province of Brabant, 8 miles N.W. by W. of Brussels, with a station on the line between Brussels and Termonde. It has breweries and soap-works. Population (communal) (1890), 7063; (1897), 7524.

Assen, a town in the Netherlands, capital of the province of Drenthe, 16 miles S. of Groningen, on the railway Meppel-Groningen of the Netherlands State railways and two canals. Peat-cutting is a considerable industry. In the neighbourhood are situated the megaliths (*Hunebedden*) mentioned by Tacitus, and a large number of prehistoric remains have been discovered. The population in 1898 was 10,964.

Assiniboia. See NORTH-WEST TERRITORIES.

Assinie. See IVORY COAST.

Assisi, a town and bishop's see of the province of Perugia, Umbria, Italy, situated on the slope of Mt Subasio, 15 miles E. by S. from Perugia by rail, still surrounded by mediæval walls, and celebrated as the birthplace of St Francis, whose tomb, in the crypt (1818) of the church of the Franciscan monastery, attracts crowds of pilgrims every year. This church is a double structure, and consists of an upper church and a lower church, the latter begun in 1228, and both finished in 1253. Both are adorned by frescoes and pictures by Giotto, Cimabue, and others. Down in the valley is the pilgrimage church of Santa Maria degli Angeli, begun by Vignola in 1569 over the oratory of St Francis, and finished about 1640; restored after the earthquake of 1832. It is decorated by works from the brush of the Della Robbias, Overbeck, and others. In the town there are, further, the cathedral, finished in 1140, and remodelled in the interior in 1572, with a marble statue of St Francis by Dupré and a Madonna and saints by Niccolò da Foligno; the new church, built in 1615 on the site of the house in which St Francis was born; and the church of Santa Chiara (1257), containing the remains of St Clara, foundress of the order of the nuns of St Clare (1212). There are also an old castle and the ruins of a Roman amphitheatre. Assisi was also the birthplace of the poet Propertius (between 50 and 44 B.C.). Population, about 7000; of commune, about 17,000.

Assiut, or **Siut**, the administrative capital of Upper Egypt, and the largest and best-built town in the Nile Valley south of Cairo, with a population which rose from 32,000 in 1882 to 42,000 in 1900. It stands near the left bank of the Nile on the Nile Valley railway, of which it is an important station, 248 miles south of Cairo. Here is a large canal communicating during the floods with the Bahr Yusuf, which runs parallel with the Nile, and discharges its overflow into the Fayyum depression. The canal is now skirted by a magnificent embankment planted with shady trees leading from the river to the town. There are several bazaars, baths, and handsome mosques, one noted for its lofty minaret, and here the American mission has established a college for both sexes. Assiut is famous for its red and black pottery, which finds a ready market all over Egypt. In the neighbouring Libyan hills are numerous rock-tombs, where are often found the remains of wolf mummies, this animal having been the tutelary deity of the place, whence its Greek name of *Lycopolis* ("wolf-town").

Assuan, or **Aswan**, a town of Upper Egypt on the right bank of the Nile, facing Elephantine Island below the First Cataract. It is a station on the Nile Valley railway, 590 miles from Cairo. In 1880, though the centre of a flourishing trade with the Sudan and Abyssinia—the annual value of the goods in transit was estimated at £2,000,000—its population was only about 4000. During the reign of the Khalifa it gained importance as the seat of the military government of the frontier provinces extending from Edfu to Wadi Halfa, and numbered some 10,000 inhabitants. After the defeat of the Khalifa at Omdurman it became popular as a winter health-resort, and in 1901 had a population of about 25,000. The great barrage immediately above Aswan will place the agricultural prospects of the surrounding country on an entirely new and improved footing. In connexion with the work upon this undertaking and the reservoirs a town of about 12,000 workmen has sprung into existence. Aswan gives its name to one of the three second-class administrative districts into which the Anglo-Egyptian Sudan was divided in 1899, and is the headquarters of the English military commandant.

Astara, a port on the Caspian, situated in 38° 27' N. lat. and 48° 53' E. long., on both sides of the river of the same name, which, according to the Turkmanchai treaty of 1828, is the frontier between Persia and Russia. Until the Mercury Steam Navigation Company made it a port of call, about 1860, it was an unimportant fishing village, but it has now a considerable trade, and much Russian merchandise is landed there and forwarded to Azerbáiján and Tabriz *via* Ardebil, 30 miles south-west. In 1897, 77 vessels (76 steamers), with a tonnage of 43,101, entered the port, and 272 vessels (240 steamers), with a tonnage of 88,011, cleared it.

Asthma. See *PATHOLOGY (Respiratory Organs)*.

Asti, a town and episcopal see of the province of Alessandria, Piedmont, Italy, on the Tanaro, 22 miles W. from Alessandria by rail. Besides the cathedral, it has the interesting church of St Peter and the church of St John, both assigned to the Longobardic epoch (middle of 8th century, but remodelled in the 10th). There is a statue of Victor Emmanuel. Asti is famous for its wine. Population, about 19,000.

Astoria, a city of Oregon, U.S.A., and capital of Clatsop county, situated on the Columbia, near its mouth, in the north-western part of the state, and has an excellent harbour. It is connected with Portland by the Astoria and Columbia River railway and by steamboat lines. Its industries consist largely in salmon-canning and

in the manufacture of lumber, the surrounding country being densely forested with fir, cedar, and hemlock. It was founded in 1811, as a depot in the fur trade, by John Jacob Astor, after whom it is named. It was seized by the British in 1813, but restored in 1818. In 1821, while occupied by the North-West Fur Company, it was burned and practically abandoned, leaving only a few settlers. Population (1880), 2803; (1890), 6184; (1900), 8381.

Astrakhan, a government of S.E. Russia, on the lower Volga. Area, 91,237 sq. miles, of which 6730 sq. miles are in the delta of the Volga and the brackish lagoons, and 62,290 sq. miles covered by the Kalmyk and the Kirghiz Steppes. The climate is very hot and dry, the average temperatures being for the year, 50° Fahr.; for January, 21°; for July, 78°; yearly rainfall, 7.3; often no rain at all in summer. Population (1897), 1,002,316, of whom 485,517 were women, and 132,383 urban. About 132,000 Kalmyks and 260,000 Kirghiz are half nomad. There are besides nearly 44,000 Tatars, 7000 Armenians, 1350 Poles, and as many Jews. The average percentage of births is 5.7, and that of deaths 3.7. Primary education remains at a low level; the total number of pupils in primary schools being only 12,337 (one school for every 2380 inhabitants). Fishing at the mouth of the Volga gives occupation to nearly 30,000 persons, as much as 278,000,000 herrings being caught in a good year. Salt is largely extracted (300,000 tons) from lakes, chiefly at Baskunchak, which is now connected with the Volga by rail. Cattle breeding is an important industry; in 1897 there were 1,075,600 horned cattle, 214,935 horses, and 3,521,000 sheep. Corn is imported, but gardening and the culture of mustard, melons, and fruit for export are on the increase. Agriculture is not much developed, there being (1899) only 1,007,300 acres under cereals, and the total cereal crop being on the average 149,600 tons. Forests cover only 430,000 acres. The Russian railways only touch the borders of the province. The government is divided into five districts, the chief towns of which are—Astrakhan, pop. 113,000; Enotaevsk, 2810; Krasnyi Yar, 4680; Tchorny Yar, 5140; and Tsarev, 8900. Several villages are very populous, such as Nikolaevskaya Sloboda (17,800). The Kalmyk Steppe (pop. 127,776), and the Inner Kirghiz Horde (213,146), are under their own internal administration. So also is the territory of the Astrakhan Cossacks (pop. 25,600).

ASTRAKHAN, capital of the above, on the left bank of the main branch of the Volga, and 60 miles from the Caspian Sea (68 feet below the level of the ocean) has, since the development of the naphtha industry and the opening of the Transcaspian railway, become a great centre for external and internal trade, the yearly returns of which are estimated at 16,100,000 roubles for the former and 52,157,000 for the latter. The port is visited yearly by about 4000 vessels; and 1242 vessels (90 steamers) belong to it. Population (1867), 47,839; (1897), 113,000. It is well provided with gymnasia for boys and girls and technical schools. Good public gardens and squares (one of which is adorned by a monument to Alexander II.) have been laid out.

Eight miles above Astrakhan, on the right bank of the Volga, are the ruins of two ancient cities, one above the other. In the upper layer, amidst all sorts of debris, charcoal, and bones, have been found gold and silver mints made by the Mongol Horde rulers, as well as various silver and gold ornaments. These ruins are separated by a layer of earth from older and scantier ruins, supposed to be the remains of the large and prosperous city Atel, or Itil (Etel, Idl), of the Arabian geographers (Ibn Fozlan, Ibn Hankal, etc.), which was the residence of the Khan of the Khazars, and was destroyed by the Russes in 969. The upper layer of ruins may represent the old city of Balanjar (Balansar, Belender).

ASTRONOMY.

PART I. of the article on **ASTRONOMY** in the ninth edition of this Encyclopædia treats of the history of the science, and needs no supplement. In the first six chapters of Part II. are developed those general principles and methods which form the basis of the science and are not subject to material revision. Our present purpose is to supplement the chapters from VII. onwards. We shall first treat the recent developments relating to the solar system, and afterwards briefly describe the progress of knowledge in regard to the fixed stars. In arranging the first subject we shall set forth the general results of telescopic and spectroscopic observations of the planets, in advance of results derived from the mathematical investigation of their motions. The subject thus divides itself into three sections:—

I. The physical and other general features of the solar system.

II. Gravitational and theoretical astronomy.

III. The recent development of our knowledge of the fixed stars.

I. PHYSICAL FEATURES OF THE SOLAR SYSTEM.

The development of this subject since 1880 is principally due to the increased power of our instruments and the more extended use of the spectroscope. Sixty years ago the spectroscope was unknown, and the telescopes most used were from 4 to 9 inches in aperture. About 1840, the successors of Fraunhofer made two telescopes of 14 inches' aperture for the observatories of Pulkowa and Harvard University. The extreme limit of size was then thought to be attained, but by 1880 the aperture was carried up to 26 inches, and now it is 40 inches. The great Yerkes telescope of the university of Chicago gives about seven times the light of the Harvard and Pulkowa instruments. It might be thought that this enormous increase of power would have resulted in the final settlement of all questions, formerly the subject of debate, as to the physical phenomena presented by the planets. But such is far from being the case, and the vast mass of observations that have been accumulated has thrown less light than might have been expected on the question of the rotation or physical constitution of these bodies, though, at the same time, critical examination may show that the results to be derived are not so discordant or doubtful as might appear from the seeming divergence of the observations themselves. The observers who, since 1880, have made careful studies upon the appearance of the planets in the telescope, are so numerous that only a few of the best known can be mentioned. The systematic work of the British Astronomical Association, which has organized sections for the special study of particular objects, offers a good example of the energy with which a large and popular body may pursue scientific investigation. This body does not, however, command the instruments or enjoy the atmospheric conditions necessary to settle the most difficult questions. Among the individual observers Schiaparelli may be assigned the first place, in view of his long-continued studies of the planets under a fine Italian sky, the conscientious minuteness of his examinations, and his eminence as an investigator. In what concerns the means and opportunities of observation, Barnard at the Lick Observatory enjoyed advantages offered to no other observer. The observatory at Flagstaff, Arizona, was founded by Mr Percival Lowell, of Boston, for the special

purpose of studying the physical phenomena presented by the planets, particularly Mars, and its situation is believed to be one of the best as regards atmospheric conditions.

Taking up the planets in order, we begin with Mercury. Only on rare occasions have observers succeeded in discerning any well-defined features on the disc of this planet. Up to 1890 the period of its rotation was generally said to be nearly twenty-four hours, a statement which rested mainly on observations made by Schroeter, the indefatigable observer of Lilienthal, about the beginning of the century. Cautious and conservative astronomers have been more and more sceptical as to the correctness of this period, on account of the failure of observers with better instruments than Schroeter's to see permanent markings that could be followed from day to day. In 1882 Schiaparelli began a careful study of the face of the planet, with a refractor of 8 inches' aperture, subsequently replaced by one of 18 inches'. His unexpected conclusion was that the rotation of Mercury resembles that of the moon, in having its period equal to that of the orbital revolution. As the moon always presents the same face to the earth, so Mercury always presents very nearly the same face to the sun. Schiaparelli also announced that the axis of rotation of the planet is very nearly perpendicular to the plane of its orbit. The rotation being uniform, while the orbital motion, owing to the great eccentricity of the orbit, is affected by a very large inequality, it follows that there is a libration in longitude of nearly 24° on each side of the mean position. Mr Lowell, in 1897, took up the question anew by combining a long series of measured diameters of the planet with drawings of its apparent surface made from time to time. The latter showed long narrow markings similar in their general character to the supposed channels seen by Schiaparelli upon Mars, and the constancy of these markings was considered to confirm the view of Schiaparelli as to the slow rotation of the planet. The diameter was found to be 0.8'' greater than the value which had before been generally accepted. The most curious result of Mr Lowell's work was that the body of the planet is possibly somewhat ellipsoidal, the longer axis being directed toward the sun. This, however, cannot be regarded as established. It is worthy of remark that the larger diameter and the ellipsoidal form may be connected with a curious discrepancy found in discussing the meridian observations of the planet. This consists in the fact that in the general average, when the planet is east of the sun the right ascension derived from observations seems to be too small, and when west of the sun too great. In either case, it is impossible to observe the real centre of the planet, because the latter always shows a phase like that of the moon, being sometimes a crescent, sometimes a semicircle, and sometimes gibbous, according to the position in the orbit. The observers sometimes directed their view upon the bright limb which, of course, was always towards the sun, and sometimes upon the apparent centre of the illuminated surface; hence reduction from the point observed to the centre of the planet was necessary to derive the position of the centre supposed to be given by the observations. This reduction was necessarily a fraction of the assumed diameter of the planet, which had to be determined from other sources. The discrepancy shows that the reduction actually applied was, in the general average, too small by a considerable fraction of a second, but it is impossible to say with certainty whether this arose from a personal equation of

the observers, due to the fact that the limb of the planet nearest the sun was so much brighter than the rest of the disc that the observers of the apparent centre set very nearly on the limb, or from the assumed diameter being too small, as supposed by Mr Lowell.

Schiaparelli made his well-known studies upon Venus contemporaneously with those upon Mercury, and his conclusions were summed up in five brief notes *Venus*. read to the Milan Academy during the year 1890. The first four of these are devoted to a very full and exhaustive history of all existing telescopic observations upon the supposed spots of the planet from the time of Bianchini (1728), the result being that no positive conclusions can be drawn from any of the observations, either as to permanent markings on the planet or its time of rotation. Herschel had devoted special attention to the subject, and, as is well known, could find no evidence of any well-defined period of rotation. The first definite clue to a conclusion which Schiaparelli could obtain, was suggested by the long continuance of two faint spots near the southern cusp of the planet. It is true that these spots were not always visible; yet, under the best conditions, they could be seen at some hour every day for weeks at a time, and sometimes during several hours on the same day. He agreed with Herschel and others of the best astronomers in concluding that these spots were not really permanent, but disappeared at the end of a few weeks at most. At the same time the faint temporary spots which he succeeded in discerning remained immovable for several hours in succession, thus precluding the idea of previous observers that the planet rotated in a period not very different from twenty-four hours. Moreover, their continued observation for several weeks seemed to show that their rotation must be very slow, and their period several months, perhaps equal to that of the revolution of the planet round the sun. Lowell reached a similar but more definite conclusion, maintaining that the planet really did always present the same face to the sun. But in the opinion of the most conservative astronomers, the whole subject of the rotation, both of Mercury and Venus, is still in doubt. The supposed spots are so indefinite, that it is not safe to rest a positive conclusion on them. The most recent and most definite result is that of Belopolsky at Pulkowa, who determined by the spectrographic method the difference of the velocities with which various points of the circumference of the disc of Venus were moving to or from us. The mean of a great number of measures gave a velocity of rotation of 0.9 km. per second, corresponding to a period of twelve hours. So short a period seems incompatible with the absence of sensible ellipticity in the figure of the planet, yet the observations greatly weaken Schiaparelli's conclusion (*Ast. Nach.* No. 3641).

Conclusive evidence that Venus is surrounded by a transparent, or at least a translucent atmosphere, was gathered at the transit of Venus in 1882, and scarcely less conclusive was the evidence that this atmosphere bears a great volume of clouds, which probably would completely obscure the surface of the planet. After one-half of the dark body of the planet had entered upon the disc of the sun, that portion of its outline without the sun became visible as a thin line of light extending around its border. This line can be attributed to no other cause than the refraction of the sun's rays produced by an atmosphere surrounding the planet. Had this atmosphere been quite transparent, we should have expected the line of light to make its first appearance at the most distant point A (see Fig. 1) of the circumference of the planet, owing to the fact that before the planet had half entered, the only rays that could be refracted to us would necessarily pass near this region.

From this point, A, the line of light should have extended in both directions, until, after more than half the planet was on the solar disc, it would have been seen complete. Instead of this the light first showed itself along a small arc at the point B. A few minutes later, small portions of it began to glimmer here and there around other parts

Fig. 1.

of the dark circumference, but it was not until the planet was almost entirely on the disc that the arc of light became plainly continuous. It is difficult to attribute this phenomenon to any other cause than clouds floating in the lower region of the atmosphere, and possibly an irregularly translucent condition of the latter rather than entire transparency.

There is a class of telescopic observations which, at first sight, seem incompatible with those made about the time of a transit. At intervals of eight years before and after a transit, Venus passes very near the sun. On such an occasion, in 1866, Lyman, at New Haven, saw the entire outline of the planet as an exceedingly fine ring of light, and on 1st and 5th December 1890 Barnard saw the entire outline except about 20°. An atmosphere refracting rays so strongly that the illumination of the entire planet would be visible under such circumstances, ought to show a bright arc of light on the side farthest from the sun, whereas, in fact, this was always the darkest portion of the outline. A very elaborate discussion of all the observations of this class has been made by H. N. Russell (*Astrophysical Journal*, ix. 284), who proposes the explanation that the visible outline which we see is not the illuminated surface of the planet but the upper illuminated region of the atmosphere, bearing suspended particles of dust or fog. He also concludes that the atmosphere of Venus is decidedly rarer than that of the earth. This seems the best explanation of the seeming paradox that has yet been offered.

The earlier telescopic observers had no difficulty in discerning bright and obscure regions on the surface of Mars, and in concluding from the varying *Mars*. aspects of these regions that it rotated on its axis in a period of a little more than twenty-four hours. The only important additions to our knowledge of the surface between the time of Herschel and Schroeter, and the opposition of 1877, were embodied in maps of the planet, which agreed in the main features, but differed greatly in details. At the opposition of 1877, the planet was unusually near the earth; and although its south declination was not favourable to observations in the northern hemisphere, Schiaparelli instituted a series of studies which, continued through several subsequent oppositions, have given rise to a large mass of literature on the subject. Observers had long seen, or fancied they could see, a remarkable resemblance between the surface of Mars and that of the earth. The brighter regions were supposed to be continents; the darker ones oceans. Schiaparelli's great discovery was that these supposed oceans were connected by comparatively narrow streaks, to which he applied the term channels (*canale*), a word which, through an unfortunate misconception, has been translated into English as "canal," thus giving rise to

the impression that the features in question were the work of the inhabitants of Mars. The studies of these features by other observers have been so numerous that it is impossible even to summarize them. Some have failed to see the channels at all, but the most successful in seeing and drawing them have been the observers at the Lowell Observatory. A careful comparison of the maps of Schiaparelli with each other, and with that of Lowell, shows that there is by no means a complete agreement as to these features. Schiaparelli depicts them as rather obscure and more or less diffused bands or streaks of appreciable breadth, whereas in Lowell's drawings they appear as sharp, fine, dark lines. The channels seen by Lowell are much more numerous than those seen by Schiaparelli, but at the same time we cannot identify all of Schiaparelli's channels on Lowell's map. An additional characteristic of the latter is that the numerous junction points of the channels are frequently marked by round, dark spots, like circular lakes, which do not appear on Schiaparelli's map. The current interpretation of these features has been contested by Barnard, who seems to have seen the planet under much more favourable conditions than either of the two other observers. He had the advantage of the great aperture of the Lick telescope, and the very fine seeing now and then obtained at Mount Hamilton. In exceptionally favourable circumstances he could see markings so minute, intricate, and abundant that it was impossible to delineate them. They were even more numerous on the so-called seas than on the broad continental regions. They were usually more or less irregular, consisting in delicate differences of shade. No straight and sharp lines were seen. Between the black spots which abounded in a certain region were seen diffuse hazy lines, rather irregularly formed (*Monthly Notices R. A. S.* vol. lvi. 1896, p. 166). These discrepancies between the two observers are all the more noteworthy, in view of the skill of each, Schiaparelli being known for his conscientious care in avoiding every sort of illusion, and training his eye to see only what is existent, while Barnard is equally conscientious, and had at his disposition telescopic power far exceeding that of Schiaparelli.

The apparent discrepancy can, we believe, be reconciled by some considerations on the psychology of vision. If we observe a stippled engraving of such an object as the human face from a certain distance, we see nothing but continuous light and shade. If we seek to draw what we see, we may form the best representation by lines representing the outlines of the human features. But if, instead of studying the engraving at a distance, we look at it through a magnifying glass, we see no lines whatever but only collections of points, perhaps without any well-defined arrangement, thicker in some regions than in others, and of various sizes. We thus learn that the eye possesses a property of representing collections and rows of points to the visual sense as continuous lines of light and shade. From this point of view it is quite natural that such features as those described by Barnard should, when seen with less sharpness, present to the eye the appearance shown on the maps of Schiaparelli. The discrepancy between the outlines, as drawn not only by the two observers, but by the same observer at various times, shows that there is something shadowy and indefinite, we may even say doubtful, in the objects depicted. Some of the channels are unmistakable. Of others the difference of shading is so slight that visual distinctness is scarcely possible, and none of them, perhaps, can be considered as anything but the result of a combination of complex features too minute to be separately visible. In this connexion a short paper by Cerulli in the *Astronom.*

Nach. (Bd. 146, S. 155) may be read with interest. This observer found that after having observed the channels of Mars for two years through a telescope, he was able, by looking at the moon through an opera-glass, to see similar lines upon its surface, but these seeming lines were shown by observations with the telescope to be unreal, being only the result of the unconscious action of the eye in joining together slight and irregular combinations of light and shade in such a way as to produce regular forms. As this action was the result of a long habit, the fact shows the possibility that long practice in observing may result in an observer seeing objects incorrectly. Could we see Mars with an optical instrument bearing the same ratio to a common telescope that the latter does to an opera-glass, the result might be the same for Mars that Cerulli found for the moon. The doubling of the channels noticed from time to time by some observers must also be placed in the category of doubtful phenomena or probable illusions, and there is on this point an absence of agreement among the observers which must throw doubt on their conclusions. On Schiaparelli's map and in Lowell's drawing the double channels are simply parallel ones of equal strength, so far apart that they are distinctly separate objects, though others find the supposed duplicity very difficult to make out. It is conceivable that an observer, under unfavourable conditions, might find these pairs of markings hard to separate; but, were such the case, they would be seen as a very broad band and not as the narrow streaks commonly depicted.

The well-known fact that the polar regions of Mars are covered with a white deposit during the Martian winter, of which the greater part melts away in the course of the Martian summer, has given rise to the belief that the planet has an atmosphere and oceans like our own. Apparent changes in the visibility of different spots at different times seem to confirm this view, by suggesting that portions of the planet are from time to time rendered invisible by clouds. But the telescopic observations of Lowell, and those made with a spectroscope by Campbell, both tend to weaken this view; Lowell, from his own observations, reached the conclusion that the atmosphere must be much rarer than that of the earth and comparatively cloudless, and Campbell, by comparing the spectra of Mars and the moon, could not certainly discern any well-marked difference between them. It is known that the moon has no atmosphere sufficient to produce an absorption spectrum. Hence Campbell's observations show that if the same thing is not absolutely true of Mars, it must be approximately so, in that no spectral lines are strengthened by the atmosphere to an obvious extent. Just how dense an atmosphere could exist without having any appreciable effect on the lines, especially how much aqueous vapour it might contain, we cannot state with precision, but we seem justified in concluding that the Martian atmosphere is much rarer and much more free from aqueous vapour than that of the earth. The problem of reconciling the supposed winter snow deposits with the great rarity of the atmosphere presents no difficulty. But there is real difficulty in supposing that the summer temperature can be so high as to melt any considerable thickness of snow or ice. The most probable explanation of this phenomenon seems to be that the polar caps are in the nature of hoar frost deposited during the extreme cold that must prevail in a region completely cut off from the rays of the sun, and not warmed as our polar regions are by air currents from the warmer equatorial regions. Ice slowly evaporates at a temperature below the melting-point. It is not, therefore, necessary to suppose that the sun's rays warm the polar regions of Mars even up to the melting-

*Atmo-
sphere of
Mars.*

point of water, in order to explain the evaporation of a thin deposit of frost during the Martian summer.

Our general conclusions as to the physical condition of the surface of Mars may be summed up as follows: (1) The dark regions on the planet are not oceans, as was formerly supposed, the more probable hypothesis being that the dark colour is simply that of the solid surface of the planet. The amount of heat received from the sun on each unit of surface is less than half that received by the earth, and it is commonly supposed that the surface of our globe is, in the general average, warmer than it would be if our atmosphere were less dense or less rich in aqueous vapour. It is therefore very unlikely that the surface of Mars can be warm enough to allow of the presence of large bodies of water in the liquid state. (2) The so-called canals or channels are probably not the definite features that appear on the drawings, but rather the result of slight suggestions made to the eye by more or less irregular differences in the minute shadings and colour tints on the surface of the planet.

Probably no astronomical discovery since that of Neptune has so surprised the astronomical world as the announcement, made in August 1877, that Professor Asaph Hall had discovered two satellites of Mars. The most remarkable feature of these bodies is their minuteness, their estimated diameter being only 8 or 10 miles, and they are the smallest known bodies in our system, except possibly a few of the more recently discovered minor planets. Among satellites the inner one is unique, in that its time of revolution round the planet is less than the Martian day, being in fact less than nine hours. The result is that to an observer on the planet it would rise in the west and set in the east. They are, of course, difficult objects to observe, especially at those oppositions when the planet is farthest from the sun; but at the favourable oppositions, when Mars is near its perihelion, they may easily be seen with a telescope of 12 inches' aperture or upwards, if the observer takes the precaution to cut off the light of Mars from his field of vision. Particulars relating to the elements and motions of these bodies are given on pages 744-5.

The number of known members of the group of minor planets now approaches 500, and is increasing so rapidly that no trustworthy estimate of its total can yet be made. The mean opposition magnitude of those most recently discovered generally lies between the 11th and 13th, and sometimes is of the 14th or 15th. New discoveries are now made entirely by photography. A sensitized plate is exposed in the focus of an equatorial photographic telescope, moved by clockwork so as to follow the stars in their diurnal motion, and on this when developed the stars appear as minute dark dots. But if the image of a planet is imprinted on the plate, it will appear as a short line, owing to the combined effect of its orbital motion and that of the earth. The ease with which such a plate can be examined under a microscope, renders this method much simpler and more expeditious than the old one of searching for the planet visually. One of the bodies recently added to the list is, in the character of its orbit, quite unique. The orbits of all the minor planets known up to 1898 were situated between those of Mars and Jupiter, but in August of that year, Witt, of Berlin, found a planet which at perihelion comes considerably within the orbit of Mars. The name of Eros has been assigned to it. A remarkable feature is that the two orbits, those of Eros and of Mars, are inter-linked in such a way that if both were material they would pass through each other like two links in a chain; but the inclination of the orbits and the large eccentricity of Eros are such that, at present, there is no very near approach of the two orbits, though this could not always

have been the case in the past, nor will it be the case in the future. One result of the secular variations must be that the two orbits will, at some period, actually intersect, and near this time Mars and Eros will approach so close to one another that the orbit of the latter may be completely changed. Not unlikely this was the case at some unknown epoch in the past, previous to which the orbit of Eros may have been very different from what it is now. Approximate elements of this body referred to the equinox of 1900 are these:—

Epoch, 1898, August 31, 5 G.M.T.

Mean long. at epoch	342° 48'
" anom. "	221° 37'
Long. of perihelion	121° 11'
" node	303° 31'
Inclination	10° 50'
Angle of eccentricity	12° 52'
Daily mean motion	2015.2326''
Log. mean distance	0.163798''
Eccentricity	0.22275''

From the mean distance and eccentricity it follows that the least distance¹ of the planet from the sun is 1.1333; the greatest, 1.7829. At the descending node on the ecliptic its distance from the earth's orbit is only 0.149, a distance much less than that of any other known planet. The earth passes this point about 24th January of each year; but it is only on rare occasions that the planet will be very near the corresponding part of its orbit at this date. A tantalizing fact for the astronomer is that such a passage occurred about 24th January 1894, before the planet was recognized, and that so near an approach will not occur again until 1975. Oppositions not much less favourable than that of 1894 will occur in 1931 and 1938. The epochs of these nearest approaches can be utilized for more exact measures of the solar parallax than have yet been made. Seven years before and after each most favourable opposition another occurs at which, though less favourable, the planet comes so near as to offer an excellent opportunity for the measures in question.

A study of the distribution of the mean motions of these bodies shows a singular feature, apparently connected with their origin, on which it may throw some light. About 1870 it was noticed by Kirkwood that when these mean motions are arranged in the order of their magnitude, gaps are found in the series corresponding to the points of commensurability with the mean motion of Jupiter; that is to say, the period of Jupiter being in round numbers twelve

Distribution of mean motions.

years, there are few or none of these bodies which have periods of one-half, one-third, or two-fifths of twelve years. If there were any of the group having any of these periods, it is known that the

¹ Distances among the planets are expressed in radii of the earth's orbit.

perturbations produced by Jupiter would be greatly exaggerated in the course of centuries. It was therefore supposed that if there ever had been planets with these mean motions, their orbits would have been unstable and subjected to large and unknown changes. This conclusion, however, is misleading. The result in question follows when the integration of the equations of motion of the planet is only approximate, but a rigorous integration shows that commensurability of the kind in question does not lead to any instability. When Kirkwood made his investigation, only about 100 of these bodies were known, but a study of the 400 members of the group whose mean motions are fairly well determined shows the matter in another and more striking light. In the preceding table is shown the distribution of those members in zones of mean motion and mean distance.

A study of this table shows that what we see in the group are not gaps in an otherwise uniform series, but a tendency to cluster into zones, which are condensed near the middle of the regions between the lines of commensurability and thin out gradually towards those lines. For the most part there is no absolute dividing line between the zones, the number being merely less near the line of commensurability. This, however, is not the case with the two outer zones. In the region 3.24 to 3.34 no planets are yet known, while in the next zone, 0.18 in breadth, there are ten. Then follows a zone 0.36 in breadth, without any, outside of which there are five. That there is a causal connexion between this system of grouping and the lines of commensurability with Jupiter can scarcely be doubted, but, as already remarked, we cannot attribute the paucity of planets approaching to commensurability to any want of stability in their motion. One cannot but suspect that the phenomenon has a cosmogonical origin, and arose from the formation of zones of different degrees of density in the original revolving nebulous mass from which these bodies were formed.

The laws of secular variation of elements show that there is a certain mean plane around which the nodes of these bodies tend to be uniformly scattered, and a certain mean longitude towards which the perihelia tend (*Astronom. Nach.* lviii. S. 210). The position of the mean plane is: longitude of node, 91° ; inclination to elliptic, $1^\circ 3'$. The eccentricity and perihelion of the mean orbit are: eccentricity, 0.0321; longitude of perihelion, 3° . This last result does not imply that we have here the mean of all the eccentricities, but that the mean value of the $e \sin \pi$ and $e \cos \pi$ for all the orbits will be very near the products of the eccentricity just given into the sine and cosine of 3° . The result may be otherwise expressed by saying that the action of each planet tends to bring the mean plane of the orbits of the small planets into its own plane, and to elongate the orbits in the direction of its own aphelion. As Jupiter exerts the most powerful action on the minor planets, a tendency thus arises among the latter to coincidence of their nodes and perihelia with the node and perihelion of Jupiter.

The most notable addition to our recent knowledge of the Jovian system consists in the discovery of a minute additional satellite by Barnard in September 1892, with the 36-inch telescope of the Lick Observatory. It is much nearer the planet than the four previously known, and the only designation which it has thus far received is that of "fifth satellite," the order of distances of the satellites thus being the fifth, first, second, &c. As regards visibility it is one of the most difficult objects—perhaps the most difficult—in the solar system, and has been seen only with a few of the largest telescopes. Its mean synodic period of revolution is 11 h. 51 m. 27.635 s. It has been assiduously observed by its original discoverer, who finds a quite appreciable eccentricity in its orbit. From his observations, combined with a consideration of the theoretical effect of the ellipticity of Jupiter, its pericentre is found to revolve with a more rapid motion than that of any other known celestial body, making more than an entire revolution in a year. The four satellites formerly known have been found by Barnard and W. H. Pickering to exhibit singular anomalies of apparent form while in transit across the disc of Jupiter. The first sometimes appeared double on such occasions, although no such form had been seen at other times, and it became a question whether it could really consist of two bodies. After a careful study of the subject, Barnard reached the conclusion that the appear-

ance was due to a bright band around the equatorial region of the satellite, while the poles were of a darker tint, the varied shading of the belts of Jupiter on which it was seen projected during the transit resulting sometimes in only the polar regions being visible. Anomalies of form noticed in the other satellites have not been confirmed by the observations of Barnard (*Monthly Notices R. A. S.* liv. 1894, p. 134).

The ease with which the complex cloud-forms on Jupiter can be observed has led to a careful study of its surface by many observers. The British Astronomical Association has a special section devoted to this study. Although a great mass of observations has thus been collected, illustrative of the changes continually going on at the surface of the planet, it cannot be said that any radically new views respecting its constitution have been gained, nor that the observations have yet led to any researches that would throw much additional light on the subject. The most noteworthy phenomenon of late years has been the garnet spot which appeared in middle southern latitude in 1878. For ten years no great changes were noticed in it; then it gradually began to fade away. About 1892 it brightened up again, then again began to fade, and has been seen only occasionally and with difficulty since 1897. The most careful investigation of its motion has been made by Lohse, whose work embraced the entire period of visibility from 1878 to 1897. His most remarkable conclusion is that the period of revolution of the spot has been undergoing a fairly continuous change. For several years before and after 1891, it was 9 h. 55 m. 41 s. But if with this motion its position is computed back during previous years, it will be found to have wandered over more than two-thirds the circumference of the parallel on which it is situated. This result emphasizes the fact already known, that if Jupiter has any solid nucleus it is invisible to us; for had the spot in question been connected with such a nucleus, had it even been in the nature of an eruption from a volcano, its period of revolution would necessarily have been uniform. Granting—as seems to be unavoidable—that the visible surface of the planet is either liquid or gaseous, the persistence of the spot through twenty years is remarkable. The most plausible hypothesis is that it is in the nature of an island floating upon a liquid surface, but it does not seem at all probable that any formation floating in an atmosphere could have lasted through such an interval. Still, it is an open question whether the so-called belts of Jupiter indicate a liquid or gaseous condition of the visible surface. The great difficulty in the way of the liquid hypothesis is the very great difference in the times of rotation of the equatorial portions of the planet and the spots in middle latitudes. It is now found that while the latter, like the red spot, rotate in 9 h. 55 m. and a somewhat variable number of seconds, the equatorial markings make a revolution in about five minutes less time, or 9 h. 50 m. plus a varying number of seconds. In this respect Jupiter resembles the sun, whose rotation follows the same law. In the case of the planet, however, it is very remarkable that no intermediate times of rotation seem to have been well made out. Whether this arises from the fact that observers have not devoted to this subject the attention which it deserves, or whether the line between the two times of rotations is a narrow one, is a question which cannot yet be decisively answered. The important point is that the difference between the two times corresponds to a difference of about 7.5° in the motion round the planet during a terrestrial day. This corresponds to a linear motion on the surface of the planet of more than 30,000 miles per day, a motion which it seems difficult to reconcile with liquidity of the visible surface.

The view expressed in the ninth edition of this work, that Jupiter shines partly by its own light, has not been confirmed by later researches. The complete disappearance of the satellites, even in the most powerful telescopes, while in the shadow of Jupiter, shows that they cannot receive sufficient light from that planet to be visible, and the uniform darkness of the shadow of the satellite when seen on the planet, shows that the latter cannot be self-luminous. It is also to be remarked that, were it only moderately self-luminous, the colour of the light which it sends to us would be red, such light being that first emitted from a heated body when its temperature is raised. While it is quite possible that a small quantity of such light may reach us from the planet, no facts to prove it have yet been adduced.

In April 1898, the probable discovery of a ninth satellite of Saturn by W. H. Pickering was announced from the Harvard College Observatory. The new object was detected by means of four photographs of the region in the immediate neighbourhood of Saturn, taken on 16th, 17th, and 18th August 1898. A minute star was found on each of the plates, occupying a position which was vacant on the other plates. The object was of the fifteenth magnitude, and therefore so faint as to be invisible to the eye by any but the most powerful telescopes. Its position relative to Saturn could not be readily determined, because the long exposure necessary to bring out so faint an object resulted in the image of Saturn being completely "burned" out on the plates; in fact, the planet and rings appeared only as a large, dark, faintly-defined blotch of light, several times larger than the planet itself. Assuming that the object in question was a satellite of Saturn, it must be at some distance outside of all the other satellites, and its time of revolution must be several months. As the object does not seem to have been certainly detected at the following opposition, some doubt may yet exist as to its nature. The planet is now in a region rich in stars, and as so faint an object is easily lost among the hundreds which surround it, its detection is difficult.

The visible surface of Saturn bears a certain resemblance to that of Jupiter, but the markings are so much fainter that it is difficult, if not impossible, to locate and identify them with precision. There have been two notable exceptions to this rule. Sir William Herschel once saw a spot which lasted several weeks and enabled him to fix the time of rotation of the planet on its axis at 10 h. 16 m. The second case occurred in 1876. On 7th December of that year a bright white spot suddenly appeared in the equatorial region. It continued more than a month, gradually extending its dimensions in an east and west direction, so as to assume the form of a long streak, and at the same time growing fainter. From observations of the brighter portion, Professor A. Hall fixed the time of rotation at 10 h. 14 m. The question whether any markings ordinarily exist on the planet strong enough to be certainly located is an open one among the best observers. Cautious students of the subject will probably give most weight to the negative side. (See *Monthly Notices R. A. S.*, for observations and discussions, by Williams and Barnard.)

The most noteworthy addition to our knowledge of the rings of Saturn has been made by Keeler. That these appendages cannot be rings of continuous matter, either solid or liquid, has long been well established by theory, which showed that the equilibrium of such an object would necessarily be unstable. The alternative hypothesis that the rings are a cloud of minute satellites, or perhaps mere particles, too small to be individually visible, but so numerous as to look in our telescope like a continuous mass, was exhaustively investigated by J. Clerk Maxwell in his Adams prize essay published about 1860; but no direct evidence bearing on the question was obtainable until the spectro-

scope was brought into requisition. By the aid of this instrument in its present refined form, the motion of a body to or from the earth can be made evident by the change produced by the motion in the wave length of the spectral rays. The method is equally applicable whether the body is self-luminous or shines by the reflected light of the sun. By photographing the spectrum of Saturn and its rings when the image was thrown upon the narrow slit of a spectrograph, Keeler found that the lines across the spectrum were bent and broken in such a way as to show that the inner part of the rings revolved with greater velocity than the outer part, the motion of each part being that which would correspond to the motion of a satellite revolving at the same distance. The extreme thinness of the rings was demonstrated in a more striking manner than ever before by Barnard and others in 1892, during one of those rare times at which the plane of the ring passes between the earth and the sun. In such a case the sun shines on one surface of the ring, while only the opposite surface is turned towards us. Considering it as a cloud of satellites, each of the latter should in such a case be fully illuminated by the sun, except so far as it might be in the shadow of those outside of it. The outer satellites of all would necessarily be fully illuminated and also be visible to us if we had sufficient telescopic power, because there would be nothing to hide their light. Now, it is a singular fact that, in these circumstances, the ring was completely invisible, even with the 36-inch telescope of the Lick Observatory. This shows that the entire ring must be so thin that its edge is completely invisible, even in the full light of the sun, at the distance which separates us from the planet. On the other hand, the objects composing it must be completely opaque, as is shown not only by their disappearance in the circumstances we have mentioned, but by the darkness of the shadow which they cast upon the planet when the sun illuminates them obliquely. The cloud of satellites is so dense that a ray of light cannot penetrate the mass.

An interesting question still open is the nature of the so-called divisions of the rings. Are these divisions real or are they simply apparent, arising from a darker colour in the matter which composes them? In the case of the sharpest and best-known division, to which the name of Cassini has been given from its first observer, there would seem to be little doubt that the division is real. But there is some doubt in the case of the other divisions. It is now well established that the dusky or crape ring, which is on the inside of the brighter one, is really in the nature of an inner border of the bright ring, the one shading off imperceptibly into the other. While many excellent observers have sometimes thought they saw a complete separation between the bright and the crape rings, no such phenomenon has been seen in the great telescopes of our times, and it is almost certain that the dark colour of the crape ring arises merely from its tenuity and transparency. From Barnard's observation of the passage of Japetus through the shadow of Saturn and its rings it appears that the transparency gradually diminishes from the centre of this ring to its line of junction with the bright ring. If there should ever be a transit of Saturn centrally past a bright star, many questions as to the constitution of the rings might be settled by noting the times at which the star was seen through the divisions of the ring.

The great distance of Uranus and Neptune, and the faintness of their illumination by the sun, have as yet prevented our reaching any well-defined views as to their physical constitution. Micrometric measures seem to show that the globe of Uranus is slightly elliptical, like that of the other outer planets; this would indicate that the planet has a some-

*Saturn's
rings.*

*Uranian
and Nep-
tunian
systems.*

what rapid rotation. In the case of Neptune, although no well-marked ellipticity has been observed, it has been established in a satisfactory though intricate way. The plane of the orbit of the satellite is found to be in continuous motion, and the only cause to which this can be attributed is the ellipticity of the planet itself. The result of this cause would be that the axis of the orbital plane would perform a slow revolution around the axis of the planet. The observed motion is undoubtedly a revolution of this kind, but up to the present time the arc described has been so small that neither its radius nor its period can be determined.

Were the planets surrounded by comparatively dense atmospheres, especially atmospheres markedly different from that of the earth, that fact would be most easily made known by the spectroscope, since unknown substances in such an atmosphere would show absorption lines differing from those of the solar spectrum. A very dense atmosphere of the same general character as that of the earth would be indicated by a strengthening of the telluric lines. We remark in this connexion that the lines observed in the solar spectrum are of two classes—those which arise from the absorption of the gases surrounding the sun and those produced by our own atmosphere. The latter seem to be principally due to the aqueous vapour in the air. As the light which reaches us from a planet necessarily comes from the sun and passes through our atmosphere, we must expect to see all the lines of the solar spectrum in the spectrum of any planet, and the important question is whether any new lines or any changes in the strength of the known ones are also found. Studies with this end in view have been made by Huggins and Vogel. In the case of the planets Mercury, Venus, Mars, and Jupiter, the evidence of any well-marked modification of the solar spectrum does not seem conclusive. If, as appears from what has just been said, the inferior and denser regions of the atmospheres of these bodies are mostly filled with clouds and vapour, we should not expect to gain much evidence in this way. In the case of Mars and Jupiter, Vogel thought he detected an increased absorption in the red region. The general conclusion from the studies of these two investigators seems to be that, at least in the case of the three inner planets, there is no evidence of an atmosphere differing materially from that of the earth. In the spectrum of Jupiter, however, a line was found in the red of wave length 6178 which does not belong either to the sun's or the earth's atmosphere. Vogel remarks that it may be doubtful whether this line arises from some new and unknown substance in the atmosphere of Jupiter or simply from some combination with which we are not familiar. The case with Uranus and Neptune is different. The extreme faintness of the light from these planets renders it difficult to distinguish the Fraunhofer lines in their spectra, but a number of dark bands were found by Huggins, Keeler, and Vogel in the easily visible portion of the spectrum of Uranus. The following is a list of the bands on which the observers are substantially in agreement:—

Wave Length.

- 618. A broad band fading off towards the red.
- 596. A narrow faint band.
- 575. Darkest part of a broad band, extending from 578 to 565.
- 543. Middle of the darkest band.
- 486. A group of fine lines.

Vogel found a few faint bands above 486, and by photographing the spectrum from F into the ultra-violet Huggins was able to distinguish the stronger Fraunhofer lines. The spectrum of Neptune seems to be of the same general character as that of Uranus; but the bands are more difficult to see, owing to the extreme faintness of

the light. The inference to be drawn from these studies is that these two planets are surrounded by very deep, dense atmospheres, probably materially different in constitution from our own; but until we learn what combinations of known substances, if any, might be adequate to produce such bands as those just described, it is impossible to reach any conclusion as to the nature of those atmospheres.

While the photometry of the fixed stars has, in recent years, been placed on a definite scientific basis, the same can scarcely be said of that of the bodies of the solar system. This is owing largely to the difficulty, if not the impossibility, of establishing general laws as to the proportion of light reflected from bodies at various angles of incidence and reflection. We must, therefore, confine ourselves to a statement of the apparent magnitude of the principal bodies of the solar system under mean conditions. A fundamental datum of the subject is an expression for the quantity of light received from the sun as compared with that from a fixed star of given magnitude, a result which is best expressed in the form of a stellar magnitude of the sun. The results of attempts to fix this datum are so discordant that entire confidence cannot be felt in any of them. To express it as a stellar magnitude of the sun we remark that, on the photometric scale now adopted, an increase of a hundredfold in the quantity of light corresponds to a drop of 5 units of stellar magnitude in the body emitting the light. In general, a change of n stellar magnitudes is equivalent to a multiplication or division of the amount of light by $10^{0.4n}$, a number whose common logarithm is 0.4 n . The best results for the stellar magnitude of the sun as thus defined seem to be -26.6 (Wollaston), -25.8 (Bond), and -26.6 (Zöllner). Giving Zöllner's result double weight, we have the stellar magnitude of sun = -26.4 .

The two best determinations of the ratio of sunlight to that of the full moon seem to be those of Bond and Zöllner, which are 470980 and 619000 respectively. Müller (*Photométrie der Gestirne*) estimates the best mean result to be 569500.

For the stellar magnitudes of the planets and satellites, we have room only to state what seem to be the best mean results. In the case of Mercury and Venus, the variations are so great that definite results cannot be given.

For details respecting the new comets, especially periodic ones, which have been discovered since 1880, reference may be made to the article on that subject; what we are here concerned with is the general question of the origin and constitution of these bodies. A striking confirmation of the view that the comets of short period from time to time become members of our system through the action of one of the larger planets, nearly always Jupiter, is afforded by the case of Comet V. of 1889, discovered by Brooks on 6th July of that year. It was soon found to be moving in an orbit with a period of about eight years, and when its motions were traced back it was ascertained to have passed very near the planet Jupiter in June and July 1886. Attempts to compute its orbit previous to this approach were made by Chandler and Poor. The

former, from a preliminary investigation, reached the conclusion that the comet was probably identical with that of Lexell, which had been thrown into some new and unknown orbit by the action of Jupiter more than a century ago. Poor's inquiry, however, which was made on more complete data, seemed to show that this view is untenable and that the comet had never before been seen. As to the origin of comets, the most important development has been the establishment of the general fact that they belong to the solar system, and are not stray wanderers through space, as was formerly thought possible. Were the latter the case, they would not partake of the motion of the solar system through space. Consequently, as the sun pursued its journey more comets would be found coming from the direction of its motion than from the opposite direction. Those which did come from the former direction would in general move in decidedly hyperbolic orbits. Now we may regard it as established that no comet moves in such an orbit. It is true that some of the computed orbits have a hyperbolic character, this being shown by the eccentricity coming out slightly greater than unity; but the excess, even in these exceptional cases, is always so small that we can only regard it as the result of accidental errors of observation on such ill-defined bodies. The fact being accepted that these bodies, before their observed entry into our system, were accompanying the sun on its journey through space, we are led to the following very probable conclusions:—All comets are to be regarded as having been in the beginning outlying nebulous masses, belonging to the same mass of matter as that which formed the solar system, and moving with it, but mostly at such great distances from the sun that their periods of revolution would be measured by tens or even hundreds of thousands of years. Were it not for the effect of planetary attraction long periods like these would be the general rule, though not necessarily universal. But at every return to perihelion a comet will be to some extent either accelerated or retarded in its movements by the action of Jupiter or any other planet in the neighbourhood of which it may pass. Commonly the action will be so slight as to have little influence on the orbit and the time of revolution. But should the comet chance to pass the orbit of Jupiter just in front of the planet, its motion would be retarded and the orbit would be changed into one of shorter period. Should it pass behind the planet, its motion would be accelerated and its period lengthened. In such cases the orbit might be changed to a hyperbola, and then the comet would never return. It follows that there is a tendency towards a gradual but constant diminution in the total number of comets. If we call Δ the amount by which the eccentricity of a cometary orbit is less than unity, Δ will be an extremely minute fraction in the case of the original orbits. If we call $\pm \delta e$ the change which the eccentricity $1 - \Delta$ undergoes by the action of the planets during the passage of the comet through our system, it will leave that system with the eccentricity $1 - \Delta \pm \delta e$. The possibilities are even whether δe shall be positive or negative. If negative, the eccentricity will be diminished and the period shortened. If positive, the minuteness of Δ may result in the eccentricity $1 - \Delta + \delta e$ being greater than unity, and then the comet will become for ever a wanderer through the stellar spaces.

Another discovery is that of the possibility of groups of comets moving in nearly the same orbit. It was formerly thought that only by a very improbable chance would two of these bodies be found describing the same orbit at a long interval of time, and, if an instance was noticed in which such appeared to be the case, it was supposed that what was observed on the second occasion

was a return of the former comet. In February 1880 a brilliant comet which was suddenly observed in the southern hemisphere was found to be moving in an orbit so nearly identical with that of the great comet of 1843 that no doubt of a relationship could be felt. Yet so slight could have been the deviation from a parabolic orbit in either case that the hypothesis of identity of the two bodies did not seem tenable. The question of possible identity was set at rest by the appearance of a third comet in the autumn of 1882 again describing nearly the same orbit. It now seems likely that these three bodies were parts of one original nebulous mass, situated far beyond the confines of our system, which gradually separated from each other in the course of successive revolutions round the sun.

The question whether the motions of Encke's comet are affected by a resisting medium is not yet conclusively settled. The careful and exhaustive researches of von Asten and Backlund seem to show that resistance is met with during some revolutions and not during others. This would scarcely be the case with a resisting medium, as this agency would always be present if it existed at all. Quite possibly the effect may be due to imperfections in the computation of the perturbations.

There is perhaps no celestial object on which observations are so much wanted as on the zodiacal light. Up to the present time the conclusions which can be definitely stated are somewhat general in their nature. The sun is surrounded by an exceedingly rare cloud of matter of very indefinite outline, lenticular in form, extending out somewhat beyond the orbit of the earth. This matter shines only by reflected sunlight, a conclusion which, probable enough in itself, is strengthened by the spectroscopic studies of A. W. Wright, who found the spectrum to be continuous. In northern latitudes, this object can best be seen in the evenings of February and March and in the mornings of September and October. Observations made in the evening seem to show that the central axis of the apparent light is one or two degrees north of the plane of the ecliptic, and this would point to a slight inclination of the median plane of the whole mass to that of the ecliptic. But it is impossible to reach any definite conclusion as to the position of that plane until the apparent axis of the light among the stars has been carefully delineated night after night through an entire year by an observer in a very clear atmosphere within the tropics. It needs only a glance at the figure of the apparent light in the neighbourhood of the horizon when it can first be seen, about the close of twilight, to show that its breadth at the horizon is very considerable, probably 40 degrees. Continuing the outline around the sun it seems probable that its visible border is nowhere less than 25 or 30 degrees from the sun. It follows that an observer stationed at a high elevation, in a very clear atmosphere, in such a position that the sun should be about 20 degrees below his horizon at midnight, should see this portion of the light as a faint glow in the northern horizon.

The existence of the mysterious counter glow, or *Gegenschein*, as it is commonly called, is now fully established. It is a patch of light in the ecliptic opposite the sun, so faint and indistinct in outline that it can be seen only under the most favourable conditions, including absence of moonlight and a considerable elevation above the horizon. It is invisible when projected on the Milky Way. Barnard has observed it to be larger and more diffused in the autumn than in the spring. No well-marked deviation from the ecliptic or from the point directly opposite the sun in longitude has been detected. The phenomenon has sometimes been supposed to be

associated with the zodiacal light, which, on rare occasions and under the most favourable conditions, some observers have thought could be traced near midnight all the way across the heavens, forming a complete arch from east to west. In that case the *Gegenschein* would be a small patch in this zodiacal arch, slightly brighter than elsewhere. Of the various explanations which have been propounded no one can be considered as sufficiently probable to merit acceptance. An ingenious suggestion, and one which it is equally difficult to prove or disprove, is that it is composed of nebulous matter thrown off from the earth, forming a tail to the latter like that of a comet. The quantity of such matter necessary to produce the phenomenon would be minute in the last degree. Similar appendages, if carried by the planets, would be entirely invisible to us, and that of our earth would be visible only because we see through it endways and on a dark sky.

Intimately associated with this subject is the question of the conditions necessary to the permanence of an atmosphere round a planet. Dr Johnstone Stoney

**Planetary
atmo-
spheres.**

has recently investigated these conditions, taking as the basis of his work the kinetic theory of gases (*Trans. Roy. Dubl. Soc.* vi. p. 305).

On this theory every molecule of a gaseous mass is completely disconnected from every other and is in rapid motion, its velocity, which may amount to one or more thousand feet per second, depending on the temperature and on the atomic weight of the gas. At any temperature the velocities of individual molecules may now and then increase without any well-defined limit. If at the boundary of an atmosphere the velocity should exceed a certain limit fixed by the mass and force of gravity of the planet, molecules might fly away through space as independent bodies. The absence of hydrogen from the atmosphere of the earth, and of an atmosphere from the moon, may be thus explained. If the fundamental hypotheses of Dr Stoney's investigations are correct and complete, it would follow that neither the satellites and minor planets of the solar system nor Mercury can have any atmosphere. If the separate molecules thus flying away moved according to the laws which would govern an ordinary body, they would, after leaving their respective planets, move round the sun in independent orbits. The possibility is thus suggested that the matter producing the zodiacal light may be an agglomeration of gaseous molecules moving round the sun; but several questions respecting the intimate constitution of matter will have to be settled before any definite conclusions on this point can be reached. It is not to be assumed that a molecule would move through the ether without resistance as the minutest known body does, and there is probably a radical difference between the minutest particle of meteoric matter and the molecule of a gas. The relations of identity or difference between such finely-divided matter as smoke and atmospheric haze and a true gas have yet to be fully established, and until this is done a definite and satisfactory theory of the subject does not seem possible.

II. GRAVITATIONAL AND THEORETICAL ASTRONOMY.

The fundamental hypothesis of modern theoretical astronomy is that the motion of each heavenly body is determined entirely by the gravitation of other bodies. Assuming such to be the case, it will be possible to predict the celestial motions with entire precision, if certain fundamental data are given. Such data would be the mass of each body, and its position, velocity, and direction of motion at some given instant. The problem would then be the construction of general formulæ by which the position of each body at any moment whatever could be expressed in terms of the time. In practice we

do not use as fundamental data positions and velocities, but the elements of the orbits, including mean distance, eccentricities, position of orbit in space, mean position of the planet at a given moment, and other quantities which do not vary with the time. When the differential equations expressing in a general way the effects of gravitation are integrated, the elements appear in the solution as arbitrary constants, to which values may be assigned at pleasure. The astronomer has then to assign such values that the observed positions of the bodies, whether planets or satellites, shall be accurately represented by the formulæ. The mathematical processes by which the equations are integrated, values assigned to the elements, and the results compared with observation, are perhaps the most difficult and most complicated with which the mathematical astronomer has to deal, and only in comparatively simple cases can he be sure that the minute deviations of the actual movement of a body from his predictions do not arise either from errors in his process or from errors of observation. The equations of motion can be integrated only in the form of an infinite series of complex terms of which all below a certain magnitude have to be dropped, and the difficulty is to be sure that no terms are omitted which could have a sensible value. Generally, it is possible to secure the necessary precision, but in some cases the question whether every possible term which could affect the result has been included may be an open one. One of the most interesting problems of the astronomer at present is whether the motions of the heavenly bodies, as determined by our most refined methods of observation, go on in rigorous accordance with the law of gravitation. This question cannot be settled by a mere comparison of the predicted motion with observations. When differences are found, the question will arise whether they may not be due to errors either in the fundamental elements or in the theoretical computations; in several instances supposed deviations have been found due to the latter cause. One notable case in history is that of the motion of the moon's perigee. This motion was found to be twice as great as was at first supposed to be due to the Newtonian theory, but Clairaut showed that when more rigorous methods were adopted the observed motion was represented. The general rule has been that, whenever an observed deviation has been well made out, it has been traced to the omission of some term of the algebraic formulæ expressing the motion of a planet. To this rule there are two notable exceptions:—

**Apparent
deviations
from the
law of
gravita-
tion.**

(a) In 1845 Leverrier found that the centennial motion of the perihelion of Mercury derived from observation was greater by 35" than it should be from the gravitation of the other planets, and his result has been more than confirmed by subsequent investigations, the most recent discussion of observations showing the excess of motion to be 43" per century. In this case there can be no question as to the correctness of the theoretical result, since the computation of the secular motion of the perihelion is a comparatively simple process. It follows that either Mercury must be acted upon by some unknown body or the theory of gravitation needs modification. The most natural explanation, and that offered by Leverrier, attributes the discrepancy to the action of a group of intra-Mercurial planets. For some time, therefore, careful search was made for these planets. One or more has been thought from time to time to be detected, but every observation of the kind has been disproved by critical examination. The simplest and surest method of discovery is afforded by the consideration that these bodies, if they exist, must

**Motions
of the
planetary
perihelia.**

from time to time pass between us and the sun, and therefore be visible as minute points on the disc of that body. But nothing of the sort has been brought to light by the photographs of the sun which have been constantly taken in recent years, nor by the observers who, during the last half century, have so assiduously watched the sun for spots. There is another difficulty in the way of accepting this explanation. A mass of bodies sufficiently large to produce the observed motion of the perihelion of Mercury would affect both the other elements of Mercury's orbit and the motions of Venus, but it is shown by the most refined discussions of the observations that these effects are not produced. The most recent surmise on the subject is that the law of gravitation may not act exactly according to the inverse square. A very simple hypothesis propounded by Professor Asaph Hall is that in the expression for the mutual gravitation of two bodies of masses m and m' , which, according to the Newtonian law is of the form $\frac{m m'}{r^2}$, the exponent 2 should be increased

by a very minute fraction. The value of the exponent which would produce the observed effect is 2.000 000 1612, so that the discrepancy is removed if we suppose

the attraction to be of the form $\frac{m m'}{r^{2.000\ 000\ 1612}}$. The effect

of this modification would be insensible except in the motion of the pericentres of the heavenly bodies. The only cases in which it could be made evident by the century and a half of observations yet made are those of Mercury, the moon, and Mars. The Perihelion of Mars does actually seem to be affected by the corresponding increase, which is about $5''\cdot45$ per century; but this excess, though made very probable by the observations, is too minute to be conclusively established. In the case of the moon's perigee the increase of motion would be $150''$ per century, a quantity too large to escape observation; but unfortunately the theoretical determination of this motion has not yet been made with such precision that it may not be affected by an error of this amount. The most refined determination is that recently made by Professor E. W. Brown, which does show a discrepancy of nearly the required amount; but the difficulties of the determination are such that a conclusive result has yet to be reached.

We may sum up our conclusions on this point by saying that the discrepancy in the case of the perihelion of Mercury is well established, and that there is some reason to believe it a general rule that the motions of the pericentres of the moon and planets are somewhat greater than the gravitation of other bodies is competent to produce. Furthermore, it may be said that the simplest way of explaining the excess of motion is to assume that gravitation increases at a minutely greater rate than the inverse square. Many other modifications of the Newtonian law have been suggested, especially some of a form analogous to that of electro-magnetic action, but none of these consistently represent all the phenomena.

(b) The other exception to which we allude occurs in the apparent mean motion of the moon around the earth, which has now been observed with an approach to modern precision since the year 1675, and with less than modern precision from 1625 to 1675. We have also eclipses of the sun and moon recorded by Ptolemy in the *Almagest*, or observed by the mediæval astronomers, by which the mean longitude of the moon may be followed for more than 2500 years. No amount of research has yet reconciled the results of these observations with gravitational theory. To make clear the existing state of the question, we remark that the inequalities in the motion of the moon are of two classes—those produced by the action of the sun,

which are always of comparatively short period, and those produced by the action of the planets, which in exceptional cases are of long period. If, in a period of twenty, thirty, or fifty years, the moon is found to be, in the general average, ahead of her computed place, or behind it, we may say with certainty that the deviation is not due to the action of the sun, because all the effects of this action would be compensated within eighteen years. It has been known for a century that deviations of this character, which are called deviations of long period, really exist in the motion of our satellite. In the middle of the 19th century Hansen announced that he had discovered two inequalities produced by the action of Venus, which completely reconciled these deviations. The theoretical computation of one of these inequalities has been repeated by several investigators since Hansen, and his result confirmed; but it has been shown that the other inequality has no existence in theory, and that it was the result of imperfections in the method employed by its discoverer. If any doubt could arise as to this conclusion, it is set at rest by the discovery that Hansen was in error in supposing that his two inequalities, singly or combined, would represent the observed deviations. Since 1870 the action of the planets on the moon has been exhaustively treated by several investigators with the special object of deciding whether their gravitation could produce any inequality of long period other than that of Hansen, but without result. The impossibility of any such inequality seems to be as well established as any proposition can be that relates to so complicated a subject. Another possible cause of apparent inequalities is to be examined, namely, variations in the earth's axial rotation. What we actually observe is not the absolute motion of the moon, but the relation of this motion to the rotation of the earth on its axis, on which we necessarily depend for our measure of time. Let us now suppose this time of rotation to be increased by a very minute amount. Then the day will be longer by this amount. The motion of the moon in one day will then seem to be greater than it was, though in fact there has been no real change in it. If the rate of rotation is accelerated the opposite effect is produced, the day is shorter, the moon does not move so far in a day, and so seems to be retarded. The discrepancies in question can be explained by variations always less than a second in a year, which, however, accumulate year after year, so that before the end of half a century they might amount to twenty or thirty seconds of time.

A decision between these two causes can be reached only by observations on other bodies. In general, the celestial motions go on so slowly that their amount during so brief an interval as twenty seconds cannot be certainly detected. Only the moon, the planet Mercury, and Jupiter's satellites move so rapidly that an accumulated error of this amount in our measure of time might be brought to light by them. In the case of Jupiter's satellites we have to depend on the time of their eclipses, and the observations of these phenomena are so far from accurate that no conclusive result has yet been derived from them. But transits of Mercury over the sun's disc have been observed with greater or less accuracy since 1677. The present state of the question is presented in the following tables. The first column gives the mean dates of eclipses or other observations of the moon, and the second the mean excess of her observed mean longitude over that computed from the theory of her motion about these dates. In the third column this excess is given in time, and shows how far we must suppose the actual earth to be in advance of a uniformly revolving earth in order to account for the apparent excess.

Test by transits of Mercury.

The moon's mean motion.

I. *Ancient Eclipses.*

Year.	Deviation of longitude.	Time in advance.
		m.
B.C. 687	+ 41.0	-76
B.C. 381	+ 12.1	-22
B.C. 189	+ 11.6	-21
A.D. 134	+ 5.2	-9
846	+ 0.9	-2
926	+ 3.1	-6
986	+ 0.4	+1

II. *Modern Observations.*

	"	s.
1625	+ 15.7	-26
1650	+ 1.0	-2
1675	0.0	0
1700	+ 3.7	-7
1725	+ 7.2	-13
1750	+ 14.5	-26
1775	+ 21.5	-39
1800	+ 21.2	-38
1825	+ 19.7	-36
1850	+ 9.0	-16
1875	0.0	0
1900	- 6.7	+12

These numbers show that either the moon was moving more slowly, or the earth rotating more rapidly, through the whole 19th century, than during the period 1675 to 1775. To decide which was the case we must have recourse to transits of Mercury. The following table shows the excess of the observed times of the ingress and egress of Mercury in November transits over the sun's disc from 1677 to 1894. May transits are omitted, because they were not observed at the earlier dates. The last column gives the weights of the observations.

	Seconds.	Weight.
1666 I	- 47	0.1
" E	+ 26	0.1
1697 E	- 25	0.2
1728 I	- 8	2.5
1736 I	- 9	0.6
" ₃₆ E	+ 1	0.6
1743 I	0	1.5
" E	- 3	4.5
1769 I	- 7	2.5
" E	- 1	0.5
1789 I	+ 10	3.5
" E	+ 6	2.5
1802 I	+ 4	6.0
1822 I	+ 11	0.4
" E	- 7	2.5
1848 I	+ 7	6.0
" E	+ 7	0.5
1861 I	+ 12	2.0
" E	+ 11	4.0
1868 I	+ 2	0.6
" E	- 5	4.0
1881 I	- 6	6.0
" E	- 2	6.0
1894 I	- 6	6.0
" E	+ 2	6.0

On the theory that the apparent variations in the motion of the moon really arise from changes in the earth's rotation, the numbers of this table should, in a general way, correspond to those in the last column of the table preceding. Evidently such is not the case, since, if we take the weighted means of the deviations during the three periods 1677-1743, 1769-1822, 1861-1894, the results are:—

Mean date	1737	1795	1880	Sec.
$\Delta + =$	-4.5	+2.4	+0.6	

We are therefore led to the conclusion that either the motion of the moon is affected by some other cause than the gravitation of other bodies, or mathematicians have not yet succeeded in rigorously computing the effect of this gravitation.

Fundamental Astronomical Constants.

The term *constant* is used in astronomy in a relative sense, most of the quantities thus designated being really subject to variation. The term is applied because the variations of these quantities are so slow that the quantities may be regarded as constant for the periods of time over which computations usually extend. Some of these constants, especially those which relate to the motions of the earth and moon, are intimately related to the first principles of gravitational astronomy. We shall develop the fundamental principles of the subject, and show how, by means of them, the values of the constants may be derived.

We begin by defining the units of those physical quantities which enter into astronomy. It will be remarked that in physics three units are regarded as fundamental or arbitrary, while all others are *Units of measure* derived from them by definition. These fundamental units are those of length, mass, and time. In the system now most widely adopted for physical investigation—that known as the C.G.S. system—the centimetre is taken as the unit of length, the gramme as that of mass, and the second as that of time. The same fundamental units of length and time may be introduced in astronomy, but it will be more convenient to take the metre as the unit of length. The passage from the metre to the centimetre, and *vice versa*, is too simple to require discussion. The second may be taken as the unit of time for our present purpose; but it is more convenient to take the unit of mass as a derived one. The astronomical units will then be as follows:—

The units of time and length are arbitrary, the second and the metre being chosen unless otherwise expressed.

Unit velocity is that which carries a point over unit space in unit time.

The unit of mass is that the gravitation of which acting on an equal mass at distance unity would generate a unit of velocity in a unit of time.

The unit of force is that which would generate a unit of velocity by acting on unit mass during a unit of time.

To distinguish the preceding unit of mass from that of physics it is called the *gravitational unit*.

The physical unit of length, metre or centimetre, can be used in astronomy only to derive the values of certain astronomical constants, because, in practice, it is too short to use in expressing celestial distances. But by the use of logarithms we may extend our physical measures over the celestial spaces without the use of unmanageably large numbers. Yet, in any case, the relations between the terrestrial measure and the distance of the earth from the sun must always remain more or less doubtful. Hence it is necessary to adhere to the usual astronomical unit, namely, the mean distance of the sun, in expressing distances among all the heavenly bodies except the moon.

The relation between the arbitrary physical unit of mass, the gramme for example, and the gravitational unit, is a fundamental problem of physics. To ascertain it we must measure the gravitation exercised by a known mass at a known distance.

This will give us the attraction of a physical unit of mass at unit distance, a quantity known as the Newtonian constant of gravitation. Those older methods of determining this constant which rest upon the observed attraction of great masses of matter—mountains, for example—or upon the increase in the force of gravity found on descending into mines, are now entirely superseded, owing to the uncertainty as to the density and arrangement of the masses whose action is measured. Recent determinations depend entirely upon the attraction of portable masses, such as spheres or blocks of lead. It

Gravitational constant.

is impossible within the space of the present article to describe in detail the methods by which these determinations have been made. There is probably no other physical experiment involving so many difficulties or requiring attention to such a multitude of minute details. Speaking in a general way, three methods have been applied in recent times. In the first, use is made of the torsion balance, consisting of a light rod suspended by its centre and carrying a ball at each end, which is attracted by leaden masses. This is known as the Cavendish experiment. The apparatus was described in the article on ASTRONOMY in our ninth edition. The apparatus for the application of the second method is a pendulum suspended very slightly above its centre of gravity. This method is new, having so far only been employed by Wilsing of Potsdam. The third method, which is also new, consists in determining the changes in the weight of bodies produced by the attraction of the leaden masses. In the application of this method a change of weight of the small fraction of a millionth part is not only to be made evident, but actually measured; yet it has been successfully carried out by Poynting at the Cavendish Physical Laboratory, Cambridge. Two determinations by this method have also been made in Germany, one by Jolly and the other by Richarz and Krigar-Menzel.

Notwithstanding the extraordinary delicacy of Poynting's work, the torsion balance seems better adapted to the purpose, owing to the horizontal direction of the minute force measured. The results reached by Mr C. V. Boys, F.R.S., at the Clarendon Physical Laboratory, Oxford, and Dr Carl Braun, S.J., at Mariaschein, Bohemia, are wonderfully accordant as well as self-consistent. Defining the gravitational constant as the attraction in C.G.S. units of one gramme of matter at one centimetre distance, they are :—

Boys : G.C. = 6.65760 + 10⁸
 Braun = 6.65786 + 10⁸

As to accuracy, Boys conceives that his factor 6.6576 cannot be more than 0.001, or at the outside 0.002, in error, while Braun estimates his probable error at ±0.00168. The agreement of the two results is much closer than we should expect from these probable errors, which we may regard as practically equal. The mean result—

$$6.65773 \pm 10^8$$

may therefore be accepted as the last word on the subject. From this may be derived the mean density of the earth by a process which we shall include in a general determination of the astronomical constants which pertain to the mass figure and dimensions of the earth.

The latest complete investigation of the dimensions and figure in question is that of Clarke, to be found in the *Ency. Brit.*, ninth edition, article EARTH, FIGURE OF. With his numbers we give, for comparison, those of Bessel, which are still to a certain extent in use :—

	Clarke.	Bessel.	C-B.
Polar axis	6356515 m.	6356079 m.	+436
Equatorial axis	6378249 m.	6377397 m.	+852
Ellipticity	1 + 293.46	1 + 299.15	

According to Helmert, the most recent measures of arcs in Europe and Asia indicate a diminution of Clarke's ellipticity to Bessel's value, but tend to confirm his larger value of the equatorial semi-axis. The datum which we need for the solution of our problem is the attraction which the earth would exert on a point at its surface if it were a perfect sphere composed of spherical layers of equal density. In deriving this quantity a theorem in the attraction of spheroids is introduced by which the force in question is found to be approximately equal to that of the actual earth at a point

the sine of whose geocentric latitude is $\frac{1}{\sqrt{3}}$. For this point we have—

Geocentric latitude = 35° 15' 52"
 Geographical latitude = 35° 26' 43"

The geometric mean of Clarke's three axes is 6370997 metres.

His radius at geocentric latitude ϕ' is
 $\rho = 6367368 \text{ m.} + 10868 \text{ m.} \cos 2\phi' + 14 \text{ m.} \cos 4\phi'.$

For $\sin \phi' = \frac{1}{\sqrt{3}}$ we then have

$$\rho = 6370980.$$

Helmert's general discussion of the length of the seconds pendulum gives for its value in terms of the geographical latitude ϕ ,
 $L = 0.990918 \text{ m.} (1 + 0.005310 \sin^2 \phi).$

This multiplied by π^2 gives for the intensity of gravity
 $g = 9.77997 \text{ m.} (1 + 0.005310 \sin^2 \phi).$

This is the earth's attraction diminished by the vertical component of the centrifugal force, of which the value is
 $0.03392 \rho \cos \phi' \cos \phi.$

This expression for the force of gravity gives for the actual attraction of the earth at the parallel of 35° 26' 43'
 $9.79743 \text{ m.} + 0.2253 \text{ m.} = 9.81996 \text{ m.,}$

which may be taken as the attraction of the whole mass of the earth, if concentrated at its centre or reduced to a sphere, upon a body at distance 6370980 metres. Taking the metre as the unit of length, we have for the mass of the earth in the astronomical units already defined 9.81996×6370980^2 , which gives for the total mass of the earth in gravitational measure:

$$\text{Logarithm of the earth's mass} = 14.600522.$$

If, instead of the metre, we take the centimetre as the unit, we have—

$$\text{Logarithm of the earth's mass} = 20.600522.$$

In other words, this is the logarithm of the gravitation of the earth's mass at 1 centimetre distance expressed in C.G.S. units. The corresponding attraction of 1 gramme of matter being the number already stated, of which the logarithm is 8.823326, it follows that the logarithm of the earth's mass in grammes is

$$20.600522 - 8.823326 = 27.777196.$$

Clarke's dimensions give for the logarithm of its volume 27.034711. It follows that we have—

$$\text{Logarithm of earth's density} = 0.742485,$$

whence density of earth = 5.5270.

This conclusion as to density supposes the whole mass included in the geoid. It will be diminished by allowing for the elevation of the continents, and increased if the ocean be excluded from the matter taken into account.

Some of the results for the density found by the other methods are as follows :—

	Method of Weighing.	D =
Poynting		5.4934
Jolly		5.69
Richarz and Menzel		5.505
Method of Pendulum.		
Wilsing		5.579

One of the most important astronomical applications of the preceding results is the determination of the mean distance of the moon from the earth. Knowing the masses m and m' of the earth and moon, and the mean motion n of the latter in one second, its mean distance a follows at once from the well-known equation of the elliptic motion,

$$a^3 = \frac{m + m'}{n^2} = \frac{m(1 + \mu)}{n^2}$$

μ being the ratio of the masses. In one second of mean time the moon moves through an arc whose logarithm is 4.425159 - 10. We shall presently find $\mu = 1 + 81.65$, and have just given the value of $\log. m$ from the seconds pendulum. We then find from the above equation $\log. a$ in metres = 8.585164

whence $a = 384737$ kilometres.

The motion of the moon is so affected by the action of the sun that this number does not rigorously represent the actual mean distance of the moon. Moreover, what is used in astronomical practice is the horizontal parallax of the moon.

Gravitational theory shows that the constant of this quantity which we call π_0 , is connected with the above value of a by the relation
 $\sin \pi_0 = 1.000907 \frac{a^2}{\rho^2}$

ρ being the diameter of the earth. Using Clarke's equatorial diameter we find :—

Equatorial horizontal parallax of the moon = 57' 2.76". This result is in good agreement with that of direct observations.

It is interesting to remark that if we regard the dimensions of the earth as unknown, observations of the seconds pendulum, combined with measures of the moon's parallax, would enable us to determine them. The form of the equations we have used to determine the earth's mass and the moon's distance show that, if we express the earth's radius in terms of the moon's parallax, it will come out in the form

$$\rho = k \sin^3 \pi_0,$$

Parallax of the moon.

k being a numerical constant. It follows from this form that the ratio of error in π_0 would be multiplied three times in the resulting value of ρ . As a matter of fact we can determine ρ with greater proportional precision than the parallax, so that the logical course is to determine π_0 from ρ rather than the reverse.

The fundamental gravitational relations on which the motions of precession and nutation depend may be stated as follows:—We put P, P' = the portions of the lunisolar precession in a Junian year, due to the action of the moon and the sun respectively, N = the constant of nutation, μ = the ratio of the mass of the moon to that of the earth, $\mu' = \frac{\mu}{1+\mu}$, A, C = the equatorial and polar moments of inertia of the earth, $q = \frac{C-A}{C}$, a quantity which may be called the mechanical ellipticity of the earth, and ϵ = the obliquity of the ecliptic.

The theory of the moon's motion and of its action on the earth gives the following equations:—

$$\left. \begin{aligned} N &= [5.40289] \mu' q \cos \epsilon \\ P &= [5.975052] \mu' q \cos \epsilon \\ P' &= [3.72509] q \cos \epsilon \end{aligned} \right\} (1)$$

In these expressions q and μ' are absolute constants to be determined, while ϵ varies slowly, but is known. The values of N and of $P+P'$ are given by observation. At a conference of the directors of four national astronomical ephemerides, held at Paris in 1896, it was decided to adopt

$$N = 9.210''$$

By a discussion undertaken at the request of the same conference it was found that, for the epoch 1900,

$$P + P' = 50.3722'' \quad (2)$$

For the same epoch the obliquity is

$$\epsilon = 23^\circ 27' 8.26''$$

With these numerical values the equations (1) and (2) are four in number, which suffice to determine $\mu', q, P,$ and P' for 1900.

The solution gives the following results:—

	Julian Year.	Solar Year.
Lunar precession for 1900	34.3877''	34.3870''
Solar " " "	15.9842''	15.9838''
Lunisolar " " "	50.3719''	50.3708''

$$q = \frac{C-A}{C} = 0.0032813$$

Mass of moon \div mass of earth = $1 \div 81.65$.

Recent research enables us to compute the obliquity of the ecliptic at past and future epochs with an error not exceeding $1''$ per century elapsed. The result is shown in the following table:—

Obliquity of ecliptic.

Year. B.C.	Obliquity.	Year. A.D.	Obliquity.
3000	24 1 16.5	0	23 41 42.4
2900	24 0 44.1	100	23 40 57.9
2800	24 0 11.1	200	23 40 13.1
2700	23 59 37.5	300	23 39 28.1
2600	23 59 3.5	400	23 38 42.8
2500	23 58 28.9	500	23 37 57.4
2400	23 57 53.7	600	23 37 11.8
2300	23 57 18.1	700	23 36 26.1
2200	23 56 41.9	800	23 35 40.2
2100	23 56 5.3	900	23 34 54.1
2000	23 55 28.2	1000	23 34 7.9
1900	23 54 50.6	1100	23 33 21.6
1800	23 54 12.5	1200	23 32 35.2
1700	23 53 34.0	1300	23 31 48.7
1600	23 52 55.1	1400	23 31 2.1
1500	23 52 15.8	1500	23 30 15.42
1400	23 51 36.0	1600	23 29 28.69
1300	23 50 55.9	1700	23 28 41.91
1200	23 50 15.3	1800	23 27 55.10
1100	23 49 34.4	1900	23 27 8.26
1000	23 48 53.1	2000	23 26 21.41
900	23 48 11.4	2100	23 25 34.56
800	23 47 29.4	2200	23 24 47.73
700	23 46 47.1	2300	23 24 0.91
600	23 46 4.4	2400	23 23 14.13
500	23 45 21.5	2500	23 22 27.40
400	23 44 38.2	2600	23 21 40.73
300	23 43 54.7	2700	23 20 54.13
200	23 43 10.9	2800	23 20 7.61
100	23 42 26.8	2900	23 19 21.19
0	23 41 42.4	3000	23 18 34.87

The obliquity was at a maximum about 7200 B.C., or 9100 years ago, when its value was $24^\circ 13'$. It will reach a minimum about 9600 years hence, when its value will probably be between $22^\circ 30'$ and $22^\circ 40'$, but cannot be more exactly stated.

The Solar Parallax.

The problem of the distance of the sun has always been regarded as the fundamental one of celestial measurement. The difficulties in the way of solving it are very great, and up to the present time the best authorities are not agreed as to the result, the effect of half a century of research having been merely to reduce the uncertainty within continually narrower limits. The mutations of opinion on the subject during the last fifty years have been remarkable. Up to about the middle of the 19th century it was supposed that transits of Venus across the disc of the sun afforded the most trustworthy method of making the determination in question; and when Encke in 1824 published his classic discussion of the transits of 1761 and 1769, it was supposed that we must wait until the transits of 1874 and 1882 had been observed and discussed before any further light would be thrown on the subject. The parallax $8.5776''$ found by Encke was therefore accepted without question for several decades. Doubt was first thrown on the accuracy of this number by an announcement from Hansen in 1862 that the observed parallactic inequality of the moon was irreconcilable with the accepted value of the solar parallax, and indicated the much larger value $8.97''$. This result was soon apparently confirmed by several other researches founded both on theory and observation, and so strong did the evidence appear to be that the value $8.95''$ was adopted in the *Nautical Almanac* for a number of years. The most remarkable feature of the discussion since 1862 is that the successive examinations of the subject have led to a continually diminishing value, so that at the present time it seems possible that the actual parallax of the sun is almost as near to the old value of Encke as to that which first replaced it.

Five fundamentally different methods of determining the distance of the sun have been worked out and applied. They are as follows:—

I. From measures of the parallax of either Venus or Mars the parallax of the sun can be immediately derived, because the ratios of distances in the solar system are known with the last degree of precision. Transits of Venus and observations of various sorts on Mars are all to be included in this class.

II. The second method is in principle extremely simple, consisting merely in multiplying the observed velocity of light by the time which it takes light to travel from the sun to the earth. The difficulty is to determine the time in question.

III. The third method is through the determination of the mass of the earth relative to that of the sun. In astronomical practice the masses of the planets are commonly expressed as fractions of the mass of the sun, the latter being taken as unity. When we know the mass of the earth in gravitational measure, its product by the denominator of the fraction just mentioned gives the mass of the sun in gravitational measure. From this the distance of the sun can be at once determined by the fundamental equation of planetary motion.

IV. The fourth method is through the parallactic inequality in the moon's motion. This method was described in the ninth edition of the *Encyc. Brit.*

V. The fifth method consists in observing the displacement in the direction of the sun, or of one of the nearer planets, due to the motion of the earth round the common centre of gravity of the earth and moon. It requires a

Methods of determination.

precise knowledge of the moon's mass. The uncertainty of this mass impairs the accuracy of the method.

I. To begin with the results of the first method. The transits of Venus observed in 1874 and 1882 might be expected to hold a leading place in the discussion. No purely astronomical enterprise was ever carried out on so large a scale or at so great an expenditure of money and labour as was devoted to the observations of these transits, and for several years before their occurrence the astronomers of every leading nation were busy in discussing methods of observation and working out the multifarious details necessary to their successful application. In the preceding century reliance was placed entirely on the observed moments at which Venus entered upon or left the limb of the sun, but in 1874 it was possible to determine the relative positions of Venus and the sun during the whole course of the transit. Two methods were devised. One was to use a heliometer to measure the distance between the limbs of Venus and the sun during the whole time that the planet was seen projected on the solar disc, and the other was to take photographs of the sun during the period of the transit and subsequently measure the negatives. The Germans laid the greatest stress on measures with the heliometer; the Americans, English, and French on the photographic method. These four nations sent out well-equipped expeditions to various quarters of the globe, both in 1874 and 1882, to make the required observations; but when the results were discussed they were found to be extremely unsatisfactory. It had been supposed that, with the greatly improved telescopes of modern times, contact observations could be made with much greater precision than in 1761 and 1769, yet, for some reason which it is not easy to explain completely, the modern observations were but little better than the older ones. Discrepancies difficult to account for were found among the estimates of even the best observers. The photographs led to no more definite result than the observations of contacts, except perhaps those taken by the Americans, who had adopted a more complete system than the Europeans; but even these were by no means satisfactory. Nor did the measures made by the Germans with heliometers come out any better. By the American photographs the distances between the centres of Venus and the sun, and the angles between the line adjoining the centres and the meridian, could be separately measured and a separate result for the parallax derived from each. The results were:—

<i>Transit of 1874</i> :	Distances ;	par. = 8·888''.
	Pos. angles ;	" = 8·873''.
<i>Transit of 1882</i> :	Distances ;	" = 8·873''.
	Pos. angles ;	" = 8·772''.

The German measures with the heliometer gave apparently concordant results, as follows:—

<i>Transit of 1874</i> :	par. = 8·876''.
<i>Transit of 1882</i> :	" = 8·879''.

The combined result from both these methods is 8·857'', while the combination of all the contact observations made by all the parties gave the much smaller result, 8·794''. Had the internal contacts alone been used, which many astronomers would have considered the proper course, the result would have been 8·776''.

In 1877 Gill organized an expedition to the Island of Ascension to observe the parallax of Mars with the heliometer. By measurements giving the position of Mars among the neighbouring stars in the morning and evening, the effect of parallax could be obtained as well as by observing from two different stations; in fact the rotation of the earth carried the observer himself round a parallel of latitude,

Transits of Venus.

so that the comparison of his own observations at different times would give the same result as if they had been made at different stations. The result was 8·78''. The failure of the method based on transits of Venus led to an international effort carried out on the initiative of Sir David Gill to measure the parallax by observations on those minor planets which approach nearest the earth. The scheme of observations was organized on an extended scale. The three bodies chosen for observation were: Victoria, 10th June to 26th August 1889; Iris, 12th October to 10th December 1888; and Sappho, 18th September to 25th October 1888. The distances of these bodies at the times of opposition were somewhat less than unity, though more than twice as great as that of Mars in 1877. The drawback of greater distance was, however, in Gill's opinion, more than compensated by the accuracy with which the observations could be made. The instruments used were heliometers, the construction and use of which had been greatly improved, largely through the efforts of Gill himself. The planets in question appeared in the telescope as star-like objects which could be compared with the stars with much greater accuracy than a planetary disc like that of Mars, the apparent form of which was changed by its varying phase, due to the different directions of the sun's illumination. These observations were worked up and discussed by Gill with great elaboration in the *Annals of the Cape Observatory*, vols. vi. and vii. The results were for the solar parallax π :

From Victoria,	$\pi = 8\cdot801'' \pm 0\cdot006''$.
" Sappho,	$\pi = 8\cdot798'' \pm 0\cdot011''$.
" Iris,	$\pi = 8\cdot812'' \pm 0\cdot009''$.

The general mean result was 8·802''. From the meridian observations of the same planets made for the purpose of controlling the elements of motion of the planets Auwers found $\pi = 8\cdot806''$. All other methods of directly measuring the parallax fall so far behind this in certainty that we may regard Gill's result as the best yet derived from measurement. But the difficulties of the measures are such that other methods may be yet better and in any case are not to be neglected.

II. The velocity of light has been measured with all the precision necessary for the purpose. The latest result is 299860 kilometres per second, with a probable error of perhaps 30 kilometres; that is, about the ten-thousandth part of the quantity itself. This degree of precision is far beyond any we can hope to reach in the solar parallax. The other element which enters into consideration is the time required for light to pass from the sun to the earth. Here no such precision can be attained. Both direct and indirect methods are available. The direct method consists in observing the times of some momentary or rapidly varying celestial phenomenon, as it appears when seen from opposite points of the earth's orbit, the only phenomena of the sort available being eclipses of Jupiter's satellites, especially the first. Unfortunately these eclipses are not sudden but slowly changing phenomena, so that they cannot be observed without an error of at least several seconds, and not infrequently important fractions of a minute. As the entire time required for light to pass over the radius of the earth's orbit is only about 500 seconds, this error is fatal to the method. The indirect method is derived from the observed constant of aberration or the displacement of the stars due to the earth's motion. The minuteness of this displacement, about 20·50'', makes its precise determination an extremely difficult matter. The most careful determinations are affected by systematic errors arising from those diurnal and annual changes of temperature, the effect of which cannot be wholly eliminated in astro-

Velocity of light.

Planetary parallaxes.

nomical observation, and the recently-discovered variation of latitude has introduced a new element of uncertainty into the determination. In consequence of it, the values formerly found were systematically too small by an amount which even now it is difficult to estimate with precision. Struve's classic number, universally accepted during the second half of the 19th century, was 20.445". Serious doubt was first cast upon its accuracy by the observations of Nyrén with the same instrument during the years 1880-82, but on a much larger number of stars. His result, from his observations alone, was 20.52"; and taking into account the other Pulkowa results, he concluded the most probable value to be 20.492". In 1895 Chandler, from a general discussion of all the observations, derived the value of 20.50". Since then, two elaborate series of observations made with the zenith telescope for the purpose of determining the variation of latitude and the constant of aberration have been carried on by Professor Doolittle at the Flower Observatory near Philadelphia, and Professor Rees and his assistants at the observatory of Columbia College, New York. Each of these works is self-consistent and seemingly trustworthy, but there is a difference between the two which it is difficult to account for. Rees's result is 20.47"; Doolittle's, 20.56". This last value agrees very closely with a determination made by Gill at the Cape of Good Hope, and most other recent determinations give values exceeding 20.50". On the whole it is probable that the value exceeds 20.50"; and so far as the results of direct observation are concerned may, for the present, be fixed at 20.53". The corresponding value of the solar parallax is 8.777". In addition to the doubt thrown on this result by the discrepancy between various determinations of the constant of aberration, it is sometimes doubted whether the latter constant necessarily expresses with entire precision the ratio of the velocity of the earth to the velocity of light. While the theory that it does seems highly probable, it cannot be regarded as fully established.

III. The combined mass of the earth and moon admits of being determined by its effect in changing the position of the plane of the orbit of Venus. The motion of the node of this plane is found with great exactness from observations of the transits of Venus. So exact is the latter determination that, were there no weak point in the subsequent parts of the process, this method would give far the most certain result for the solar parallax. Its weak point is that the apparent motion of the node depends partly upon the motion of the ecliptic, which cannot be determined with equal precision. Notwithstanding this drawback the elements of admissible error seem smaller by this method than by any other. The derivation of the distance of the sun by it is of such interest from its simplicity that we shall show the computation.

From the observed motion of the node of Venus, as shown by the four transits of 1761, 1769, 1874, and 1882, is found

$$\text{Mass of (earth + moon)} = \frac{\text{Mass of sun}}{332600}$$

We have already found in gravitational units of mass, based on the metre and second as units of length and time,

$$\begin{aligned} \text{Log. earth's mass} &= 14.60052 \\ \text{,, moon's ,,} &= 12.6895. \end{aligned}$$

The sum of the corresponding numbers multiplied by 332600 gives

$$\text{Log. sun's mass} = 20.12773.$$

Putting a for the mean distance of the earth from the sun, and n for its mean motion in one second, we use the fundamental equation

$$a^3 n^2 = M_0 + M',$$

M_0 being the sun's mass, and M' the combined masses of the earth

and moon, which are, however, too small to affect the result. For the mean motion of the earth in one second in circular measure, we have

$$n = \frac{2\pi}{31558149}; \text{ log. } n = \bar{7}.29907$$

the denominator of the fraction being the number of seconds in the sidereal year. Then, from the formula

$$a^3 = \frac{M_0}{n^2} = \frac{[20.12773]}{-15.59814}$$

we find

Log. a in metres =	11.17653
Log. equat. rad. \oplus	6.80470
Sine \odot 's eq. hor. par.	5.62817
Sun's eq. hor. par.	8.762".

The writer regards this as at present the most trustworthy of all the methods of determining the distance of the sun.

IV. The determination of the solar parallax through the parallactic inequality of the moon's motion also involves two elements—one of observation, the other of purely mathematical theory. The inequality in question has its greatest negative value near the time of the moon's first quarter, and the greatest positive value near the third quarter. Meridian observations of the moon have been heretofore made by observing the transit of its illuminated limb. At first quarter its first limb is illuminated; at third quarter, its second limb. In each case the results of the observations may be systematically in error, not only from the uncertain diameter of the moon, but in a still greater degree from the varying effect of irradiation and the personal equations of the observers. The theoretical element is the ratio of the parallactic inequality to the solar parallax. The determination of this ratio is one of the most difficult problems in the lunar theory. Using Hansen's determination, the values of the solar parallax derived from three independent series of observations of the moon are:—8.802" (from Greenwich and Washington meridian observations); 8.789" (Battermann, from occultations of stars by the moon); 8.767" (Franz, from observations of a lunar crater). Giving these three results the respective weights 5, 2, and 1, the result is 8.794". But the most recent and as yet unfinished researches of E. W. Brown and G. W. Hill throw doubt on the precision of Hansen's theoretical ratio. If the latter is corrected by the work of these investigators, the value of the solar parallax derived by this method is reduced to about 8.773".

V. The fifth method is, as we have said, the most uncertain of all; it will therefore suffice to quote the result, which is

$$\pi = 8.818".$$

The following may be taken as the most probable values of the solar parallax, as derived independently by the five methods we have described:—

From measures of parallax	. 8.802"
,, velocity of light	. 8.777"
,, mass of the earth	. 8.762"
,, par. ineq. of moon	. 8.773"
,, lunar equation	. 8.818"

The question of the possible or probable error of these results is one on which there is a marked divergence of opinion among investigators. Probably no general agreement could now be reached on a statement more definite than this; the last result may be left out of consideration, and the value of the solar parallax is probably contained between the limits 8.77" and 8.80". The value 8.80" was chosen at the Paris conference of 1896, and is now generally adopted in astronomical ephemerides. The most likely distance of the sun may be stated in round numbers as 93,000,000 miles. It is possible that observations of Eros, the remarkable asteroid of which we have already

Motion of moon.

Motion of earth.

Mass of the earth.

spoken, may settle the question; but there is no prospect of its being soon settled in any other way.

Variation of Latitudes.

The development of an important feature of the rotation of the earth is due very largely to the investigations of S. C. Chandler. This is a minute periodic change in the point at which the axis of rotation intersects the earth's surface; that is, in the position of the pole of the earth. The result is a variability of the terrestrial latitudes generally.

To make clear the nature of the movement in question we must begin with a statement of some results of theory. Let EQ (see Fig. 2) represent the section of an oblate spheroid through its shortest axis, PP. We may consider this spheroid to be that of the earth, the ellipticity being greatly exaggerated. If it is set in rotation around its axis of figure PP, it will continue to rotate around that axis for an indefinite time.

Fig. 2.

then, calling one day the period of rotation of the spheroid, the axis RR will make a revolution around PP in a number of days represented by the fraction C/C-A. In the case of the earth we have found that the inverse of this ratio is 0.0032813. It follows that the period in question is 305 days. It has for more than half a century been recognized as possible that the axis of rotation of the earth might not coincide with its axis of figure, and, in consequence, that such a rotation as this might be going on.

The latitude of a point on the earth, as determined by astronomical observations, is determined with respect to the axis of rotation RR, and not with reference to PP, because the latter cannot be fixed by any direct method. Hence, if such a change in this axis were going on, it was supposed that there would be a harmonic variation of the latitudes of all points of the earth's surface in a period of about 305 days. Up to 1890 the most careful observations and researches failed to afford evidence of a rotation in this period, though there was strong evidence of a variation of latitude. Observations for the value of the constant of aberration made at Pulkova and Berlin between the years 1880 and 1890 seemed to show that the latitudes of those places did actually change from time to time to the amount of about half a second of arc. Chandler, from an elaborate discussion of these and a great number of other observations, showed that there was really a variation of the latitude of the points of observation; but, instead of the period being 305 days, it was about 428 days. At first sight this period seemed to be inconsistent with dynamical theory. But a defect was soon found in the latter, the correction of which reconciled the divergence. In deriving a period of 305 days the earth is regarded as an absolutely rigid body, and no account is taken either of its elasticity or of the mobility of the ocean. A study of Fig. 2 will show that the centrifugal force round the axis RR will act on the equatorial protuberance of the rotating earth so as to make it tend in the direction of the arrows. A slight deformation of the earth will thus result; and the axis of figure of the distorted spheroid will no longer be PP, but a line P'P' between PP and RR. As the latter moves round, P'P' will continually follow it through the incessant change of figure produced by the change in the direction of the centrifugal force. Now the rate of motion of RR is determined by the actual figure at the moment. It is therefore less than the motion in an absolutely rigid spheroid in the proportion RP':RP. It is found that, even though the earth were no more elastic than steel, its

yielding combined with the mobility of the ocean would make this ratio about 2:3, resulting in an increase of the period by one-half, making it about 457 days. Thus this small flexibility is even greater than that necessary to the reconciliation of observation with theory, and the earth is shown to be more rigid than steel—a conclusion long since announced by Kelvin, for other reasons.

Chandler afterwards made an important addition to the subject by showing that the motion was represented by the superposition of two harmonic terms, the first having a period of about 430 days, the other of one year. In order to state his conclusion we have to express the position of the pole of rotation on the earth's surface relative to the mean pole. Let us represent the fixed position of the latter by O, while P represents the position of the movable pole. We then have to express the position of P relative to O in terms of the time. Let us imagine two co-ordinate axes going out from O—the one towards Greenwich, the other in 90° E. longitude. We represent the co-ordinate in the direction of Greenwich by y, that in the direction 90° E. by x. Then P revolves round O in a direction from west towards east in a curve such that the co-ordinates of P may be expressed in the form:

$$x = r \sin \theta t + 0.11'' \sin (\odot + 60^\circ)$$

$$y = r \cos \theta t + 0.11'' \cos \odot$$

\odot being the sun's mean longitude, and r and θ quantities which Chandler believes to be slowly variable. He represents the variations in terms of an angle χ having a period of 24,000 days, or a daily motion of 0.015°, of which the value was 0° at the date 31st March 1865. At this date the pole P passed the meridian of Greenwich. If only the first terms of x and y are included, the other dates T of passage—that is, the dates when θt is a multiple of 360°—are by the equation

$$T = 1865.25 + 428.6^d E + 55^d \sin \chi,$$

E being an entire number, expressive of the number of periods from 1865.25.

He also finds

$$r = 0.135'' + 0.05'' \sin \chi$$

$$\text{Period} = 428.6^d + 5.26^d \cos \chi$$

$$\theta = \frac{360^\circ}{\text{Period}}$$

The angle χ is a purely empirical quantity, introduced to represent past observations. There can be no certainty that it will represent future ones.

If the supposed variation of r and P or θ are unreal, the motion of the angle θt is 0.843° per day, the period about fourteen months, and $r = 0.148''$. The expressions for x and y then become

$$x = 0.148'' \sin 0.843^\circ t + 0.11'' \sin (\odot + 30^\circ)$$

$$y = 0.148'' \cos 0.843^\circ t + 0.11'' \cos \odot,$$

the time t being counted in days from the day 2412646 of the Julian period or 1st July 1893. The difference of 30° between the sine and cosine arguments of the annual term shows that this term represents an elongated ellipse.

The variation of the latitude of any place of which the longitude east of Greenwich is λ is given by the formula

$$\phi - \phi_0 = x \sin \lambda - y \cos \lambda$$

ϕ being the instantaneous, and ϕ_0 the mean latitude.

While there can be no doubt as to the reality of the fourteen-month term, there is not as yet a general agreement as to the amount and nature of the annual term. It is difficult to determine the latter with certainty, because the effect of the diurnal variations of the temperature of the instrument and the atmosphere, which cannot be accurately ascertained and allowed for, might lead to minute apparent terms having a period of a year. The reason of this is, that the observations have to be made upon stars while they are crossing the meridian; in the case of any one star, the transit occurs at all hours of the day in succession in the course of twelve months. For example, a star which at midsummer would be observed at six in the morning would, at midwinter, be observed at six in the evening, when the conditions might be materially different. The present state of the question, so far as theory is concerned, may be summed up as follows:—

Summary of conclusions.

(1) The fourteen-month term is an immediate result of the fact that the axes of rotation and figure of the earth do not strictly coincide, but make with each other a small angle of which the mean value is about 0.15". If

the earth remained invariable, without any motion of matter on its surface, the result of this non-coincidence would be the revolution of the one pole round the other in a circle of radius $0.15''$ in a period of about 429 days. This revolution is called the *Eulerian motion*, after the mathematician who discovered it. But owing to meteorological causes the motion in question is subject to annual changes. These changes arise from two causes—the one statical, the other dynamical.

(2) The statical causes are deposits of snow or ice slowly changing the position of the pole of figure of the earth. For example, a deposit of snow in Siberia would bring the equator of figure of the earth a little nearer to Siberia and throw the pole a little way from it, while a deposit on the American continent would have the opposite effect. Owing to the approximate symmetry of the American and Asiatic continents it does not seem likely that the inequality of snowfall would produce an appreciable effect.

(3) The dynamical causes are atmospheric and oceanic currents. Were these currents invariable their only effect would be that the Eulerian motion would not take place exactly round the mean pole of figure, but round a point slightly separated from it. But, as a matter of fact, they are subject to an annual variation. Hence the motion of the pole of rotation is also subject to a similar variation. The annual term in the latitude may be readily accounted for in this way. But it seems unlikely that a motion thus produced should have a sensible eccentricity. It therefore appears at present more likely that the seeming eccentricity of the annual motion is unreal and due to the cause already mentioned.

(4) Six Eulerian periods are very nearly seven years. In consequence, the effect of the annual change is to produce an inequality in the amplitude having a period of seven years. During one part of this period the distance of the two poles is nearly double, being increased to $0.25''$ or $0.30''$. At another part of the period, three and a half years later, the motion almost ceases. Times of greatest motion were in 1890-92, and again in 1897-99; of least motion about 1894, 1901, 1908, &c.

Besides Chandler, Albrecht of Berlin has investigated the motion of the pole P. The methods of the two astronomers are in some points different. Chandler has constructed empirical formulæ representing the motion, with the results already given, while Albrecht has determined the motion of the pole from observation simply, without trying to represent it either by a formula or by theory. It is noteworthy that the difference between Albrecht's numerical results and Chandler's formulæ is generally less than $0.05''$.

Masses, &c., of the Planets and Satellites.

The elements, masses, and other particulars relating to the major planets and their satellites, so far as these were known in 1875, are given in the *Ency. Brit.*, ninth edition, vol. ii. pp. 782-83, and the adopted elements of most of these bodies have been so slightly changed that a repetition of them is not deemed necessary. What we shall now present is a *résumé* of the masses, diameters, and other more important constants which have been worked out to the present time, necessarily limiting our review to what may be considered the best-established results. For ordinary astronomical purposes the masses are not expressed in terms of the gravitational units already defined, but as fractions of the sun's mass taken as unity. This fraction is commonly written in the form $\frac{1}{\mu}$, μ being the number of times that the sun's mass exceeds that of the planet. The masses of the satellites are expressed in the same form in terms of the mass of the primary.

The minuteness of the planet Mercury and the absence of a satellite make the determination of its mass difficult

and uncertain. In the new planetary tables issued from the office of the *American Nautical Almanac*, and now most used, μ is taken as 6000000. Other values of the mass are generally less than this, μ ranging up to 10000000 or more. G. W. Hill, from a consideration of the probable density, finds values ranging from 10194200 to 10826200. The uncertainty of the diameter renders this result uncertain; an increase of one-tenth in Hill's adopted diameter, $6.68''$, would increase the resulting volume by one-third and the mass by nearly one-half. The value 7500000 seems as likely as any. The best values of the diameter are those found during transits over the sun's disc. Todd, with double-image micrometer, found the value $6.604''$ ($\Delta=1$), and Barnard, with filar micrometer, $6.126''$. Both results are liable to be too small from the effects of irradiation. Off the sun's disc, results of measures with the filar micrometer are Lowell at Flagstaff $7.4''$, and Barnard at Mount Hamilton $6.14''$.

The mass of the planet Venus derived from all the observations of the sun and Mercury, and adopted in the new planetary tables, is $\mu=408000$. It is not likely to be in error by 1 per cent. of its amount. For the angular diameter at distance unity Auwers, from heliometer measures during the transits of 1874 and 1882, found the value $16.820''$; Newcomb, from double-image micrometer measures during the transit of 1882, that of $16.88''$; Barnard, off the sun from measures near inferior conjunction, $17.397''$; and German observers, with the heliometer, $17.30''$. This difference between the results of measures on and off the sun might be attributed to irradiation; but it is singular that a comparison of numerous measures made at widely different distances from the earth seems to indicate the anomaly of negative irradiation, the diameters measured at the greater distances being proportionately too small instead of too large.

The mass of the moon has been already derived as one of the fundamental constants. The most exact value of the diameter is that derived from the occultations of groups of stars, especially when the moon is totally eclipsed. From occultations of the Pleiades J. Peters found, for the mean semi-diameter $15' 32.49''$; Struve, from occultations during total eclipses, $15' 32.65''$; while the most likely value, as concluded by Peters, is $15' 32.59''$. As the apparent diameter varies with the distance, and can be computed only when the moon's parallax is known, it is common to express the moon's diameter in terms of that of the earth as unity. From the value of the parallax already found, it follows that

$$\frac{\text{Diameter of moon}}{\text{Eq. diam. of earth}} = 0.272480.$$

For particulars as to the motion of the moon, see article Moon.

The motions of the orbital planes and of the pericentres of the satellites of Mars offer interesting problems to both the observing and the mathematical astronomer. These problems have been most successfully attacked by Hermann Struve in a memoir presented to the St Petersburg Academy in 1898. The preliminary results of theory may first be set forth:—

Let M (Fig. 3) be the pole of rotation of Mars, O the pole of the orbit of that planet, and S the pole of the orbit of one of its satellites, all projected on the celestial sphere. The arc OM of the sphere will then be equal to that between the equator of Mars and the plane of its orbit; SO will be equal to the inclination of the orbit of the satellite to that of the planet, and SM to the inclination of the same orbit to the equator of Mars. In consequence of the action of the sun, the pole S moves constantly in a direction at right angles to OS, as shown by arrow *a*; while the ellipticity of Mars gives it a much more rapid motion in a direction at right angles to MS, as shown by the other arrow *b*. The actual motion

is the resultant of these two components, and is such as to carry S round in a circle, of which the centre is at a third point F. This centre is the pole of a certain plane called the "fixed plane" of the satellite orbit, which makes but a small angle with the plane of the planet's equator. The position of the plane of Mars's equator relative to the plane of the orbit has been found in two ways—

Fig. 3.

from measures on the polar spot, giving the position of the pole of rotation, and from observations of the satellites. The best result of this first method is derived by combining the results of Schiaparelli and Lohse. H. Struve has applied the second. The results are, for the inclination of the equator of Mars to that of the earth,

$$J_0 = 36.42^\circ \text{ (Schiaparelli and Lohse)}$$

$$J_0 = 37^\circ 27.1' - 0.239' (t - 1880) \text{ (Struve);}$$

and for the longitude of ascending node of equator on that of the earth,

$$N_0 = 48.26^\circ \text{ (Schiaparelli and Lohse)}$$

$$N_0 = 47^\circ 5.7' + 0.463' (t - 1880) \text{ (Struve).}$$

Struve also finds, from the motions of the pericentres of the satellites, ellipticity of Mars = $1/190.4$; but owing to a doubt as to the revolutions of the pericentre of Phobos, this possibly should be $1/178$.

In representing the elements of the orbits of the satellites, the following notation is used:—

J_1, N_1 , inclination and node of the "fixed plane" of the satellite's orbit, referred to the earth's equator for the epoch 1880; J, N , the same for the orbit of the satellite; L_0 , the mean longitude at the epoch 1894 October, 0.0 Greenwich mean time; n , the tropical mean daily motion; a , the angular semi-major axis of the orbit, as seen from distance unity; π , the longitude of the pericentre on the equator of Mars; e , the eccentricity; K , an angle varying uniformly with the time, whose rate of motion is equal to that of the pericentre, and of the node of the satellite's orbit on the fixed plane; and t , the time in years from 1894.80.

The numerical values of the elements as found by Struve are:—

	Deimos.	Phobos.
K	$29.9^\circ - 6.375^\circ t$	$358.7^\circ - 158^\circ 0t$
J_1	$36^\circ 46.5'$	$37^\circ 26.7'$
N_1	$46^\circ 2.6'$	$47^\circ 5.0'$
$(N - N_1) \sin J$	$1^\circ 37.6' \sin K$	$0^\circ 53.1' \sin K$
$J - J_1$	$1^\circ 37.6' \cos K$	$0^\circ 53.1' \cos K$
L_0	186.25°	298.13°
n	285.16198°	1128.84396°
a	$32.373''$	$12.938''$
π	$231^\circ + 6.375^\circ t$	$272.6^\circ + 158^\circ 0t$
e	0.0031	0.0217

From the values of a follows:—

$$\frac{\text{Mass of Mars}}{\text{Mass of sun}} = \frac{1}{3090000}$$

Professor Hall's figure, now generally used in astronomy, is $1/3093500$.

Schur has measured the diameters of Mars with the heliometer, Barnard with the filar micrometer. The results for the equatorial and polar diameters, as seen from distance unity, are:—

	Equat.	Polar.
Schur	$9.526''$	$9.325''$
Barnard	$9.673''$	$9.581''$

Each value of the ellipticity is markedly greater than that found by Struve from the motion of the pericentre of Phobos.

The minor planets individually are too minute to exert a sensible action on the other planets; but the question

whether the mass of the entire group, which may number thousands, can be sufficient to produce an appreciable secular variation of the node and perihelion of Mars is an important one. A rude estimate of the total mass of the group may be made in the following way:—From the stellar magnitude of each known minor planet we may roughly infer its diameter,

and hence its probable mass. The statistical law of progressive diminution of the magnitudes or volumes, as derived from the known members of the group, may be extended to the undiscovered members. That a law of progressive diminution extends to the unknown members may be inferred from the fact that, if there were a very great number above a certain limit of magnitude, the whole mass would be visible as a band of light spanning the heavens. The writer has found that by no probable hypothesis as to the number and size of these bodies, consistent with the absence of this band, can the total mass be sufficient to exert any appreciable action on any other planet.

The mass and diameter of Jupiter can be determined in two ways—by measures of the satellites and by the action of Jupiter on other bodies. The satellites are not well adapted to give an accurate value of the mass, as any proportional error in their mean distances from the planet is multiplied threefold in the result. The following are the results for the reciprocal of the mass reached by different methods, with the weight that may be assigned to each:—

Observations of the satellites	$\mu = 1047.82$	Wt. 1
Action on Fayes's comet (Möller)	$\mu = 1047.79$	" 1
" Themis (Krueger)	$\mu = 1047.54$	" 5
" Saturn (Hill)	$\mu = 1047.35$	" 7
" Winnecke's comet (Haerdtl)	$\mu = 1047.17$	" 10
" Polyhymnia (Newcomb)	$\mu = 1047.34$	" 20

The mean result,

$$\frac{\text{Mass of Jupiter}}{\text{Mass of sun}} = \frac{1}{1047.35 \pm .05}$$

is that now adopted in the planetary tables. In 1901 De Sitter published an important additional result derived from heliometer observations by Gill and Finlay at the Cape Observatory. This was—

$$\mu = 1047.226 \pm 0.067.$$

No definitive changes have been made in the adopted elements of the satellites of Jupiter in recent times.

The measures of the diameter of Jupiter are very numerous, and the differences between the results must be regarded as due to personal equation and peculiarities of instrument rather than to accidental errors. The latest results by the two methods are:—

	Equat.	Polar.
Schur, from observations with the heliometer	$37.40''$	$35.13''$
Barnard, from observations with the filar micrometer	$38.52''$	$36.11''$

This difference between the results of the two methods appears to be common to all observers, the method of double images always giving a smaller diameter than the micrometer. It may be attributed to a certain softness of outline of Jupiter's disc, which is easily remarked by a careful observer.

The ball, rings, and satellites of Saturn show mechanical features of great interest, not found elsewhere in our system. One of the simplest of these is that the planes of Saturn's equator, of its rings, and of at least its seven inner satellites, have a common secular motion due to the action of the sun. If the latter acted on each of these bodies separately, the secular motions of the planes would be greater the farther the satellite is from the planet, and the motion of the nodes would take place around the plane of the orbit of the planet, the planes of the orbits preserving a nearly constant inclination of almost 27° . The ultimate result of the unequal motion would be that the nodes would be scattered all round the circle, and the planes of the several orbits of the satellites might have mutual inclinations to each other amounting to 53° . But the mutual interaction of the equatorial protuberance of the planet, the rings, and the satellites keeps

the motion of the whole system nearly in the same plane, as if it were a rigid body. Especially is this the case with the ring, in the form of which not the slightest deviation from a plane can be detected, whereas, if each of its particles moved independently, the whole would form a mass so broad as to quite conceal the planet from our view.

The most remarkable features of this system are the cases of libration among the motions of the satellites, most of which are quite unique in form. We note for comparison the well-known relation among three of the satellites of Jupiter: if L , L' , and L'' are the respective mean longitudes of the first, second, and third of these bodies, we find that they always move so as to satisfy the equation—

$$L - 3L' + 2L'' = 180^\circ.$$

Let us, for brevity, call W the combination $L - 3L' + 2L''$. It was shown by Laplace that, if W differed slightly from 180° , there would be small residual forces arising from the mutual action of the three bodies, tending always to bring it towards 180° . That is, if W were less than 180° , the force would tend to increase it; if greater, to diminish it, and thus W might swing back and forth on each side of 180° as a pendulum swings on each side of the vertical. This swing would be a libration. As a matter of fact, the swing is too slight to be observed; W stays at 180° as a pendulum might constantly hang in the vertical position.

The similar librations in the Saturnian system have the remarkable feature that not only the mean longitude, but also the longitudes of the pericentres come into ten equations. The first case of this sort noticed was between the sixth and seventh satellites, Titan and Hyperion—the latter being the outer one of the two, and the faintest of the eight known satellites. Its orbit has long been known to be the most eccentric of the system, the eccentricity being 0.10. Professor Hall, by comparing his own observations with those of his predecessors, showed that the pericentre of the orbit performs a complete revolution in about eighteen years in a retrograde direction, this being the reverse of the secular motion due to the action of a disturbing body. It was found that this seeming anomaly arises from a peculiar action of Titan, having its origin in a near approach to commensurability between the mean motions of the two bodies, three times that of Titan being nearly equal to four times that of Hyperion. The motions are so adjusted that if we put L , L' = the mean longitude of Titan and Hyperion, π' the longitude of the pericentre of Hyperion, and $V = 4L' - 3L - \pi'$, then the angle V will never differ much from 180° , but will continually oscillate on each side of this value, as just explained in the case of the angle W for Jupiter. The annual retrograde motion of π' is, from the observations of Hermann Struve, 18.663° , so that the period of its revolution is 19.3 years. The eccentricity of Titan has the effect of making all the elements of Hyperion go through a change in nearly this period, which is determined by the angular distance of the pericentres of the two satellites. The expression for the inequalities thus arising in the eccentricity and pericentre of Hyperion are—

$$\begin{aligned} \Delta \pi' &= 14.0^\circ \sin(\pi - \pi') \\ \Delta e' &= 0.0230 \cos(\pi - \pi'). \end{aligned}$$

The motion in question has also been theoretically investigated by G. W. Hill and Ormond Stone. They have established it to determine the mass of Titan, which is shown to be about $1/4300$ that of Saturn itself. This is remarkable, because it seems certain that the angular diameter of the satellite is much less than one second, while that of Saturn when nearest the earth is about twenty seconds. The satellite would therefore seem to be

less than $1/10000$ the size of Saturn, so that the mass found by Hill and Stone shows its density to be at least twice that of the planet. The masses of the other satellites have been found by Struve to be very minute, varying from $1/250000$, in the case of Rhea, to $1/13610000$ in that of Mimas.

The determinations of the mass of Saturn have been singularly discordant. They are made by measures of the major axes of the orbits of the satellites and by the action of Saturn on Jupiter. From measures with the heliometer on the brightest satellite, Titan, Bessel found $\mu = 3501.6$. A subsequent correction increases the number by one or two units. Leverrier, from the action of Jupiter, found 3529.6 (*Annales de l'Observatoire de Paris*, xii. p. 9). Asaph Hall, from measures of Japetus with the 26-inch Washington telescope, 3481.3 ± 0.54 (*Washington Observations for 1882*, app., p. 70). The small probable error of this last value, the great power of the instrument, and the considerable mean distance of the satellite, more than 500", would seem to inspire confidence in it. It was strengthened by the use of two quite distinct methods of observing—one with the micrometer, the other by transits giving differences of R. A. between the planet and the satellite. But Hill, from the action on Jupiter, found a result in substantial agreement with Bessel's. To decide the question Asaph Hall, jun., observed Titan with the heliometer of the Yale Observatory, and obtained a result confirming Bessel's. Yet H. Struve, from measures of Japetus and Titan with the Pulkowa 14-inch equatorial, found 3498; and from Titan and the nearer satellites, with the great 30-inch instrument, 3495.3. In Hill's tables of Jupiter, and the other tables of the American Ephemeris, the value 3501.6 is adopted. Still, the preponderance of evidence at the present time seems to favour a number rather below than above 3500.

For the angular diameters of Uranus and Neptune Barnard found, with the filar micrometer:—

Uranus, 4.040" at dist. 19.183

Neptune, 2.433" " 30.0551.

Uranus and Neptune.

The masses adopted in the new tables are:—

Uranus, $\mu = 22869$

Neptune, $\mu = 19314$.

III. THE FIXED STARS.

Our knowledge of the fixed stars has in recent years been widened to an extent which would not have been deemed possible two generations ago. The revelations of the spectroscope have given rise to a branch of astronomy so wide in its scope that it is sometimes regarded as a new science, that of astrophysics—a term now applied to the results of studies on the physical constitution of the heavenly bodies generally, whether the planets or the stars. It is impossible to draw a sharp line between the results of this branch of study and those of the older methods of investigation, sometimes called astrometry, which includes all forms of celestial measurement, whether of distance, motions, or magnitudes; as astrophysics progresses, it necessarily enters this field. Its most remarkable discoveries have resulted from the measurements of motions in the line of sight, the results of which belong strictly to astrometry. Our summary of the advances in stellar astronomy may be introduced by a brief general view of activity in the field at large.

One prominent feature of recent progress has been the study of the southern heavens. A natural result of the great preponderance of observatories and means of recent research in the northern hemisphere was that, before the present generation, our knowledge of the southern heavens lagged far behind that

Recent progress.

of the northern ones. When we recall the expedition of Sir John Herschel to the Cape of Good Hope in 1832-34, and the rather limited work of the observatories at the Cape, Melbourne, Paramatta, &c., before 1870, we shall have included the most important researches in this part of the sky. The first step towards a marked extension of our knowledge in this field dates from the foundation of the National Argentine Observatory at Cordoba by Dr Gould in 1871. This observatory has, since its foundation, been devoted to the work of cataloguing and mapping the southern heavens with instruments of precision. The results of this work are found in the splendid volumes, now eighteen in number, published by the observatory. A few years later, Sir David Gill, F.R.S., on his appointment as astronomer of the Cape Observatory, so enlarged the means of that establishment and gave such an impetus to its work that it is now one of the leading observatories of the world. In the field of astronomy his work has differed from that of the Cordoba Observatory in being directed very largely towards the most precise measurements of a limited number of stars, Cordoba having devoted most attention to cataloguing all the stars which could be advantageously reached with the instruments. Gill's most remarkable work has been done with the heliometer, an instrument which he has done much to bring to its present state of perfection. Determinations of stellar parallax have been pursued by him with such success that we have now, so far at least as the brightest stars are concerned, a better knowledge of this subject for the southern heavens than for the northern. Yet more recently the foundation of the Arequipa Observatory, a branch of the Harvard Observatory, has marked an epoch in stellar photometry, to which branch it has been very largely devoted. Through its work, our knowledge of the magnitudes of the stars of the southern heavens now surpasses that of the northern heavens as it was in 1880.

Another prominent feature of the advance we are making has been the application of photography to astronomical investigation. From the time, about 1840, that Dr Draper took a daguerreotype of the moon, up to the year 1882, the photographic art played only a minor part in astronomical work. Perhaps Rutherford's work, that of Gould at Cordoba in photographing clusters of stars, the practice of photographing the sun at Greenwich in order to have a record of the changes of its surface, and the application of the art to the transits of Venus in 1874 and 1882, were the most important astronomical applications of photography during this interval. In 1882 Gill, in having the great comet of that year photographed with a portrait lens, found that all the stars in the field of view, down to the 9th or 10th magnitude, were imprinted upon the negatives. Following up the idea thus suggested, he undertook the enterprise of forming by photography a catalogue of all the stars down to the 10th magnitude between the south pole and 23° of south declination. This work has been brought to a completion with the aid of Professor Kapteyn of Groningen, who, with a disinterestedness to which it would be difficult to find a parallel in any other field than that of science, has devoted years of patient toil to the measurements of the positions of the stars on Gill's plates. As a result of this work, and that of Thome, Gould's successor at Cordoba, it may fairly be said that the stars are now even more completely catalogued for the southern heavens than for the northern.

Gill's demonstration, and the use in photography of more sensitive chemicals than had formerly been known, led to the idea on the part of the Paris astronomers of photographing the entire heavens by an international association of observatories. A conference to decide upon the methods of doing this was invited by Admiral

Mouchez, director of the Paris Observatory, in April 1887. Here was formulated the plan for the international *Carte Photographique du Ciel*, which was undertaken by some eighteen observatories in both hemispheres. The work is all being done with similar instruments on a uniform plan. The charts in question form two series—one including only the stars down to about the 11th magnitude, the positions of which were to be determined by measurement, so as to form a catalogue, and the other all the stars which could be photographed with the longest available exposure. This work is not yet finished. Some portions of it were undertaken by observatories which appear not to have had the means for its successful prosecution, but other portions have been brought nearly or quite to a completion.

The application of the photographic method has been a prominent feature in the remarkable work of the Harvard Observatory. On assuming the direction of that establishment in 1876 Professor Pickering decided to make astrophysics its speciality. The munificence of those interested in his work has enabled him to command a wealth of appliances almost without example, and to devote to their use one of the largest and best-trained corps of assistants ever engaged in astronomical observation. Before the Paris Conference he had planned a work somewhat similar to that undertaken by the conference and begun to put it in execution. His object was, however, in one point at least, essentially different from that of the international enterprise, for his main idea was to photograph the sky from time to time with a view of detecting at the earliest possible moment any change that might take place among the stars. A striking result of this system has already been mentioned—the discovery of the new planet Eros on a great number of plates taken before the existence of the body was known. Another result has been the discovery of several so-called new stars which have suddenly blazed forth, although, up to the present time, none have become objects that would strike the ordinary spectator. Another speciality of this observatory has been the study of stellar spectra by photography. In this connexion, the aid afforded by the Draper Memorial Fund is worthy of mention. The wealth of material thus accumulated is so vast that its complete publication is scarcely possible. Yet every spectrum photographed is subjected to careful scrutiny, and any remarkable peculiarity that may be exhibited is published and discussed. Photometry has been one of the main branches of Professor Pickering's work, and the volumes already published contain estimates of the magnitudes of stars measured photometrically, now including the entire heavens in the scope of their contents.

Two other important photometric works have appeared which are especially noteworthy, because made with instruments radically different from each other and from that of Pickering. The photometric work of the late Professor Charles Pritchard, F.R.S., at Oxford, was carried out by the use of the extinction wedge, of which a description will be found in the article PHOTOMETRY, STELLAR. The same subject has been a leading feature of the work at the Astrophysical Observatory at Potsdam. The founding of this institution by the German Government soon after the close of the Franco-German war marked an epoch in the development of astrophysics, both because of being contemporaneous with the beginning and early growth of that science and because of the wisdom which has marked its administration. In stellar photometry the special feature of its work has been a very careful determination, by two observers, of a list of stars more limited than that investigated at the Harvard Observatory. The field to be covered includes the

hemisphere between the equator and the northern celestial pole. It is divided into zones of 20° in breadth. The zones from the equator to 40° of declination have already been published.

The most remarkable work now done with the spectro-scope is the determination of the motions of stars in the line of sight. The earliest attempts at such measures were those made by Sir William (then Mr) Huggins; and after the practicability of making such determinations was demonstrated by him, the work was taken up at the Royal Observatory at Greenwich. In these early researches only optical methods were used which were not susceptible of the highest precision. The introduction of more sensitive chemicals into photographic practice led to the great improvement of photographing the spectra of stars instead of observing them visually. A twofold advantage is thus gained: fainter spectra can be photographed than can be measured with the eye, and the errors to which the eye observations are liable can be almost entirely done away with. The first extended application of the photographic method to this purpose was made by Dr Vogel at the Potsdam Observatory; he measured the motions of forty-eight of the brighter stars in the line of sight with a precision that could not easily be reached by the optical method. The most interesting results of the new system of observation have been the discovery of binary systems among the stars. In this work, Campbell of the Lick Observatory has been remarkably successful; the results reached by him, Deslandres, and others will be summarized in their proper connexion.

Parallaxes and Proper Motions of the Stars.

The methods of determining the parallax of a star are of two kinds. In the one the actual parallax is deduced from the annual change in the right ascension or declination of the star produced by the motion of the earth round the sun, and shown by comparing observations with a meridian instrument of the highest precision. Parallaxes determined in this way are termed absolute. It is now found that, owing to the annual and diurnal changes in the instrument and in the air caused by the varying temperature of night and day, summer and winter, it is impossible to determine precisely, even with the most refined appliances of modern astronomy, variations in the absolute position of a star so minute as its parallax. Efforts to determine absolute parallaxes have therefore been abandoned. The method now in universal use consists in referring the displacement of the star whose parallax is measured to small stars lying in nearly the same direction. The numbers thus obtained are the relative parallax between the star measured and those with which it is compared; and if the stars of comparison are so distant as to have no appreciable parallax, the result will give the actual parallax required. How far this is the case we cannot yet say with certainty; but it is probable that, as a general rule, the stars of comparison have rarely any parallax amounting to a hundredth of a second. In recent times the heliometer has been the most powerful instrument for such determinations; and in the hands of Gill, Elkin, Peter, and others it has been applied in making a revision of many results previously obtained with other instruments, and in investigating suspected new cases of parallax. But at the present time it bids fair to be eventually superseded or even superseded by the photographic telescope. The great advantage of the photographic method lies in the ease with which a plate can be taken and the leisure with which the images of the stars can be measured upon it; the attempts recently made in this direction seem to show that the precision is not markedly less than that attainable by the use of the heliometer.

It is difficult to make a selection of the stars whose parallax can be said to be determined, but, roughly speaking, we may state the number to be 100. Among these are several cases in which the instrument or method of using it was so imperfect that the results are more or less doubtful, and many others in which the apparent parallax is so minute that it is questionable whether the result may not be due to errors of measurement rather than parallax. Such is undoubtedly the case when the result comes out with a negative algebraic sign, as has happened with some apparently good determinations. The following is a list of the determinations which may be regarded as actual, including all which have been made with the heliometer, even when the result is so minute as to be doubtful. The letter *g* signifies that the result is one of an exceptionally good class reached under Gill's direction by the heliometer of the Cape Observatory. The probable error in these cases is generally between 0.01" and 0.02". A colon indicates that the parallax is of a rather doubtful character, needing to be re-determined by modern methods, and two colons that it is among the more doubtful of this class. The results given without any indication may be supposed to be affected by a probable error varying from 0.03" to 0.05".

All that we can say with certainty is that, in the general average, the fainter stars are more distant than the brighter ones in a ratio which admits of approximate determination, a statement which tells us nothing about the actual distance of any single star. More information is afforded by the proper motions of which we shall next speak.

The work of cataloguing the stars and determining their exact positions, which is now being pursued on so large a scale, naturally involves the determinations of their proper motions. Every star may be considered as having a proper motion of its own; but the number for which the proper motion has been determined is comparatively small, because, apart from the results of spectroscopic measurements of motion in the line of sight, which are necessarily extremely limited, the motion can be detected only by a comparison of observations taken at long intervals of time. The longer the interval the slower the motion that may be detected. We have now an interval of more than a century in the case of the stars observed by Bradley at Greenwich, about the year 1750-63, and one of the greater part of a century in the case of several other catalogues. From Auwers's discussion of the Bradley stars, 3240 in number, it appears that a little more than one-half of these objects have a proper motion of 5" per century or more. A little more than one-half of Bradley's stars are easily visible to the naked eye, and the greater part of the remaining half are between the 6th and 7th magnitude. Consequently the conclusions derived from this work apply only to the brighter stars. Speaking in a general way, we may say that about one-half of these stars are known to have a measurable proper motion. In the case of the fainter stars the proportion would undoubtedly be much smaller than this, but it cannot be exactly stated at present. A few stars have a proper motion so abnormally rapid that it could be detected within a single year. Of these the most rapid known up to a recent time was that of Groombridge 1830, pointed out by Argelander. In 1897 Gill and Innes, at the Cape of Good Hope, found a star of yet greater proper motion. This case was carefully investigated by Kapteyn, who, by a comparison of the Cape photographs and Cordoba observations, found the motion to be the greatest yet known. The following is a list of the stars now known to have a proper motion exceeding 3" per year :—

This table presents two notable features. One is the minuteness of many of the stars. That the star having the most rapid motion yet known should be below the 8th magnitude is illustrative of the great range of absolute brightness among the stars. The other feature is that two fourths of the circle of right ascension, namely, those from 5 h. to 11 h. and from 15 h. to 21 h., scarcely

A desideratum of astronomy is a general survey of the heavens with a view of determining all the stars which have an appreciable parallax. Such a survey is now made possible by photography. To carry it out it is necessary to take two or three plates of each region of the heavens at those opposite seasons when the stars in the region have the maximum displacement by parallax in opposite directions. A comparison of the plates then shows whether any such displacement can be detected. The only attempt in this direction which has thus far been carried out was made by Professor Donner at Helsingfors, with the co-operation of Kapteyn, the photographic telescope being that used for the international chart of the heavens. Each plate taken for parallax was exposed three times, at intervals of six months. At the first exposure three images were made on the plate in slightly different positions. At the second, six months later, six images were made in the same way. At the third, a year after the first, three more were made. Thus, twelve impressions of each star were taken, forming together a rectangle of three stars on one side and four on the other. On such a plate the detection of a parallactic displacement is very easy. Unfortunately, only a region little more than 2° square, extending from 20 h. 1 m. to 20 h. 10 m. in right ascension, and from 35° to about 37° in declination, has yet been examined. The plates were carefully measured by Kapteyn. In three or four cases there is some presumption of a parallax of 0.1", but in no case is it so strongly marked as to be beyond doubt. The probable error of a result from each plate is 0.034"; but it is quite in accord with the theory of probabilities that errors of three or four times this amount should occur in one or more of the results. The extremely limited number of stars having a certainly measurable parallax renders it desirable to find other methods of estimating their distances. It was formerly supposed that the actual magnitude of the stars did not differ greatly from each other, and, if that were the case, an approximate estimate of the distance could be obtained from the apparent brightness. But it is now known that this is so far from the case that brightness alone scarcely affords any clue to the distance of a star.

Parallactic survey.

contain any of the sixteen stars, except at their limits. This may be attributed to the effect of the solar motion in exaggerating the apparent motion of stars far from its apex.

A desideratum of the present time is an exact knowledge of how many stars in the heavens have a measurable proper motion, or, in greater detail, how many have proper motions of each order of magnitude. The data for completely solving this question are still wanting, but the most complete attempt in this direction is that of Auwers, who observed the zone of the "Astronomische Gesellschaft," 15° - 20° , at Berlin. He made a comparison of the 8000 stars in his zone with the older observations as far as they were available, and the result was the discovery that 1200 of the stars had proper motions large enough to be detected. Assuming that in the whole heavens the number is proportional to the area, we may regard it as probable that 20,000 stars have a proper motion, extending $5''$ per century. Several astronomers have made catalogues of stars having exceptionally large proper motion; the most thoroughly worked up of these catalogues is that of Porter for 1890, *Publications of the Cincinnati Observatory*, No. 12, but Bossert's in the *Paris Observations* for 1890 contains more stars—2675 in all.

That our sun is to be included among the stars having a proper motion has long been inferred from an apparent motion of the stars in the opposite direction, called the parallactic motion. If we regard the general mean position of the mass of stars as at rest, our solar system is relatively to this mean moving toward a point, now known as the Solar Apex, which was long supposed to be situated in the constellation Hercules. Although the approximate situation of this point has been known since the time of the elder Herschel, yet its exact determination is a matter of extreme difficulty, owing to the diversity of the actual motions of the stars and the irregular distribution of those which have been determined. In the following summary of the results of recent researches, we put A for the right ascension of the apex and D for its declination. Professor Lewis Boss, from 279 stars of large proper motion in the zone 1° to 5° , derived $A=283.3^{\circ}$; $D=+44.1^{\circ}$. This result might be seriously influenced by the introduction of stars of abnormally large motions; had he excluded twenty-six motions exceeding $40''$ per century, the result would have been $A=288.7^{\circ}$; $D=+51.5^{\circ}$. Porter of Cincinnati, and Stumpe of Berlin, have each made determinations based on all the well-determined proper motions available at the time. Porter's list included 1300 stars, Stumpe's 996, the greater number of the stars being common to the two lists. Each investigator classified his material according to the proper motions of the stars. Stumpe excluded all motions less than $16''$ or greater than $128''$ per century. Between these limits they were divided into three groups: Group I., from $16''$ to $32''$; II., from $32''$ to $64''$; III., from $64''$ to $128''$. The separate results were:—

Group I. (551 stars)	$A=287.4$	$D=+45.0$
" II. (339 ")	287.2	43.5
" III. (106 ")	280.2	33.5

Porter (*Ast. Jour.* xii. p. 89) divided his proper motions into four groups: I., those less than $30''$; II., those between $30''$ and $60''$; III., those between $60''$ and $120''$; IV., those exceeding $120''$. The results were:—

Group I. (576 stars)	$A=281.9$	$D=+53.7$
" II. (533 ")	280.7	40.1
" III. (142 ")	285.2	34.0
" IV. (70 ")	277.0	34.9

All three of these agree in the general conclusion that the smaller the proper motions used the greater the declination of the resulting apex, and, in a less degree, the greater its right ascension. But this conclusion needs farther examination before it can be accepted as fully established. Some doubt is thrown upon it by the fact that the position of the solar apex from all the stars of Bradley's catalogues having a small proper motion is $A=274.2^{\circ}$; $D=+31.2^{\circ}$. The discrepancy, especially in the declination of the apex, is far outside the normal limits of error on any probable hypothesis, and suggests the necessity of a more thorough examination of the question than has been made. The general conclusion which may be drawn from these results is that our system is moving toward the constellation Lyra, not Hercules. The point is probably near right ascension 280° and declination $+38^{\circ}$; but there is an uncertainty of several degrees in this position which cannot be removed until an improved method is applied.

An important and interesting point is that of the speed of the motion. The most obvious method of determining this is through the apparent parallactic motion of the stars whose parallaxes have been actually measured. When we see a star at a known distance moving away from the sun's apex with a given angular velocity, the transformation of this given velocity into a linear velocity is extremely simple, and gives the relative velocity between the sun and star. The measure of these results from all the stars included will give the speed of the sun relative to their mean position. In this way, from the list of stars whose parallaxes have already been given, it would follow that the speed in question was 6 radii of the earth's orbit in a year, which would correspond to nearly 28 kilometres per second, about that of the earth in its orbit. But this result has an unavoidable defect arising from the fact that the stars selected for measures of parallax have been those having large apparent proper motions. A star whose actual motion is in the opposite direction to that of the sun will have a large apparent motion, while one moving towards the solar apex may have little or no apparent motion, though its actual angular motion may be the same. In consequence, the selection is biased by including mainly those stars whose absolute motion is away from the apex. Consequently, the result is too large. The speed in question can also be derived from the observed motions in the line of sight or radial motions. Kapteyn has done this by a statistical method. From a study of the apparent angular motions of the stars can be derived the ratio between the velocity of the sun and the mean velocity of the stars in general. This mean velocity is found in linear measure from the observed motions in the line of sight, and its product into the ratio derived from the angular motions gives the actual linear velocity of the sun. The resulting speed of the sun's motion was, in round numbers, 16 kilometres, or 10 English miles, per second. This result is now superseded by a recent research of Campbell, based on 280 radial motions (*Astrophys. Jour.* January 1901), giving a speed of 19.89 ± 1.92 km. This speed is almost exactly 4 radii of the earth's orbit per year.

It will be seen that the apparent proper motion of a star is made up of two components—the actual motion relative to the mean of all the stars, sometimes called the *motus peculiaris*, and the parallactic motion, which is only apparent, being due to the motion of the sun. It has been shown by Stumpe that, when we take a large number of stars and classify them according to their total proper motions, the ratio of the parallactic motion to that peculiar to each star is nearly the same, for large and for small

Speed of
solar
motion.

motions. The former is proportional to the sine of the angular distance of the star from the apex divided by its distance from the earth. It follows from the approach to uniformity in the ratio that the peculiar motions of the stars are also, in the general mean, inversely proportional to their distance from us. Consequently, the actual mean linear velocity of the motion may be taken as the same for stars of various distances, so that the apparent motion will be inversely as the distance. Of course this equality in the general mean by no means implies any approximation to equality in the case of individual stars; yet there is some reason to believe that it is only in exceptional cases that the linear velocity of motion of the stars exceeds a certain limit which it is difficult to fix with precision, but which may be estimated at 40 or 50 kilometres per second. To such a limit there are two remarkable exceptions, one of which has been known for some time, while the other is of recent discovery. Although the proper motion of the star 1830 Groombridge is, with one exception, the greatest of any known, measures of its parallax show that it is by no means among the nearer stars. The combination of the parallax already given with the observed motion indicates a component of linear velocity perpendicular to the line of sight amounting to about 240 kilometres per second. The recent measures of Elkin on the parallax of Arcturus indicate that its linear velocity is probably nearly as great as and possibly much greater than that of the Groombridge star. The parallax found by Elkin was 0.016"; but in view of the fact that other measures, though far less trustworthy, have given a larger value in the table, 0.03" has been assigned as the most probable parallax. This gives a linear velocity of some 350 kilometres per second.

One of the most interesting questions growing out of the proper motions of the stars is whether there is any general law among them which indicates that they move in definite orbits and that the universe as a whole forms a stable system. Up to the present time nothing in the way of a general law has been discovered. In a few cases, some of which are mentioned in the original article in the ninth edition of the *Ency. Brit.*, stars in the same region are found to have a common proper motion, indicating that they may form a system among themselves, but these cases are so exceptional as to prove nothing: the general rule seems to be that the proper motion of a star has no connexion with its location in space or its relation to the universe in general. On no probable hypothesis that we can make respecting the mass of the stars could the attraction of all the known bodies of the universe hold either Arcturus or 1830 Groombridge in an orbit.

Law of proper motion.

Variable Stars.

The study of variable stars has in recent times, in connexion with measures of motions in the line of sight, opened up a new and interesting branch of Sidereal Astronomy, and the number of these objects which have been made the subject of accurate observation is now so great that a classification according to the law and period of the variations is possible. The statistical basis on which such a classification must begin is found in Chandler's catalogues, of which the third was published in the *Astronomical Journal*, vol. xvi. Omitting from our consideration η Argus and other irregularly variable stars, as well as the so-called new stars, we find in that catalogue 280 periodic stars, properly so called; that is, such as go through all their changes in a definite period. Classifying the periods according to the length, we find them to be as follows:—

Periods.	Stars.
Less than 50 days	63
50 to 100 "	6
100 ,, 150 "	9
150 ,, 200 "	18
200 ,, 250 "	29
250 ,, 300 "	40
300 ,, 350 "	44
350 ,, 400 "	44
400 ,, 450 "	18
450 ,, 500 "	6
500 ,, 550 "	1
550 ,, 600 "	1
600 ,, 650 "	1

The most suggestive feature of this table is the well-marked limitation of the period. From the maximum of about 350 days, the number of periods having a given length continually falls off until we reach 610 days. This is the longest yet known. It follows that there is something in the constitution of these bodies, or in the cause on which their variation depends, which limits the period. It was formerly supposed that the eleven-years period in the magnitude and frequency of spots on the sun made the sun a variable star; in fact, that the periodicity of the stars might be due to the same cause as that of the solar spots. But the great length of the sun-spot period, taken in connexion with this limitation, seems to disprove the analogy. Passing up towards the other end of the table we are struck by the rapid falling off towards the limit of 50 days and the great number less than 50 days. It might seem that we have here a sharp line of distinction between the two classes—those of long and those of short period. But an examination of the periods in detail does now show any such line. Eight periods are less than 1 day, and about 40 between 1 and 10 days, and from this point up to 100 days they are scattered with a fair approach to uniformity.

The law of change of a periodic star may be represented graphically by a curve. A straight horizontal line or axis of abscissæ is taken to represent the time, and on it equal spaces represent equal times. At each point upon it an ordinate is erected proportional to the amount of light emitted by the star at the corresponding moment. A curve through the ends of these ordinates is the light curve of the variable star. It will be readily seen that, in the case of a star of constant brightness, the ordinates will all be equal, and the curve will be a straight horizontal line. Whatever the law, if the star be a periodic one, the ordinate will return to the same value at the end of a period, and the continuance of the curve through successive periods will be repetitions of the curve corresponding to the first period. It is therefore only necessary to continue the curve through a single period.

A classification of variable stars has been facilitated by the discovery of the cause of variation in certain classes of the stars of shorter periods. The most distinctive class of such stars are those which remain constant during the greater part of the period, and then temporarily lose a portion of their light, soon to recover it again. The brightest and longest-known of this class being Algol or β Persei, stars which vary in this way are said to be of the "Algol type." The curve of such a type is a straight line with a depression at the end of each period. This feature strongly distinguishes the type from those in which the variation, whatever its law, is continuous, for in those cases, which include a great majority of variable stars, the curve is nowhere a straight line.

The great development of the subject in our times began with the discovery of the cause of the change in the case of stars of the Algol type. Ever since the variability of Algol was observed, it was suspected to be due to a partial eclipse of the star by the

Algol type.

interposition of a dark body nearly as large as the star revolving around it; but this explanation remained only a surmise until Vogel of Potsdam, by repeated measurements of the motion of Algol in the line of sight, showed that the star is always receding from us before the loss of light, and approaching us afterwards. This was so exactly the result that would be produced by the revolution of such a body as that supposed that no doubt could remain on the subject, and by a legitimate induction the variations of all stars of the Algol type are now assumed to be partial eclipses caused by the interposition of a dark companion moving around them. The number of stars of this class is small, only about 12 being yet known. This may be partly due to the difficulty of detecting variations of the type. Owing to the temporary character of the loss of light, the magnitude of such a star might be observed a great number of times without the variation being detected, since it would be noticed only when the observation happened to be made during the partial eclipse. The following list shows the main particulars relating to stars of this type, their positions, periods, magnitudes, and loss of light when eclipsed:—

Variable Stars of the Algol Type.

Name.	Position.		Period.	Magnitude.		Diminution.

Another but analogous type of variation is that of β Lyræ. The characteristic of this type is that in each period there are two equal maxima and two unequal minima. The variation of light is seemingly continuous. G. W. Meyers (*Astrophysical Journal*, vii.) has offered a theory of this type of variation which explains the phenomena so precisely that we cannot seriously doubt its correctness. Two unequal bodies, so near together as to be almost in contact, revolve round each other. By their mutual attraction and the centrifugal force they are drawn out into prolate ellipsoids, each rotating in the same period as that of revolution, so that they revolve as a single mass. Each star partially or wholly eclipses the other in each revolution. When the line of centres is at right angles to our line of sight, the two bodies present to us their greatest apparent surface, and therefore send us their maximum of light. As the line becomes oblique from the revolution they are seen more and more foreshortened, and consequently diminish in brilliancy. Were the two bodies of equal surface brilliancy, the apparent magnitude of minimum would be the same whichever was eclipsed. The inequality of the alternate minima indicates a difference in magnitude and brilliancy. It will seem that this type resembles the Algol type in that the variations of light are due to the different aspects under which a pair of stars is seen as they revolve around each other, and especially by one star of the pair eclipsing the other, and not by any actual changes in the bodies themselves. It is now found that the two types merge into each other by insensible gradations. The principal intermediate type is one in which, calling the two stars A and B, A eclipses B and B

eclipses A at each revolution. In such a case, if the orbits were quite circular, it would be impossible by eye-observation alone to distinguish this type from the Algol type, in which the eclipsing body is dark. But if the orbit is eccentric the alternate minima will occur at unequal intervals. Even if such is not the case, the period may be detected by spectroscopic measures of velocity in the line of sight, if only the star is bright enough to admit of its motion being determined in this way.

Systems of Stars, Clusters, and Nebulæ.

Since 1880 there have been discovered great numbers of double stars, now more properly known as binary systems, which had formerly escaped detection, owing to the difficulty of ascertaining their character with telescopes less perfect than those of our time. Few general facts, however, have been brought out by these discoveries. The advance of our knowledge has mainly consisted in the more accurate determination of the elements of the orbits and the times of revolution of those systems whose period of revolution is less than a century. The trend of recent research is towards extending the conception of systems of stars almost indefinitely in two opposite directions. Since, with every increase of telescopic power, closer binary systems of shorter and shorter periods are found in constantly increasing numbers, we cannot set any limit either to the actual minuteness of such objects or to the shortness of the period. Far within the limit to which telescopic vision can ever extend, such systems are now being brought to light by the spectroscope. These systems appear as a connecting link between certain variable stars on the one hand and the telescopic double stars on the other. Stars of the class to which the Algol type of variables belongs will appear to us to vary in brightness only in the very exceptional cases when the plane of the orbit which one body describes around the other passes so near our sun that the one seems to pass over the other, and so causes an eclipse. In all cases, except those in which the line of sight is nearly perpendicular to the plane of the orbit, the revolution of the two bodies around their common centre of gravity will result in a periodic variation of the motion of each in the line of sight. Such a motion may be detected by the spectroscope. If only one of the two bodies is luminous, its motion will be shown by a periodic change in the displacement of its spectral lines. This, so far as yet known, is the usual case. If both are luminous, especially if they do not differ much in brightness, the motion of revolution will be shown by a periodic doubling of the lines. When, were they visible, they would appear to us in conjunction, their spectra are merged into one, which will show nothing unusual; but if one is moving from us and the other towards us, the spectral lines will be displaced in opposite directions, so that all of the lines strong enough to be seen in both spectra will appear double.

But while there is thus no well-defined inferior limit to the dimensions of systems of two stars, recent research shows that we cannot set any superior limit to the number of stars which may form a system or to the dimensions of such a system. Considering those binary systems whose components are distant from each other, we may, at the first step, meet with a difficulty in deciding whether two stars apparently near each other really form a system, or appear to us together because they happen to be in the same line from us. If their distance is a very few seconds, the presumption would be in favour of a physical connexion. At greater distances the only evidence yet available is found in their relative motion. If the smaller star shares the proper motion of the brighter one, the

Binary systems.

evidence of connexion is nearly conclusive. If it does not, we assume that they are simply two isolated stars. In the article *Astronomy* (*Ency. Brit.* vol. ii. p. 820) it was shown that five stars of *Ursa Major* have a common proper motion, all moving nearly in the same direction and with equal velocity. But though no other case like this has yet been discovered, there are several cases of pairs of stars near each other betraying a relationship by their proper motion, which would never have been suspected on any other ground. The two most remarkable cases of this sort are—(1) a pair of stars in R. A. 15 hours 4 minutes Dec. $-15^{\circ} 54'$, five minutes apart, and (2) *A Ophiuchi*, which has a star of the same proper motion following it about $13'$. It is not unlikely that pairs like these form binary systems with very eccentric orbits and long periods of revolution.

It does not now appear that we can draw any sharp line as regards numbers of stars between the binary systems which we have been considering and clusters whose components are too numerous to be counted. Triple or quadruple stars have long been familiar; of the latter θ *Orionis* in the great nebula of *Orion* affords a typical example. In this case two other stars much more minute belong to the system. Sometimes it is possible to make an actual count of the stars in a cluster, as is the case with *Præsepe*, in *Cancer*, which appears to the naked eye as a nebula, and which the telescope shows to be composed of a definite number of comparatively bright stars. We have also such agglomerations as the great cluster of *Hercules*, where a complete resolution into stars is just possible with the best telescopic power yet reached. The application of photography to these objects has thrown much light on their general character. Many of them have been photographed at the *Harvard Observatory*, but even there it has not always been possible to separate all the individual stars in the densest clusters. Perhaps the most remarkable feature brought out has been the great number of variable stars in some of the clusters. The following statement is extracted from a *Harvard circular* :—

Cluster.	Stars examined.	Number of variables.
ω <i>Centauri</i>	3000	125
<i>Messier 3</i>	900	132
<i>Messier 5</i>	900	185

In all 509 variable stars were found among 19,050 examined in twenty-three clusters, a number which exceeds that known to exist in the rest of the sky. Perhaps the most interesting questions suggested by these cluster systems is that of their stability. On any probable hypothesis that we can make as to the constitution of the individual stars, their mutual attraction must be such as would bring them into a single mass in the course of a few thousand years. Why, then, have they not condensed into such a mass? Perhaps the most plausible answer that can now be made is that the individual stars are all moving in irregular orbits under their mutual attraction. If such be the case, the motion would be made manifest by the comparison of photographs taken at intervals of twenty, fifty, or 100 years.

The questions which have arisen in our time respecting the constitution of various nebulae, the changes which they may undergo, their individual forms, and their relations to the stars seen among them, are so numerous that no discussion of them is possible within our present limits. The greatest addition to our means of knowledge has been made, as in many other cases, by the application of photography. Here the works of *Dr Isaac Roberts, F.R.S.*, and *Dr A. A. Common, F.R.S.*, are worthy of special study; their results are for the most part to be found in the publications of the *Royal*

Astronomical Society. One fact brought out quite recently is the superiority of the reflecting telescope over the refractor in this connexion, owing to the absence of chromatic aberration which, even in the secondary character it assumes in the best refracting telescopes, is very appreciable in the long exposures necessary. The great advantage of photography is due to the fact that, in a clear dark sky, it is possible to obtain images of objects which escape vision. This is the case not only with the smaller stars, but apparently in a still higher degree with the nebulae. Among the most remarkable objects brought out by photography is a great nebulous mass winding through a considerable portion of the constellation *Orion*, first discovered by *W. H. Pickering*, and afterwards confirmed by *Barnard*. Among other remarkable nebulosities of this sort is one in the region of ρ *Ophiuchi*, photographed by *Barnard* in 1894; while a third is the singular nebulosity surrounding the *Pleiades*, carefully studied by *Barnard* (*Monthly Notices R. A. S.* January 1900). Quite recently a surprising number of new nebulae have been photographed by the *Crossley reflector* of the *Lick Observatory*. *Professor Keeler* concludes that, judging from the number of these objects brought out with this instrument, there must be as many as 100,000 in the heavens, an average of between two and three to every square degree. It would, therefore, scarcely be an overstatement to say that the heavens are to be regarded as filled with nebulae. The spectrum of these objects (see *Ency. Brit.* vol. ii. p. 821) seems to show that they are gaseous in constitution, as it consists almost wholly of a very small number of bright lines. An apparent exception is afforded by the great nebula of *Andromeda*, which gives a continuous spectrum; but in interpreting such a spectrum it must be noted that a gaseous mass gives a bright line spectrum only when it is transparent through and through. If the mass is of such size that a ray of light cannot pass through it the spectrum will, in general, be continuous, like that of a solid body. If the superficial portions are cooler and more tenuous than the interior, the continuous spectrum will be crossed by dark lines, as in the case of an incandescent body surrounded by a cool atmosphere. We conclude, therefore, that the continuous character of the spectrum of the *Andromeda nebulae* does not prove it to be composed of solid particles. The transparency of the nebulae in general, which would be evident even without spectroscopic analysis, shows how extremely tenuous these masses are. We cannot seriously doubt that as a general rule their distances from us are at least as great as those of the fixed stars, possibly much greater. In dimensions the most compact of them must far exceed our whole solar system; probably the great majority, even if we omit the diffused masses to which we can assign no definite outline, may exceed the diameter of the orbit of *Neptune* a hundredfold. Yet we have reason to believe that a ray of light would not suffer any sensible absorption, except selectively, in passing through them.

Constitution of the Stars and Structure of the Heavens.

The view that the sun and stars are not bodies fitted to exist for ever in their present form is strengthened by all recent researches on their constitution. They are now regarded as bodies of intensely hot matter in the gaseous state, continually losing energy by the radiation of their heat into space, and therefore contracting in volume. This view was first developed by *J. Homer Lane* in a paper published about 1865 in the *American Journal of Science*; but his results were merely embodied in mathematical formulæ, and not stated with such distinctness as to command attention at the time.

Stellar evolution.

More recently Ritter has developed the subject with great fulness in a series of papers published in the Leipzig *Annalen der Physik und Chemie*. As we have not room for even an abstract of these researches, we can state only what seem to be the most obvious conclusions. That the sun and stars are masses of gas is shown not only by their density, so far as ascertained, but by the fact that solid or liquid masses would cool with such rapidity that they would cease to shine at the end of a few centuries. The superficial portions would first cool and eventually become solid. It was shown by Lane that a mass of gas, held in equilibrium by the mutual attraction of its parts, grows hotter through the loss of energy by radiation, because the temperature gained by the resulting contraction exceeds that lost by the radiation. The effect is analogous to that of a resisting medium upon a planet. The direct result would be to retard the motion of the planet, so that it would fall nearer to the sun, but the velocity gained by the fall would exceed that lost by the resistance. As a planet would go faster by being resisted, so the temperature of a gaseous mass like a star rises as it contracts in volume. This rule ceases to hold when the attraction has become so great that liquefaction takes place, and then the radiation of light by the body is nearly at an end. Another result of the theory is that the greater the mass of a star the higher will be its temperature in a given stage of its development. There may, therefore, be a wide range among the temperatures of the stars, the older and the larger ones generally being the hotter.

The volume of a star is so great that its interior, though gaseous, is not transparent, and it therefore radiates heat only from its superficial portions. These are thus subject to a rapid cooling process; they probably liquefy or solidify, and then by their superior gravity sink into the interior and are replaced by gaseous masses from the interior. Thus a circulation is constantly going on, the hot matter of the interior rising to the surface, and the cool matter of the surface sinking to take its place. A star cannot radiate heat more rapidly than the heat is supplied by this process; consequently, the superficial temperature is limited by the rapidity of circulation, which cannot go on at more than a definite rate, depending on the temperature and the nature of the gas. A necessary result of this view is that each star is constantly contracting in volume, and must continue to do so until the interior becomes liquid or solid. At this stage the increased friction resisting the circulation will result in a continuous fall of the temperature of the surface, which in process of time must cease to radiate light. Recent discoveries give colour to the hypothesis of evolution implied in this view of the physical constitution of stars in general. Their agglomeration into systems is what we should naturally expect as the result of the condensation of irregular nebulous masses.

One of the most suggestive conclusions of recent science is that the stars differ greatly in density, and that, in the large majority of cases, the brighter ones at least are much rarer than the sun, probably even of gaseous density. In the case of the Algol type of variable stars, we can, by the comparison of the duration of the eclipse with the periodic time, form an approximate idea of the size of the star. If the elements of the orbit can be determined, the mass will also become known, and thus we may form an idea of the density. So far as this method has been carried out, the conclusion is that already stated. Revolving double stars, when the elements of the orbit become known, afford evidence that points in the same direction. Knowing the parallax of a star and the elements of the orbit of a companion moving around it, we can determine the mass of the two bodies. Their absolute brilliancy compared with that of

the sun is also known from the parallax and the apparent brilliancy; and it is thus found that, while the mass of Sirius is a little more than double that of the sun, it emits some thirty times as much light. It is now known that a relation between the mass and brilliancy of a double star can be derived from the elements of the apparent orbit without a knowledge of the star's distance. Were all these bodies of the same density and the same intrinsic brilliancy per square mile of surface as the sun, then to every star of a given apparent magnitude, whatever its distance, would correspond a certain relation between the periodic time and the apparent mean distance of a companion revolving around it. Assuming the distance of the companion to be $1''$, its period on this hypothesis is shown for stars of various magnitudes in the following table:—

Magnitude.	Period. y.	Magnitude.	Period. y.
0	0·9	4	14·1
1	1·8	5	28·2
2	3·6	6	56·2
3	7·1	7	112·0

If the apparent mean distance is different from $1''$ the time of revolution is given by Kepler's third law in the form $T^2 = T_1^2 S^3$, S being the mean distance in seconds, and T_1 the period in the above table. In a large majority of double stars whose orbits have been approximately determined it is certain that the time of revolution is much greater than would result from this rule. It follows that the stars in general are either much less dense, or much more brilliant, than the sun. For reasons that we cannot state here it is likely that the former alternative is more usual than the latter. It is remarkable that, in the case of those bright stars the mass of whose faint companions has been determined, the brilliancy of the latter deviates in the opposite direction; their masses are disproportional to their brightness. Thus the mass of the companion of Sirius is nearly half that of Sirius itself, although the latter gives several thousand times as much light as the companion. The same is probably true of the companion of Procyon, and, in a less degree, of η Cassiopeia. It would seem that in these cases the companion, being of the same age as the bright star, has cooled off more rapidly, and perhaps condensed to a solid or liquid.

The variety of spectra among the stars also emphasizes the diversity of their physical constitution. Sir W. Huggins (*Publications of Sir W. Huggins's Observatory*, vol. i. page 75) shows that the evidence of the spectro-scope agrees with the general evolutionary theory. The spectra of the stars may be made to fall into line, so as to form a series, leaving little room for doubt that the actual differences between them represent in the main successive epochs of star life rather than original differences of chemical constitution. When the spectra of close pairs of stars are examined, the difference between the two sets corresponds to the view that the fainter star of the two is in a more advanced stage of condensation.

The problem of the structure of the heavens, if structure they may be said to have, may be regarded as the ultimate one of sidereal astronomy. Branches of this problem are the questions of the physical constitution of the stars, their possible separation into systems, the stability of those systems, and the duration and stability of the universe itself. The central question around which all the others may be grouped is that of the actual distribution of the stars in space. If we could determine the distance of a star as readily as we do its direction from us, this question would be immediately settled, and a geometric model of the universe could be constructed showing its form and

Distribution of the stars.

arrangement. But, with the exception of the few stars whose parallax can be measured, the distances of the individual stars are a matter of extremely vague and uncertain inference, and not even the mean distance of any class or group can be settled definitely by any one method of research.

It will conduce to clearness in bringing out the bearing of various facts on the problem in question if we state its main point in advance. The most definite form in which it may be considered by the astronomer is this:—As, by increasing the power of our telescopes, we see smaller and smaller stars—are the smallest that are brought into view no more distant than others already known; are they within the sphere of others already observed, or, does every increase of telescopic power bring into view stars farther away? To put the question into another shape—Is the universe of stars limited in extent? Intimately associated with this is the question of the actual distribution in space of the stars which we see with our telescopes. Whether the universe is finite or infinite, it is certain that the portion which we see is of finite extent. Has this visible portion a definite boundary, and, if so, what is the figure of this boundary? The statement of this question may suggest a doubt as to the possibility of answering it. Since the range of vision of our telescopes is necessarily limited, is it not necessarily impossible for

Limit of universe.

us to gather evidence of the finitude of the universe? If with every increase of power we see smaller stars of which we cannot estimate the distance, how can we decide that we are not simply penetrating farther into a mass of infinite extent? An answer to this is reached by the following consideration:—So far as stars of various magnitudes have yet been counted there are about three times as many of each order as of the order next brighter. For example, there are three times as many stars of the 7th magnitude as of the 6th, three times more of the 8th, and so on, to at least the 10th or 11th magnitude, a point beyond which the count is uncertain. An individual star of each order gives about four-tenths the light of one of the next brighter order. It follows that the total amount of light which we receive from all the stars of any one order continually increases as we go to the fainter orders, the greater number of the stars more than compensating for the less amount of light received from each. Consequently, if the stars continued indefinitely so would the total amount of light received from them, and the heavens would be filled with a blaze as bright as the sun. As such is not the case, the series must stop. Where the stopping-point is, we cannot exactly say; but, so far as we can judge from appearances, it can go little farther than the count has thus far extended, except perhaps in the Milky Way. We have therefore every reason to believe that by an increase in the power of our telescopes the number of new stars brought into view would begin to diminish, thus showing the total number to be limited. Hence we conclude that the universe of stars which we study has some bounding limit. The question now is, Can we form any conception of the limit and of the arrangement of the universe within it?

Direct observation of the apparent distribution of the stars, irrespective of any question of their arrangement, makes one feature of the universe certain. The stars which compose it are not equally numerous in every direction; a large majority lie in or near the zone of the Milky Way. What follows from this fact may be readily

Form of universe.

seen from Fig. 4, which we conceive to represent a section of the universe by a plane perpendicular to the Milky Way, S being the position of the sun, which, for the moment, we may conceive to be near the centre. What we actually observe is that a

very large majority of the stars are contained within the regions ASB and CSD, while the number contained within the larger angles, BSD and ASC, is relatively

Fig. 4.

small. An indefinite number of arrangements, all consistent with this fact, may be conceived; but they are all in some way intermediate between the following:—

I. All, or at least the great mass of, the stars may be contained between two planes, AC and BD, parallel to the Milky Way. We see more stars in the region ASB and CSD, because there is, so to speak, a greater depth of stars there, while toward M and N we see only a comparatively thin stratum. This was the view developed first by the elder Herschel and then by Struve in his *Etudes d'Astronomie Stellaire*.

II. The actual form of the universe may be spherical, the galaxy being formed by a dense ring of stars around the sphere.

III. The same hypothesis of a universe spherical in general form may be made, but, instead of being a ring, the galaxy is a number of clusters of stars mostly situated near one central plane.

The hypothesis that the boundary of the universe is spherical admits of being tested in a very simple way. Were such the case, the stars would be equally numerous throughout the regions ASC and BSD, the increase in their number beginning only when we reached the boundary of the Milky Way. But all the counts of stars yet made, from the time of Herschel till now, show that the number of stars per square degree continually increases from the two poles of the galaxy to the galaxy itself. Moreover, the rate of increase is as rapid as it would be if the boundary of the universe were two planes parallel to the galactic plane. Unless we make a very improbable hypothesis as to the distribution of the stars around us, this fact must lead us to the conclusion that we actually see to the limits of the universe in all directions away from the galaxy. For, if we did not, the increase in the number of stars in the direction of the galaxy could not be so rapid as it is. It would seem therefore that the first hypothesis of the form of the universe, that of Herschel and Struve, must be at least an approximation to the truth. But that it is not the whole truth will be evident on farther consideration.

We have room only to state in the briefest way the main facts, so far brought to light, on which our conclusion must be based. Beginning with the region immediately around us, what evidence have we of the distribution of the stars, especially of their tendency to condense in the direction of the Milky Way? If we consider that greater brilliancy of the stars implies greater nearness to us, then we should answer this question by considering the relation of the brighter stars to the galaxy. It is a remarkable fact that the condensation towards the galactic zone begins with the brighter stars—we might even say with those of the first magnitude—though we can hardly conceive this to be anything else than the result of accident. From Schiaparelli's maps of the distribution of the stars visible to the naked eye, the position of the Milky Way can be laid down with great exactness. But this

does not show that the condensation in the plane of the Milky Way begins with the nearest stars; it only shows that some of the brighter stars are as far as the Milky Way, and emphasizes the extraordinary difference in their absolute brightness.

As we have already said, the proper motions of the stars afford the best index to their distance. Now it is a remarkable and suggestive fact that, when we make a count of the stars of known proper motion in every direction, we find them to be no more numerous in the region of the Milky Way than elsewhere. It appears therefore that the stars which compose the Milky Way are outside the limits within which proper motion has been detected, and that within these limits the stars are distributed with a fair approach to uniformity. A careful look at the Milky Way, especially the region south of Aquila, will suffice to show that it suggests agglomerations of stars rather than a continuous zone in which there is a uniform distribution of the stars. Moreover, it seems that our system is nearer to this part of the Milky Way than to the opposite; in other words, we are not centrally situated. It is a remarkable fact that in the intervals between the brighter portions of the Milky Way, about 17 hours of right ascension and between 20° and 22° of south declination, we have regions several degrees

square where the stars are comparatively few in number. This is in general true of the openings in this region. We conclude from this that in the latter we have a phenomenon distinct from that of merely increased star density arising from greater depth. Our general conclusions as to the structure of the universe may be summed up in these four propositions:—

1. The general form of the universe of stars to which our sun belongs is that of a flattened cylinder, or extreme oblate spheroid, as was supposed by Herschel and Struve.

2. The phenomenon of the Milky Way is not due alone to the fact that we see more stars in the equatorial regions of this spheroid, but to the fact that this region is occupied through its entire extent by a series of agglomerations of stars, within which space is richer in stars than in the interior where we are situated.

3. Our sun is situated near the central plane of the spheroid, but eccentrically so as to be nearer the boundary in a direction of perhaps 18 hours in right ascension, between the equator and 50° of south declination.

4. It is possible, but not yet certain, that we are so near the galactic stars in this region that we may soon be enabled to discover a proper motion among them.

(S. N.)

Astropalia, classical *Astypalœa*, an island with good harbours, in the south part of the Ægean, situated in 36°5' N. lat. and immediately west of 26°5' E. long. The Roman emperors recognized it as a free state; and in the Middle Ages it was called *Stampalia*, and belonged to the noble Venetian family of Quirini. It was taken by the Turks in the 16th century, and is now noted for its sponges. The customs and dress of the people, who speak a patois of romaic origin, are interesting.

Asua, R. See NILE.

Asunción, or **La Asunción**, capital of the Paraguay Republic, is situated on the left bank of the Paraguay river, in 25° 16' 04" S. lat. and 57° 42' 40" W. long. The population in 1887 was 24,838, but it now exceeds 47,000. Railway communication has been established with Pirapó, and the town is rapidly becoming modernized. It is served by a tramway, has its principal streets lighted by electricity, and is well supplied with telephones. There are a National College, attended by over two hundred students, a public library, and, in the neighbourhood, an agricultural school with a model farm. Near the town, too, are several breweries, tanneries, flour mills, and factories for matches, soap, bricks, earthenware, palm-leaf hats, etc. In 1890 the imports were valued at \$2,725,611 (gold), in 1899 at \$2,147,838; exports were valued at \$2,901,589 in 1890 and \$2,021,023 in 1899. Both imports and exports fluctuate considerably in value. In 1898 in the foreign trade only 418 vessels (mostly "liners") entered, and 408 cleared.

Atbara, R. See ABYSSINIA.

Atchison, the capital of Atchison county, Kansas, U.S.A., in 39° 34' N. lat. and 95° 8' W. long., on the west bank of the Missouri. The river is navigable at this point. The elevation on the river bank is 795 feet, most of the city being situated at a higher level. The

city is divided into five wards, is regularly laid out, supplied with water by pumping from Missouri river, and is well drained. It is entered by four great railways, the Atchison, Topeka and Santa Fé, the Chicago, Burlington and Quincy, the Chicago, Rock Island and Pacific, and the Missouri Pacific. It is the site of Midland and St Benedict colleges. Founded in 1854, it at once grew rapidly, and four years later it received a city charter. Population (1880), 15,105; (1890), 13,963; (1900), 15,722.

Ath, a town of Belgium, in the province of Hainaut, on the river Dender, about 30 miles by rail from Brussels. The tower of the church of Saint-Julien now lacks the high spire for which it was noted, and the ancient Tour du Burbant has become ruinous. Population (communal) (1880), 9301; (1890), 9868; (1897), 10,646.

Athabasca (*Athapescow* or *Elk*), a river of Alberta and Athabasca districts, Canada, rises in the Rocky Mountains in 52° 10' N. lat. and 117° 10' W. long., and flows in a north-easterly direction into the lake of the same name. It is 740 miles long and has a number of important tributaries, including the McLeod, Pembina, Lesser Slave, and Clearwater. *Athabasca Lake* is 195 miles long, W. to E., from 20 to 32 miles wide, has an area of 3085 square miles, and is at an altitude of 690 feet above the sea. Shallow-draught steamers navigate the lake and river and Lesser Slave Lake and River with one interruption—at Grand Rapids near the mouth of the Clearwater river.

FOR ATHABASCA DISTRICT SEE NORTH-WEST TERRITORIES.

Athenry, an inland town in the county of Galway, Ireland, 14 miles E. of Galway, on the Midland Great Western railway. The old Dominican monastery was extensively repaired by the Board of Works in 1893. Population, 910.

ATHENS.

I.—ANCIENT ATHENS.

RECENT investigation on scientific lines has thrown a new and unexpected light on the art, the monuments, and the topography of ancient Athens. Numerous and costly excavations have been carried out by the Greek Government and by native and foreign scientific societies, while accidental discoveries have been frequently made during the building of the modern town. The museums, enriched by a constant inflow of works of art and inscriptions, have been carefully and scientifically arranged, and afford opportunities for systematic study denied to scholars of the past generation. Improved means of communication have enabled many acute observers to apply the test of scrutiny on the spot to theories and conclusions mainly based on literary evidence; five foreign schools of archæology, directed by eminent scholars, lend valuable aid to students of all nationalities, and lectures are frequently delivered in the museums and on the more interesting and important sites. The native archæologists of the present day hold a recognized position in the scientific world; the patriotic sentiment of former times, which prompted their zeal but occasionally warped their judgment, has been merged in devotion to science for its own sake, and the supervision of excavations, as well as the control of the art-collections, is now in highly competent hands. Athens has thus become a centre of learning, a meeting-place for scholars, and a basis for research in every part of the Greek world. The attention of many students has naturally been concentrated on the ancient city, the birthplace of European art and literature, and a great development of investigation and discussion in the special domain of Athenian archæology has given rise to a voluminous literature. Many theories hitherto universally accepted have been called in question or proved to be unsound: the views of Leake, for instance, have been challenged on various points, though many of the conclusions of that great topographer have been justified and confirmed by modern research. The supreme importance of a study of Greek antiquities on the spot, long understood by scholars on the Continent and in America, is gradually coming to be recognized in England, where a close attention to ancient texts, not always adequately supplemented by a course of local study and observation, has hitherto fostered a peculiarly conservative attitude in regard to the problems of Greek archæology. Since the foundation of the German Institute in 1874, Athenian topography has to a large extent become a speciality of German scholars, among whom Wilhelm Dörpfeld occupies a pre-eminent position owing to his great architectural attainments and unrivalled local knowledge. Many of his bold and novel theories have provoked strenuous opposition, while others have met with general acceptance, except among scholars of the more old-fashioned type.

Prehistoric Athens.—Numerous traces of the "Mycenæan" epoch have recently been brought to light in Athens and its neighbourhood. Among the monuments of this age discovered in the surrounding districts are the rock-hewn tombs of

The early citadel.

Spata, accidentally revealed by a landslip in 1877, and the domed sepulchre at Menidi, near the ancient Acharnæ, excavated by Lolling in 1879. Other "Mycenæan" landmarks have been laid bare at Eleusis, Thoricus, Halæ, and Aphidna. These structures, however, are of comparatively

minor importance in point of dimensions and decoration; they were apparently designed as places of sepulture for local chieftains, whose domains were afterwards incorporated in the Athenian realm by the *συννοικισμός* attributed to Theseus. The situation of the Acropolis, dominating the surrounding plain and possessing easy communication with the sea, favoured the formation of a relatively powerful state—inferior, however, to Tiryns and Mycenæ; the myths of Cecrops, Erechtheus, and Theseus bear witness to the might of the princes who ruled in the Athenian citadel, and here we may naturally expect to find traces of massive fortifications resembling in some degree those of the great Argolid cities. Such, in fact, have been brought to light by the recent excavations on the Acropolis (1885-1889). Remains of primitive polygonal walls which undoubtedly surrounded the entire area have been found at various points a little within the circuit of the existing parapet. The best preserved portions are at the eastern extremity, at the northern side near the ancient "royal" exit, and at the south-western angle. The course of the walls can be traced with a few interruptions along the southern side. On the northern side are the foundations of a primitive tower and other remains, apparently of dwelling-houses, one of which may have been the *πικινὸς δόμος Ἐρεχθίδος* mentioned by Homer (*Od.* vii. 81). Among the foundations were discovered fragments of "Mycenæan" pottery. The various approaches to the citadel on the northern side—the rock-cut flight of steps north-east of the Erechtheion, the stairs leading to the well Clepsydra, and the intermediate passage supposed to have furnished access to the Persians—are all to be attributed to the primitive epoch. Two pieces of polygonal wall, one beneath the bastion of Nike Apteros, the other in a direct line between the Roman gateway and the door of the Propylæa, are all that remain of the primitive defences of the main entrance.

These early fortifications of the Acropolis, ascribed to the primitive non-Hellenic Pelasgi, must be distinguished from the Pelasgicum or Pelargicum, which

The Pelasgicum.

was in all probability an encircling wall, built round the base of the citadel and furnished with nine gates from which it derived the name of Enneapylon. Such a wall would be required to protect the clusters of dwellings around the Acropolis as well as the springs issuing from the rock, while the gates opening in various directions would give access to the surrounding pastures and gardens. This view, which is that of Curtius, alone harmonizes with the statement of Herodotus (vi. 137) that the wall was "around" (*περί*) the Acropolis and that of Thucydides (ii. 17) that it was "beneath" (*ὑπό*) the fortress. Thus it would appear that the citadel had an outer and an inner line of defence in pre-historic times. The space enclosed by the outer wall was left unoccupied after the Persian wars in deference to an oracular response apparently dictated by military considerations, the maintenance of an open zone being desirable for the defence of a citadel. A portion of the outer wall has been recognized in a piece of primitive masonry discovered near the Odeion of Herodes Atticus; other traces will probably come to light when the northern and eastern slopes of the Acropolis have been completely explored. Leake, whom Frazer follows, assumed the Pelasgicum to be a fortified space at the western end of the Acropolis; this view necessitates the assumption that the nine gates were built one within the other, but early

antiquity furnishes no instance of such a construction; Dörpfeld believes it to have extended from the grotto of Pan to the sacred precinct of Asclepius. The well-known passage of Lucian (*Piscator* 47) cannot be regarded as

PLAN OF ATHENS AND ENVIRONS.

decisive for any of the theories advanced, as any portion of the old *enceinte* dismantled by the Persians may have retained the name in later times.

To the Pelagic era may also be referred (with Curtius

and Milchhöfer) the terraces of the Pnyx with the wall of massive masonry supporting the lower platform: the theory of these scholars, however, that the whole precinct was a sanctuary of the *The Pnyx.*

Pelasgian Zeus cannot be regarded as proved, nor is it easy to abandon the generally received view that this was the scene of the popular assemblies of later times, notwithstanding the apparent unsuitability of the ground and insufficiency of room for a large multitude. These difficulties are met by the assumption that the Cyclopean retaining-wall rose to a considerable height, supporting a theatre-like structure capable of seating many thousand persons. The pre-historic rock-dwellings in this neighbourhood (the quarter of Melite) have been found to extend to a considerable distance towards the S.E. in the direction of Phaleron.

The Hellenic Period.—While modern research has added considerably to our knowledge of pre-historic Athens, a still greater light has been thrown on the architecture and topography of the city in the earlier historic or “archaic” era, the subsequent age of Athenian greatness, and the period of decadence which set in with the Macedonian conquest. We must here group these important epochs together, as distinguished from the later period of Roman rule, and confine ourselves to a chronological record of the principal discoveries by which they have been illustrated in recent years.

In 1870, the Greek Archæological Society undertook a series of excavations in the Outer Cerameicus, which had already been partially explored by various scholars. The operations, which were carried on at intervals until 1890, resulted in the discovery of the Dipylon Gate, the principal entrance of ancient Athens. The Dipylon consists of an outer and an inner gate separated by an oblong courtyard and flanked on each side by towers; the gates were themselves double, being each composed of two apertures intended for the incoming and outgoing traffic. An opening in the city wall a little to the south-west, supposed to have been the Sacred Gate (*ἱερὰ πύλη*), was in all probability an outlet for the waters of the Eridanus. This stream, which has hitherto been regarded as the eastern branch of the Ilissus rising at Kæsariæ, has been identified by Dörpfeld with a brook descending from the southern slope of Lycabettus and conducted in an artificial channel to the north-western end of the city, where it made its exit through the walls, eventually joining the Ilissus. The channel was open in Greek times, but was afterwards covered by Roman arches; it appears to have served as the main drain of the city. Between this outlet and the Dipylon were found a boundary-stone, inscribed *ὄρος Κεραμεικοῦ*, which remains in its place, and the foundations of a large rectangular building, possibly the Pompeion, which may have been a robing-room for the processions which passed this way. On both sides of the Dipylon the walls of Themistocles, faced on the outside by a later wall, have been traced for a considerable distance. The excavation of the outlying cemetery revealed the unique “Street of the Tombs” and brought to light a great number of sepulchral monuments, many of which remain *in situ*. Especially noteworthy are the *stelæ* or reliefs representing scenes of leave-taking, which, though often of simple workmanship, are characterized by a touching dignity and restraint of feeling. In this neighbourhood were found a great number of 7th century tombs containing pottery with geometric designs. A considerable portion of the district remains unexplored.

Within the same period was carried out the complete excavation of the Dionysiac theatre. The site, which had been accurately determined by Leake, was explored by Strack in 1862, and the researches subsequently undertaken by the Greek Archæological Society were concluded in 1879. It was not,

however, till 1886 that traces of the original Greek orchestra were pointed out by Dörpfeld. The arrangement of the stage and orchestra as we now see them belong to Roman times; the *cavea* or auditorium dates from the administration of the orator Lycurgus (337-323 B.C.), and nothing is left of the theatre in which the plays of Æschylus and Sophocles were acted, save a few small remnants of polygonal masonry. These, however, are sufficient to mark out the circuit of the ancient orchestra, on which the subsequently-built *proscenium* encroached. The oldest stage-building was erected in the time of Lycurgus; it consisted of a rectangular hall with square projections (*παρασκήνια*) on each side; in front of this was built in late Greek or early Roman times a stage with a row of columns which intruded upon the orchestra space; a later and larger stage, dating from the time of Nero, advanced still further into the orchestra, and this was finally faced (probably in the 3rd century A.D.) by the “*bema*” of Phædrus, a platform-wall decorated with earlier reliefs, the slabs of which were cut down to suit their new position. The remains of two temples of Dionysus have been found adjoining the stoa of the theatre, and an altar of the same god adorned with masks and festoons: the smaller and earlier temple probably dates from the 6th century B.C., the larger from the end of the 5th or the beginning of the 4th century.

Immediately west of the theatre of Dionysus is the sacred precinct of Asclepius, which was excavated by the Archæological Society in 1876-78. Here were discovered the foundations of the celebrated *The Asclepieion*, together with several inscriptions and a great number of votive reliefs offered by grateful invalids and valetudinarians to the god of healing. Many of the reliefs belong to the best period of Greek art. A Doric colonnade with a double row of columns was found to have extended along the base of the Acropolis for a distance of 54 yards; behind it in a chamber hewn in the rock is the sacred well mentioned by Pausanias. The colonnade was a place of resort for the patients; a large building close beneath the rock was probably the abode of the priests.

The great excavations on the Acropolis, begun in November 1885 and completed in December 1888, rank among the most surprising achievements of modern research. The results of these operations, which were conducted by the Archæological Society under the direction of Kavvadias and Kawerau, must be summarized with the utmost brevity. The great deposits of sculpture and pottery now unearthed, representing all that escaped from the ravages of the Persians and the burning of the ancient shrines, afford a startling revelation of the development of Greek art in the 7th and 6th centuries. Numbers of statues—among them a series of draped and richly-coloured female figures—masterpieces of painted pottery, only equalled by the Attic vases found in Magna Græcia and Etruria, and numerous bronzes, were among the treasures of art now brought to light. All belong to the “archaic” epoch; only a few remains of the greater age were found, including some fragments of sculptures from the Parthenon and Erechtheion. Among the inscriptions now discovered was a record of the gold and ivory bought for the great statue of Athena Parthenos, which enables us to determine the ratio of silver to gold in the age of Phidias. We are principally concerned, however, with the results which add to our knowledge of the topography and architecture of the Acropolis. The entire area of the summit was now thoroughly explored, the excavations being carried down to the surface of the rock, which on the southern

Progress of research 1870-74. The Dipylon.

Complete excavation of the Acropolis, 1885-88.

The Dionysiac theatre.

side was found to slope outwards to a depth of 14 metres. In the lower strata were discovered the remnants of Cyclopean or pre-historic architecture already mentioned.

The foundations of the Parthenon were now for the first time completely investigated, as well as the area of the interior. The huge substruction, probably built under Cimon's administration soon after the Persian war, is 250 feet long by 105 feet broad; it was designed for a longer and somewhat narrower building than the Parthenon, the stylobate of which measures 228 feet by 101. This earlier or Cimonian temple, which was never finished, was of Pentelic marble, with eight columns at the ends and nineteen at the sides; only some of the lower drums, which are unfluted, have been found, and there is nothing to show that an upper portion ever existed. With regard to the interior of the

Parthenon much controversy exists; the western compartment, which corresponds to the opisthodomos in other temples, appears to have been the Παρθενών proper or "maiden's chamber," and like the eastern compartment, or "Hekatompedon," to have given its name to the whole building; the arrangement and interpretation of the sculptures have also been a fertile theme for discussion. For details regarding the Parthenon and the older temple the special authorities enumerated in the bibliography should be consulted. In the deep interval between the substruction and the south wall of the Acropolis ran a long retaining-wall constructed for temporary use during the building of the temple. The lower portion of the substruction is believed by Penrose to have been the foundation of the ancient "Hekatompedon" destroyed by the Persians. The name was subsequently applied to the cella or eastern chamber of the Parthenon, which is exactly

PLAN OF THE ACROPOLIS, ATHENS. (By permission of the Hellenic Society.)

 Cyclopean Masonry.

100 feet long, and also became a popular designation of the temple itself.

The ancient Hekatompedon, however, may in all probability be identified with an early temple, also 100 feet long, the foundations of which were pointed out in 1885 by Dörpfeld on the ground immediately adjoining the south side of the Erechtheion.

On this spot was apparently the primitive sanctuary of Athena, the rich temple (πίων νηός) of Homer, in which the cult of the goddess was associated with that of Erechtheus (*Il.* ii. 549); the Homeric temple is identified by Furtwängler with the "compact house of Erechtheus" (*Od.* vii. 81), which, he holds, was not a royal palace but a place of worship, and traces of it may perhaps be recognized in the fragments of prehistoric masonry enclosed by the existing foundations. The foundations seem to belong to the 7th century, except those of the colonnade, which was added possibly by Pisistratus. According to Dörpfeld, this was the "old temple" of Athena Polias, frequently mentioned in literature and inscriptions, in which was housed the most holy image or εἶδον of the goddess which fell from heaven; it was burnt, but not completely destroyed, during the Persian war, and some of

its external decorations were afterwards built into the north wall of the Acropolis; it was subsequently restored, he thinks, with or without its colonnade—in the former case a portion of the peristyle must have been removed when the Erechtheion was built so as to make room for the porch of the maidens; the building was set on fire in 406 B.C. (*Xen. Hell.* i. 6. 1), and the conflagration is identical with that mentioned by Demosthenes (*In Timocr.* xxiv. 155); its opisthodomos served as the Athenian treasury in the fifth and fourth centuries; the temple is the ἀρχαῖος νεὸς τῆς Πολιάδος mentioned by Strabo (ix. 16), and it was still standing in the time of Pausanias, who applies to it the same name (i. 27. 3). The conclusion that the foundations are those of an old temple burnt by the Persians has been generally accepted, but other portions of Dörpfeld's theory—more especially his assumption that the temple was restored after the Persian war—have provoked much controversy. Thus J. G. Frazer maintains the hitherto current theory that the earliest temple of Athena and Erechtheus was on the site of the Erechtheion; that the Erechtheion inherited the name ἀρχαῖος νεὸς from its predecessor, and that the "opisthodomos" in which the treasures were kept was the west chamber of

the Parthenon; Fürtwangler and Milchhöfer hold the strange view that the "opisthodomos" was a separate building at the east end of the Acropolis, while Penrose thinks the building discovered by Dörpfeld was possibly the Cecropeion. Curtius and J. W. White, on the other hand, accept Dörpfeld's identification, but believe that only the western portion of the temple, or opisthodomos, was rebuilt after the Persian war. Admitting the identification, we may perhaps conclude that the temple was repaired in order to provide a temporary home for the venerated image and other sacred objects: no traces of a restoration exist, but the walls probably remained standing after the Persian conflagration. The removal of the ancient temple was undoubtedly intended when the Erechtheion was built, but superstition and popular feeling may have prevented its demolition and the removal of the *ἑόρατον* to the new edifice. The temple consisted of an eastern cella with pronaos; behind this was the opisthodomos, divided into three chambers—possibly treasuries—with a portico at the western end. The peristyle, if we compare the measurements of the stylobate with those of the drums built into the wall of the Acropolis, may be concluded to have consisted of six columns at the ends and twelve at the sides.

The internal arrangements of the Erechtheion are still a subject of controversy. The peculiar design of the temple is attributable to the necessity imposed on the architect of including within the building a number of sacred places, and combining several cults. Within its precincts Pausanias (i. 26. 5) found altars to Poseidon, with whose worship that of Erechtheus was associated, to the hero Butes and to Hephæstus, also a well of salt water and the imprint of Poseidon's trident. Whether he also found here the ancient image of Athena and her ever-burning lamp is open to doubt owing to the vagueness of his language; he may mean to attribute these objects either to the Erechtheion or to the old temple adjoining it. If he places them in the Erechtheion that name can strictly apply to only a portion of the existing building, the remainder of the temple, which he describes as "double," being the "sanctuary of Athena" (*ναὸς τῆς Πολιάδος*) which he subsequently mentions. On this assumption the eastern and larger chamber of the Erechtheion has generally been identified with the shrine of Athena Polias. The western chamber adjoining the porch of the Maidens may possibly have contained the tomb of Cecrops, and the altars mentioned by Pausanias; the identification of the rock-hewn cistern beneath the pavement in this compartment with the salt well of Erechtheus is very doubtful. The mark of the trident is in the crypt beneath the north portico. The beautiful north door of the temple is held by E. Gardner and R. Schultz (*Journal Hell. Stud.* 1891) not to be identical with the original one, the present heavy door-jamb and the lintel being restorations.

The excavation of the Pandroseion or temenos of Pandrosos, the daughter of Cecrops, which adjoins the Erechtheion on the west, has revealed no traces of a temple. The site of this precinct, in which the sacred olive tree of Athena grew, has been almost certainly fixed by an inscription found in the bastion of Odysseus. At its north-western extremity is a platform of levelled rock which may have supported the altar of Zeus Hypsistus. The excavation of the ground immediately west of the Parthenon brought to light the remains of a large rectangular building, apparently fronted by a colonnade. This has been identified with the Chalcotheke, a storehouse of bronze implements and arms, which was formerly supposed to lie against the north wall near the Propylæa. The site was

hitherto erroneously believed to be the temenos of Athena Ergane. The adjoining temple of Nike is proved by an inscription found in 1896 to have been built before the Propylæa.

During the course of the excavations on the Acropolis the bastion built by the Greek chieftain Odysseus, to protect the staircase leading down to the well Clepsydra below the north-western cliff, was ^{Removal of historic} demolished. The "Tower of the Franks," ^{monuments.} an interesting remnant of the Middle Ages which stood near the temple of Nike, had been taken down in 1874, despite the protests of Freeman, Penrose, and other scholars. The projected removal of the Turkish minaret in the south-west corner of the Parthenon has happily not been carried out; its preservation is essential to the stability of the adjoining masonry.

In 1892 Dörpfeld began a series of excavations in the district between the Acropolis and the Pnyx with the object of determining the situation of the ^{Excavations in 1892-98.} buildings described by Pausanias as existing in the neighbourhood of the Agora, and more especially the position of the Enneacrunus fountain. The Enneacrunus has hitherto been generally identified with the spring Callirrhoe in the bed of the Ilissus, a little to the south-east of the Olympieion; it is apparently placed by Thucydides (ii. 15) in proximity to that building, as well as the temple of Dionysus *ἐν λίμναις* and other shrines which he mentions as situated to the south of the Acropolis. On the other hand Pausanias (i. 14. 1), who never deviates without reason from the topographical order of his narrative, mentions the Enneacrunus in the midst of his description of certain buildings which were undoubtedly in the region of the Agora, and unless he is guilty of an unaccountable digression the Enneacrunus which he saw must have lain west of the Acropolis. It is now generally agreed that the Agora of classical times covered the low ground between the hill of the "Theseion," the Areopagus, and the Pnyx; and Pausanias, in the course of his description, appears to have reached its southern end. The excavations revealed a main road of surprisingly narrow dimensions winding up from the Agora to the Acropolis. A little to the south-west of the point where the road turns towards the Propylæa was found a large rock-cut cistern or reservoir which Dörpfeld identifies with the Enneacrunus. The reservoir is supplied by a conduit of 6th-century tiles connected with an early stone aqueduct, the course of which is traceable beneath the Dionysiac theatre and the royal garden in the direction of the upper Ilissus. These elaborate waterworks were, according to Dörpfeld, constructed by the Pisistratids in order to increase the supply from the ancient spring Callirrhoe; the fountain was furnished with nine jets, and henceforth known as Enneacrunus. This identification has been hotly contested by many scholars, and the question must still be regarded as undecided. An interesting confirmation of Dörpfeld's view is furnished by the map of Guillet and Coronelli, published in 1672, in which the Enneacrunus is depicted as a well with a stream of running water in the neighbourhood of the Pnyx. The fact that spring water is not now found in this locality is by no means fatal to the theory: recent engineering investigations have shown that much of the surface water of the Attic plain has sunk to a lower level. In front of the reservoir is a small open space towards which several roads converge; close by is a triangular enclosure of polygonal masonry, in which were found various relics relating to the worship of Dionysus, a very ancient wine-press (*Ληνός*), and the remains of a small temple. Built over this early precinct, which Dörpfeld identifies with the Dionyseion *ἐν λίμναις*, or Lenæon, is a

basilica-shaped building of the Roman period, apparently sacred to Bacchus: in this was found an inscription containing the rules of the society of the Iobacchi. There is an obvious difficulty in assuming that *λίμναι*, in the sense of "marshes," existed in this confined area, but stagnant pools may still be seen here in winter. Another enclosure, a little to the south, is proved by an inscription to have been a sanctuary of the hitherto unknown hero Amynus, with whose cult those of Asclepius and the hero Dexion were here associated; under the name Dexion, the poet Sophocles is said to have been worshipped after his death. The whole district adjoining the Areopagus was found to have been thickly built over. The remains of the *Stoa Basileios*, in which the Archon Basileus held his court and the Areopagus Council sat, were perhaps brought to light in the winter of 1897-98, when the excavations were extended to the eastern slope of the "Theseion" hill. Here was found a rectangular structure resembling a temple, but with a side door to the north: it possessed a portico of six columns. The north slope of the Areopagus, where a number of early tombs were found, was also explored, and the limits of the Agora on the south and north-west were approximately ascertained. A portion of the main road leading from the Dipylon to the Agora was discovered.

In 1896 excavations with the object of exploring the whole northern and eastern slopes of the Acropolis were begun by Kavvadias. The pathway between the citadel and the Areopagus was found to be so narrow that it is certain the Panathenaic procession cannot have taken this route to the Acropolis. On the north-west rock the caves known as the grottoes of Pan and Apollo were cleared out: these consist of a slight high-arched indentation immediately to the east of the Clepsydra and a double and somewhat deeper cavern a little farther to the east. In the first mentioned are a number of niches in which *πίνακες* or votive tablets were placed: some of these offerings, inscribed with dedications to Apollo, have been discovered. The whole locality was the seat of the ancient cult of this deity, afterwards styled "Hypakraeos," with which was associated the legend of Creusa and the birth of Ion. The worship of Pan was introduced after the Persian wars, in consequence of an apparition seen by Pheidippides, the Athenian courier, in the mountains of Arcadia. Another cave more to the west was revealed by the demolition of the bastion of Odysseus. To the east a much deeper and hitherto unknown cavern has been revealed, which Kavvadias identifies with the grotto of Pan. Close to it are a series of steps hewn in the rock which connect with those discovered in 1836 within the Acropolis wall. Farther east is an underground passage leading eastwards to a cave supposed to be the sanctuary of Aglaurus; with this passage is connected a secret staircase leading up through a cleft in the rock to the precinct of the Errephori on the Acropolis. It is conceivable that the priestesses employed this exit when descending on their mysterious errand.

The Cynosarges, from earliest times a sanctuary of Heracles, later a celebrated gymnasium and the school of Antisthenes the Cynic, has hitherto been generally supposed to have occupied the site of the Monastery of the Angels (*Asomati*) on the eastern slope of Lycabettus; its situation, however, has been fixed by Dörpfeld at a point a little to the south of the Olympieion, on the left bank of the Ilissus. Here a series of excavations, carried out by the British School in 1896-97 under the direction of Cecil Smith, revealed the foundations of an extensive Greek building, the outlines of which correspond with those of a gymnasium; it possessed a large bath or

cistern, and was flanked on two sides by water-courses. An Ionic capital found here possibly belonged to the palæstra. The identification, however, cannot be regarded as certain in the absence of inscriptions. To the north-east were found the remains of a very large rectangular structure of the Roman epoch, bearing a striking resemblance in design and construction to the "Stoa," or Library of Hadrian, situated to the north of the Acropolis: this may in all probability be identified with the Gymnasium of Hadrian, the position of which was hitherto entirely unknown.

The Roman Period.—The most important achievement of recent research with regard to the Roman period has been the uncovering of the new or Roman Agora. In 1890 and 1891 the ground immediately to the west of the "Tower of the Winds" was excavated by the Archæological Society, and though the operations have been interrupted, owing to the difficulty of expropriating the neighbouring owners, the dimensions of the Agora have been practically ascertained. It consisted of an open square surrounded by an Ionic colonnade, into which opened a number of shops or storehouses. The eastern gate was adorned with four Ionic columns on the outside and two on the inside, the western entrance being the well-known portico of Athena Archegetis. The whole conclave may be compared with the enclosed bazaars or khans of Oriental cities, which are usually locked at night. Immediately to the north of the new Agora is a vast rectangular building of Roman date, the eastern side of which was explored in 1885-86. A portion of its western front, adorned with monolith unfluted Corinthian columns, is still standing—the familiar "Stoa" of Hadrian; another well-preserved portion, with six pilasters, runs parallel to the west side of Æolus Street. The interior consisted of a spacious court surrounded by a colonnade of 100 columns, into which five chambers opened at the eastern end. A portico of four fluted Corinthian columns on the western side formed the entrance to the quadrangle. This cloistered edifice may be identified with the library of Hadrian mentioned by Pausanias; the gymnasium, which he tells us also possessed 100 columns, being probably the building discovered by the British School near the Ilissus: the books were, perhaps, stored in a square building which occupied a portion of the central area. In 1883 the substructure of the gigantic Olympieion was excavated by Penrose, who proved the correctness of Dörpfeld's theory that the building was octostyle; it possessed 104 Corinthian columns, of which 48 stood in triple rows under the pediments, and 56 in double rows at the sides. Fragments of Doric columns and foundations were discovered, probably belonging to the temple begun by Pisistratus, the orientation of which differed slightly from that of the later structure. In 1898 the peribolos of the temple was excavated without important results: it is to be hoped that the stability of the columns has not been affected by the operations. Numerous Roman mosaics and other remains had already been found in the adjoining public garden over which the "city of Hadrian" extended. Excavations round the monument of Philopappus on the Museion Hill showed that the structure was nearly square, the curved front still remaining being only a portion of the building. On the Acropolis the foundations of the little circular temple of Rome and Augustus were laid bare during the excavations of 1885-88: the temple was of white marble, and had a peristyle of nine Ionic columns. An inscription in bronze letters, attached in A.D. 61 to the eastern architrave of the Parthenon, has been successfully recovered by E. Andrews of the American School. The letters and the nails by which they were fastened have disappeared, but an accurate observation of the nail-marks enabled the

The Grottoes of Pan and Apollo.

The Cynosarges and gymnasium of Hadrian.

shapes of the letters to be determined. The inscription apparently records the erection of some monument by the Athenians in honour of the Emperor Nero.

The Parthenon escaped without serious injury from the earthquakes of 1894. A piece of one of the drums of a column on the north side fell to the ground and a portion of one of the blocks in the architrave of the opisthodomos. These injuries, however, fortunately attracted attention to the condition of the building. A committee composed of Greek and foreign architects was appointed to superintend the necessary repairs, and the opinion of three distinguished authorities, Joseph Durm, L. Magne, and F. C. Penrose, was invited. It was wisely decided to abstain from any attempt at restoration and only to employ new material when necessary for the preservation of the existing remains. The repairs were begun in 1896 under the supervision of the Greek architect Balanos. It was found that several of the blocks in the architrave of the opisthodomos were in a very defective condition, probably owing to the action of fire at some past time. One of these, which supported two slabs of the Panathenaic frieze, has been replaced by new marble, and the delicate operation of removing and readjusting the sculptured slabs has been successfully carried out. Others of the blocks have been carefully pieced as well as some of the capitals of the inner row of columns. The broken lintel of the great western door will be replaced with a large new stone, and the brick masonry which encumbers the doorway will be removed. The operations, which were interrupted by the war of 1897, will probably extend over several years. It is proposed to clean out the crevices in the upper parts of the building and to fill them with cement or lead, special care being taken to prevent the percolation of rain water. The Panathenaic frieze has already suffered considerably from exposure to the weather. As the proposal to remove the sculptures to a museum and to replace them by casts will hardly be entertained, steps should be taken to protect them against rain and also to render them accessible to close inspection.

II. MODERN ATHENS.

At the conclusion of the War of Independence, Athens was little more than a village of the Turkish type, the poorly-built houses clustering on the northern and eastern slopes of the Acropolis. The narrow, crooked lanes of this quarter still contrast with the straight, regularly laid-out streets of the modern city, which extends to the north-west, north, and east of the ancient citadel. The greater commercial advantages offered by Nauplia, Corinth, and Patras were outweighed by the historic claims of Athens in the choice of a capital for the newly-founded kingdom, and the seat of government was transferred hither from Nauplia in 1834. The new town was, for the most part, laid out by the German architect Schaubert. It contains several squares and boulevards, a large public garden, and many handsome public and private edifices. A great number of the public institutions owe their origin to the munificence of patriotic Greeks, among whom Andreas Syngros and George Averoff may be especially mentioned. The royal palace, designed by Gärtner, is a tasteless structure; attached to it is a beautiful garden laid out by Queen Amalia, which contains a well-preserved mosaic floor of the Roman period: the grounds, together with the adjoining public garden, lie within the boundaries of the ancient Hadrianopolis, or *Neve Athenæ*. On the S.E. is the newly-built palace of the Crown Prince. The Academy, from designs by Hansen, is constructed of Pentelic marble in the Ionic style: the colonnades and pediments are richly coloured and gilded, and may perhaps convey some idea of the ancient style of decoration. Close by is the University, with a colonnade adorned with paintings, and the Vallianean Library with a handsome doric portico of Pentelic marble. The Observatory, which is connected with the University, stands on the summit of the Hill of the Nymphs; like the Academy, it was erected at the expense of a wealthy Greek, Baron Sina of Vienna. In the public garden is the Zappeion, a large building with a Corinthian portico, intended for the display of Greek industries; here also is a monument to Byron, erected in 1896. The Boulé, or parliament-house, possesses a considerable library. Other public buildings are the Polytechnic Institute, built by contributions from Greeks of Epirus, the theatre, the Arsakeion (a school

for girls), the Varvakeion (a gymnasium or boys' school), the military school (*σχολή εὐελπίδων*), and several hospitals and orphanages. The Cathedral, a large modern structure, is devoid of architectural merit, but some of the smaller, ancient, Byzantine churches are singularly interesting and beautiful. Among the private residences, the mansion built by Dr Schliemann, the discoverer of Troy, is the most noteworthy; its decorations are in the Pompeian style.

The museums of Athens are daily growing in importance with the progress of excavation. They are admirably arranged, and the remnants of ancient art which they contain have fortunately escaped injudicious restoration. The National Museum, erected in 1866, is especially rich in archaic sculptures and in sepulchral and votive reliefs. A copy of the Diadumenos of Polykleitos from Delos and temple-sculptures from Epidaurus, and the Argive Heræon are among the more notable of its recent acquisitions. It also possesses the famous collection of prehistoric antiquities found by Schliemann at Tiryns and Mycenæ, other "Mycenæan" objects discovered at Nauplia and in Attica, as well as the still earlier remains excavated by Tsountas in the Cyclades and by the British School at Phylakope in Melos; terra-cottas from Tanagra and Asia Minor; bronzes from Olympia, Delphi, and elsewhere, and numerous painted vases, among them the unequalled white *lekythoi* from Athens and Eretria. The Epigraphical Museum contains an immense number of inscriptions arranged by H. G. Lolling and A. Wilhelm of the Austrian Institute. The Acropolis Museum (opened 1878) possesses a singularly interesting collection of sculptures belonging to the "archaic" period of Greek art, all found on the Acropolis; here, too, are some fragments of the pedimental statues of the Parthenon and several reliefs from its frieze, as well as the slabs from the balustrade of the temple of Nike. The Polytechnic institute contains a museum of interesting objects connected with modern Greek life and history. In the Academy is a valuable collection of coins superintended by Svoronos. Of the private collections those of Schliemann and Karapanos are the most interesting: the latter contains works of art and other objects from Dodona. There is a small museum of antiquities at the Piræus. A museum of casts of the Greek masterpieces in foreign collections is much needed for the purposes of comparative study.

Owing to the numbers and activity of its institutions, both native and foreign, for the prosecution of research and the encouragement of classical studies, Athens has become once more an international seat of learning. The Greek Archæological Society, founded in 1837, numbers some distinguished scholars among its members, and displays great activity in the conduct of excavations. Important researches at Epidaurus, Eleusis, Mycenæ, Amyclæ, and Rhamnus may be numbered among its principal undertakings, in addition to the complete exploration of the Acropolis and a series of investigations in Athens and Attica. The French *École d'Athènes*, founded in 1846, is under the scientific direction of the *Académie des Inscriptions et Belles Lettres*. Among its numerous enterprises have been the extensive and costly excavations at Delos and Delphi, which have yielded such remarkable results. The monuments of the Byzantine Epoch have latterly occupied a prominent place in its investigations. The German Archæological Institute, founded in 1874, has carried out excavations at Thebes, Lesbos, Paros, Athens, and elsewhere; it has also been associated in the great researches at Olympia, Pergamos, and Troy, and in many other important undertakings. The British School, founded in 1886, has been unable, owing to insufficient endowment, to work on similar lines with the French and German institutions: it has, however, carried out extensive excavations at Megalopolis and in Melos, as well as researches at Abæe, in Athens (presumed site of the Cynosarges), in Cyprus, and at Naucratis. It has latterly taken part in the exploration of Knossos and other important sites in Crete. The American school, founded in 1882, is supported by the principal universities of the United States. In addition to researches at Sicyon, Plataea, Eretria, and elsewhere, it has undertaken two works of capital importance—the excavation of the Argive Heræon and the exploration of ancient Corinth. An Austrian Archæological Institute was founded in 1898.

Notwithstanding certain disadvantages inherent in its situation the trade and manufactures of Athens have considerably increased in recent years. Industrial and commercial activity is mainly centred at the Piræus, where 9 cotton mills, 45 cognac distilleries, 14 steam flour mills, 5 soap manufactories, 13 shipbuilding and engineering works, chair manufactories, tanneries, and a dynamite factory have been established in recent years. The shipbuilding and engineering trades are active and advancing. The export trade is, however, inconsiderable, as the produce of the local industries is mainly absorbed by home consumption. The annual value of exported cognac is about 1,400,000 francs, of raw hides about 700,000 francs. As a place of import, the Piræus surpasses Patras, Syra, and all the other Greek maritime towns, receiving about 53 per cent. of all the merchandise brought into Greece. The principal imports are coal, grain, manufactured articles, and articles of luxury. The total value of exports in 1894 was 9,207,535 francs, of imports,

Museums.

Scientific institutions.

Industry and commerce.

55,994,191 francs; no later figures have been published. The customs revenue in 1899 was 18,036,425 drachmas. The number of ships entered and cleared in 1898 was 3866 with a tonnage of 3,449,895 tons, of which 217 with a tonnage of 284,365 tons were British.

The Piræus, which had never revived since its destruction by the Romans in B.C. 86, was at the beginning of the last century a small fishing village known as Porto Leone. When Athens became the capital in 1834 the ancient name of its port was revived, and since that time piers and quays have been constructed, and spacious squares and broad regular streets have been laid out. The town now possesses an exchange, a large theatre, a gymnasium, municipal buildings, and several hospitals and charitable institutions erected by private munificence. The harbour, in which ships of all nations may be seen, as well as great numbers of the picturesque sailing craft engaged in the coasting trade, is somewhat difficult of access to larger vessels, but will be improved by the construction of new breakwaters and dry docks. The port and the capital are now connected by railway with Corinth and the principal towns of the Morea: a line opening up communication with Northern Greece and Thessaly is in process of construction; its eventual connexion with the Continental railway system will greatly enhance the importance of the Piræus, already one of the most flourishing commercial towns in the Levant.

The population of Athens has rapidly increased. In 1834 it was below 5000; in 1870 it was 44,510; in 1879, 63,374; in 1889, 107,251; in 1896, 111,486. The Piræus, which in 1834 possessed only a few hundred inhabitants, in 1879 numbered 21,618; in 1889, 34,327; in 1896, 43,848. The total population of Athens, Piræus, Phaleron, and the suburbs is now probably little short of 200,000.

(J. D. B.)

Athens, a city in the northern part of Georgia, U.S.A., and capital of Clarke county; altitude, 680 feet. It is entered by several railways, and has extensive and growing manufactures, largely of cotton. It is the site of the University of Georgia and of the Lucy Cobb Institute. Population (1880), 6099; (1890), 8639; (1900), 10,245.

Atherton, or CHOWBENT, a township in the Leigh parliamentary division of Lancashire, England, 13 miles W.N.W. of Manchester by rail. A new church has been built and another rebuilt. There is a volunteer hall. Population of urban district in 1881, 12,602; in 1891, 15,833. In 1894 part of the township and urban district was transferred to the urban district of Leigh. Population (1891), on area thus altered, 13,720; (1901), 16,211.

Athletic Sports.—Since 1875 the number of athletic meetings held throughout the United Kingdom has continued to increase, and the number of amateur athletes has become very much greater. The most noticeable feature of the increase during this period is that the movement has spread from the "classes" to the "masses." Except at the universities, public schools, and military colleges, where running and jumping competitions are still carried on with the greatest zest, and retain their social prestige, and in London, where the London Athletic Club still continues to attract members of good standing, throughout the rest of the country the great majority of athletes who compete at meetings are not drawn from the upper or middle classes as was the case twenty or thirty years ago. The form of competitions has hardly varied at

all, the competitions at what are called athletic sports, in the limited sense of the word "athletic," being running at short, middle, and long distances, hurdle races, jumping (high and long), weight-putting, and hammer-throwing. The two last named have been falling into desuetude in most parts of England, though still carried on in Scotland and Ireland. A new feature is the increase of what are called steeplechases—*i.e.*, long-distance races over hurdles, water jumps, and other obstacles. A two-mile steeplechase was introduced into the programme of the amateur championship meeting in 1879. Since 1880 the entire management of the amateur championship meeting has been in the hands of a representative body called the Amateur Athletic Association. It is divided into three branches—a northern, midland, and southern—and its general committee manages an annual championship meeting, issues laws, and governs the sport in the same manner as the Jockey Club governs horse-racing. No meeting can be held without the licence of this body, which also licenses the handicappers who allot the starts in open events.

The definition of an amateur adopted by this body is wide, and only excludes those who have competed for money or against a professional pedestrian. There are similar bodies which work under identical rules in Scotland and Ireland. The standard of excellence continues to improve. A carefully-tabulated set of British records is kept by the Amateur Athletic Association, and a copy is appended below. This list is confined to performances done in the United Kingdom.

Another feature of the progress of athletic sports is the growth of the movement in the United States

of America, and particularly in the colleges of that country (see below). A party of American athletes took part in the English Championship meeting of 1900 and won the majority of the events, being conspicuously the superiors of the Englishmen in the short-distance races. Indeed, the American records of every distance up to and including half a mile are slightly better than the English. In the longer distances the Englishmen seem more than able to hold their own.

Except at the universities all the athletic meetings in England are now held in the summer months. During the winter the athletes occupy themselves with paper-chases and cross-country races. There are many scores of paper-chasing clubs throughout the country, and the popularity of cross-country running seems to be steadily upon the increase. The only other remaining feature in connexion with athletic sports which requires chronicling is the new method of starting in sprinting or short-distance races. The runner bends down and rests his hands lightly on the starting mark, and no longer "toes the scratch." When the pistol fires he pushes off from his hands and raises himself gradually in the first stride or two. There is no doubt that this is the quickest method of starting, and it is now almost universal.

United States.—The American adopted all his sports, except base-ball, from the English; but, as in the case of American political institutions, while the origins have been English the genius of the people has determined the lines of development. All forms of athletic contests tend in America to become shorter and more intense. The national game of base-ball, for instance, is nervous and rapid in its movement, as compared with cricket. A base-ball contest is decided in two hours, as against the day or more required for a game of cricket; and instead of the two long innings there are nine short

¹ On grass.
² Hurdle race on grass, over ten 3 ft. hurdles not less than thirty yards apart.

³ In matches against time.
⁴ P. O'Connor jumped 24 ft. 11¼ in. at Kilkenny, 15th July 1901.

innings, in the course of which the score may be half-a-dozen times reversed. Again, in American football, which developed from the Rugby Union game, the contrast is equally striking, the American game having developed a thoroughly-planned and dramatic series of manœuvres often of much complexity. In track and field athletics the performances of Americans are as excellent in all contests requiring a single burst of nervous energy, such as sprinting, hurdling, and jumping, as those of English athletes are in the longer runs. It was not until shortly before the Civil War (1861-65) that there seemed to spring up something of athletic interest in America—boating being almost the only sport which until that time possessed any rules and permanent organizations. But the period of the war interrupted what might have been a speedy development along English lines. After peace was established, athletics appeared to take root once more, and in the succeeding decade (1870-79) there was a rapid increase in general organization and interest. Rowing, which had been less interrupted during the war, and had had a longer existence than the other sports, came once more into prominence, and especial interest was added by the inter-collegiate regattas and by the centennial races (1876). Football was still in a chaotic stage, but the year 1876 saw the inauguration of the Rugby Union rules, and with them the beginning of football as it is played to-day in the United States. Base-ball had for some half-dozen years been decidedly successful in the colleges, and among both amateurs and professionals outside. Track athletics, which had hitherto been only incidental to college boat-racing, had now made an independent place for itself. Thus in 1876 the four principal American sports had begun to push forward along the lines which were followed during the next quarter of a century.

In rowing, since the introduction of eight-oared shell racing over a four-mile course, there has been but little variation, this distance and this number of oars proving the most satisfactory. Upon several occasions there has been an agitation in favour of shortening the distance or of altering the methods in one way or another, but the movement has not met with more than temporary favour. In football the growth has been most rapid and most distinctly American—though here the rules adopted originally were those of the Rugby Union—and at first there was no legislation save where the rule failed specifically to cover a disputed point, and where there was only tradition to be relied upon. But with the growth of the game rule-making became necessary, and the inventive genius of the American player developed special “plays” and formations until now the game is almost as distinctly American as base-ball. Track athletics had a very small beginning, but was taken up by an increasing number of colleges; more events were added and greater interest was developed, until it grew in the last twenty years of the 19th century into a well-equipped and permanent branch of amateur sport. In fact, there is no branch which has as much strength among athletic clubs outside the colleges as track athletics. The new sports since 1875 are bicycling, tennis, and golf, together with the minor sports of basket ball, hockey, and polo. Tennis has both waxed and waned in the same period, but is now once more gaining in popularity, and bids fair to secure and maintain a permanent place. Golf has withdrawn many from the tennis ranks, and is probably as widely engaged in to-day as any sport in the country, largely owing to the fact that it can be played by individuals who have passed the age for the more violent athletic sports.

In the country at large the percentage of men who engage in athletic pastimes has been almost inappreciable.

Professional sport is limited to leagues of base-ball teams representing the great cities; and the main cultivation of amateur sport outside the universities is in the great athletic clubs which are now to be found in many of the large cities. These clubs differ from such organizations as the London Athletic Club in that they maintain large club-houses, which, in addition to expensively equipped gymnasiums, have luxurious lounging rooms, billiard rooms, and marble swimming baths. The ruling spirit is social rather than athletic. They have been strongly influenced by university sportsmen and sports, but the university element has never been dominant. The sports most successfully pursued are track and field athletics. Those sports which require more extensive organization and preparation, such as base-ball, football, and rowing, are practised with indifferent success. The oldest and most characteristic development of sport has been, as in England, in the universities, but even the percentage of men engaged has not been large. Whereas in England almost 80 per cent. of the undergraduates engage in some athletic pastime, the percentage of American undergraduate athletes had not until the closing decades of the 19th century exceeded 20; and even in those universities in which athletics are most enthusiastically pursued, the percentage is not yet even 40. This is in part due to the intensity characteristic of sports, and in part to the lack of that athletic rivalry within the university, and the consequent multiplication of contests, which is afforded in England by the division of the university into colleges. Whereas an English ‘varsity crew is content to row together for a month or two, the candidates for an American crew that is to race in July usually train in a gymnasium through the greater part of the preceding winter. And whereas in England football teams rely on practice games and a few informal “squashes,” an American team, in addition to one or two practice games a week, works hard every afternoon in developing complicated “plays” and in perfecting team work.

The methods of training and the spirit of sportsmanship have shown a very characteristic development. Owing partly to the extremes of the climate and the severity of nervous tension induced by it, and partly to the lack of more general participation in sports, the training has become in all instances more elaborate and more thorough than in England, and the winning of athletic victories is considered of more importance. Rivalries have been, and still are, of great intensity. At the same time the athletic spirit has run into grave excesses. All college teams have at one time or another been under strong and well-founded suspicion of inducing athletes to play for them by improper means. Excessive partisanship has involved excessive training, crafty diplomacy in arranging games, and trickery. All of the objectionable features have been intensified by the fact that the great games have often been held in the cities, where they are apt to take on the character of public gladiatorial contests. In the closing decade of the 19th century a marked reaction began. The publicity attending university sports gave occasion for a vigorous protest against all forms of unsportsmanship, and the members of the university faculties now exercise a strong and, in many cases, a wise supervision. Except in occasional instances, for which individuals only are responsible, the representatives of the eastern universities are amateurs in the full sense of the word; and in the western universities, where the development of sports was very sudden, and was attended by flagrant abuse, wise counsels prevail. The spirit of moderation has been strongly abetted by the abandonment of the old league championships in favour of independent meetings between one college and another, and this practice in turn tends to limit inter-university games to university grounds. The rapid increase, moreover, in

the popularity of minor sports has drawn ever-increasing numbers of men into active competition, and there is a strong tendency to develop contests within the university. On becoming more general, the athletic spirit has become less intense. Though American sports will doubtless always retain the peculiar strenuousness of the American character, the influences controlling them are becoming more and more representative of the best spirit in American life.

The American amateur records for the events most commonly competed for in track and field athletics are as follows:—

Running, 100 yards	9 $\frac{1}{4}$ sec.
" 220 "	21 $\frac{1}{5}$ "
" 440 "	47 "
" 880 "	1 min. 53 $\frac{3}{4}$ "
" 1 mile	4 " 15 $\frac{3}{8}$ "
" 3 miles	14 " 24 "
Walking, 1 mile	6 " 29 $\frac{3}{4}$ "
Hurdles, 120 yards (five hurdles, 3 ft. 6 in. high)	15 $\frac{1}{8}$ "
" 220 " (ten hurdles, 2 ft. 6 in. high)	23 $\frac{3}{8}$ "
Jumping, standing high, without weights	5 feet 4 inches
" running high, without weights	6 " 5 $\frac{5}{8}$ "
" running long, without weights	24 " 7 $\frac{1}{4}$ "
Pole vault for height	11 " 10 $\frac{1}{2}$ "
Throwing the hammer, 16 lb head (thrown by both hands from a mark; handle 4 feet long)	113 " 11 "
Ditto from circle	175 " 4 $\frac{3}{8}$ "
Putting the shot, 16 lb	47 "

(W. CA.)

Athlone, a market town and urban sanitary district in the county of Westmeath, province of Leinster, Ireland, on both sides of the river Shannon, 76 miles west of Dublin by rail. It ceased to be a parliamentary borough in 1885. In 1898 the portion situated in Roscommon was added to Westmeath. A woollen mill has been recently established, in addition to the already existing factory. Population (1881), 6755; (1891), 6742; (1901), 6617.

Athol, a town of Worcester county, northern Massachusetts, U.S.A., having an area of 35 square miles. Its surface is quite irregular and hilly. The village of Athol is on the Miller river, at an altitude of 556 feet, and is entered by two railways, the Boston and Albany and the Fitchburg. The plan of the village is quite irregular. Athol was incorporated in 1762. Population (1880), 4307; (1890), 6319; (1900), 7061.

Athos, the most easterly of three peninsulas of Turkey in Europe, projecting at its south-western extremity into the *Ægean* Sea. The north-western border is about 50 miles S.E. of Salonica, to which there is a bridle-path. The peninsula takes its name from Mount Athos (6350 feet), the extreme summit of a chain of heights occupying the peninsula; and on account of the number of religious houses, now totalling about 1000, it is also known as "The Holy Mount." None but males are allowed access to the peninsula, and all the inhabitants are Christians, with the exception of one Turkish officer. The recluses number about 3000, with 3000 servants.

Atkinson, Major the Hon. Sir Harry Albert, K.C.M.G. (1831-1892), British colonial statesman; prime minister and Speaker of the legislative council, New Zealand; was born at Chester in 1831, and in 1855 emigrated to Taranaki, New Zealand, where he became a farmer. In 1860 the Waitara war broke out, and from its outset Atkinson, who had been selected as a captain of the New Plymouth Volunteers, distinguished himself

by his contempt for appearances and tradition, and by the practical skill, energy, and courage which he showed in leading his Forest Rangers in the tiresome and lingering bush warfare of the next five years. For this work he was made a major of militia, and thanked by the Government. Elected to the house of representatives in 1863, he joined Sir Frederick Weld's ministry at the end of November 1864 as minister of defence, and, during eleven months of office, was identified with the well-known "self-reliance" policy, a proposal to dispense with imperial regulars, and meet the Maori with colonials only. Parliament accepted this principle, but turned out the Weld ministry for other reasons. For four years Atkinson was out of parliament; in October 1873 he re-entered it, and a year later became minister of lands under Sir Julius Vogel. Ten months later he was treasurer, and such was his aptitude for finance that, except during six months in 1876, he thenceforth held that post whenever his party was in power. From October 1874 to January 1891, Atkinson was only out of office for about five years. Three times he was premier, and he was always the most formidable debater and fighter in the ranks of the Conservative opponents of the growing Radical party which Grey, Stout, and Ballance led in succession. It was he who was mainly responsible for the abolition of the provinces into which the colony was divided from 1853 to 1876. He repealed the Ballance land-tax in 1879, and substituted a property-tax. He greatly reduced the cost of the public service in 1880, and again in 1888. In both these years he raised the customs duties, amongst other taxes, and gave them a quasi-protectionist character. In 1880 he struck 10 per cent. off all public salaries and wages; in 1887 he reduced the salary of the governor by one-third, and the pay and number of ministers and members of parliament. By these resolute steps revenue was increased, expenditure checked, and the colony's finance reinstated. Atkinson was an advocate of compulsory national assurance, and the leasing as opposed to the selling of crown lands. Defeated in the general election of December 1890, he took the appointment of Speaker of the legislative council. There, while leaving the council chamber after the sitting of 28th June 1892, he was struck down by heart disease, and died in a few minutes. Though brusque in manner, and never popular, he was esteemed as a vigorous, upright, and practical statesman. He was twice married, and had seven children, of whom three sons and a daughter survived him. (W. P. R.)

Atlanta, the largest city of Georgia, U.S.A., capital of the state and of Fulton county. It is situated in the northern part of the state, in 33° 45' N. lat. and 84° 24' W. long., at an altitude of 1050 feet. Its mean annual temperature is 62°, and the annual rainfall is 45 inches. The city is regularly laid out, is divided into seven wards, is supplied with water by the Holly pumping system, and is well drained and paved. It is one of the principal railway centres of the south, being entered by six railways, the Atlanta and West Point, the Central of Georgia, the Georgia, the Seaboard Air Line, the Southern, and the Western and Atlantic, which meet at a union depot. Amongst several institutions for higher education are the Atlanta Baptist College, Atlanta University, Morris Brown College, and the State Normal School of Technology. Of its newspapers the *Atlanta Constitution* is well known throughout the Union. Among the many fine buildings of the city the State Capitol, erected at a cost of \$1,000,000, should be mentioned. Atlanta is probably the most progressive city of the south, having made vast strides during the past generation. In 1890 it had 410 manufacturing establishments of all kinds, employing

\$9,500,000 of capital, and 8684 persons. Chief among these were cotton manufactories, in which \$1,900,000 were invested, and foundries and machine shops, with nearly \$1,000,000. Lumber and furniture factories are also of great importance. The assessed valuation of property, real and personal, was, in 1899, \$52,240,058, the tax rate \$21.60 per \$1000, and the indebtedness of the municipality \$2,808,910. The death-rate, 23.01 per 1000, is enhanced by the large proportion of negroes among the population. Since the Civil War, which practically destroyed it, the city has grown with great rapidity. Population (1880), 37,409; (1890), 65,533; (1900), 89,872, of whom 2531 were foreign-born and 35,912 were negroes.

Atlantic, capital of Cass county, Iowa, U.S.A., situated on the East Nishnabotna river, at the intersection of the Chicago, Rock Island, and Pacific railway with a branch of the Chicago, Burlington, and Quincy railway. Population (1890), 4351; (1900), 5046.

Atlantic City, a city of Atlantic county, New Jersey, U.S.A., situated in 39° 22' N. lat. and 74° 26' W. long., on a sand-bar running parallel with the coast, and separated from the mainland by a strip of marsh about five miles in breadth. The city is but slightly elevated above tide-level, is regularly laid, and is divided into four wards. Water is supplied by pumping, the water-works being privately owned. It is a popular seaside resort both in summer and winter, especially with dwellers in Philadelphia, with which city it is connected by two railways, the Atlantic City (Philadelphia and Reading system) and the West Jersey and Seashore (Pennsylvania system). It is a city of hotels and boarding-houses, and in the summer season has a large floating population, estimated at 100,000. The first settlement was made about 1783, and the place received a city charter in 1852. Population (1880), 5477; (1890), 13,055; (1900), 27,838.

Atlantic Ocean.—The Atlantic Ocean forms a belt of water, roughly of an S-shape, between the western coasts of Europe and Africa and the eastern coasts of North and South America. It extends northwards to the Arctic Basin and southwards to the Great Southern Ocean. For purposes of measurement the polar boundaries are taken to be the Arctic and Antarctic circles, although in discussing the configuration and circulation it is impossible to adhere strictly to these limits. The Atlantic Ocean consists of two characteristic divisions, the geographical equator forming a fairly satisfactory line of division into North and South Atlantic. The North Atlantic, by far the best known of the main divisions of the hydrosphere, is remarkable for the immense length of its coast-line and for the large number of enclosed seas connected with it, including on the western side the Caribbean Sea and Gulf of Mexico, the Gulf of St Lawrence, and Hudson Bay, and on the eastern side the Mediterranean and Black Sea, the North Sea, and the Baltic. The North Atlantic is connected with the Arctic Basin by four main channels: (1) Hudson Strait, about 60 miles wide, communicating with the gulfs and straits of the North American Arctic archipelago; (2) Davis Strait, about 200 miles wide, leading to Baffin Bay; (3) Denmark Strait, between Greenland and Iceland, 130 miles wide; and (4) the "Norwegian Sea," about 400 miles wide, extending from Iceland to the Faroe Islands, the Shetland Islands, and the coast of Norway. The width of the North Atlantic in lat. 60°, approximately where it breaks up into the branches just named, is nearly 2000 miles; in about lat. 50° N., the coasts of Ireland and Newfoundland approach to 1750 miles; the breadth then increases rapidly to lat. 40° N., and attains its maximum

of 4500 miles in lat. 25° N.; farther south the minimum breadth is reached between Africa and South America, Cape Palmas being only 1600 miles distant from Cape St Roque. In marked contrast to this, the South Atlantic is distinguished by great simplicity of coast-line; inland seas there are none, and it attains its greatest breadth as it merges with the Southern Ocean; in lat. 35° S. the width is 3700 miles.

The total area of the North Atlantic, not counting inland seas connected with it, is, according to Karstens, 36,438,000 square kilometres, or 10,588,000 square miles; including the inland seas the area is 45,641,000 square kilometres, or 13,262,000 square miles. The area of the South Atlantic is 43,455,000 square kilometres, or 12,627,000 square miles. Although not the most extensive of the great oceans, the Atlantic has by far the largest drainage area. The "long slopes" of the continents on both sides are directed towards the Atlantic, which accordingly receives the waters of a large proportion of the great rivers of the world, including the St Lawrence, the Mississippi, the Orinoco, the Amazon, the rivers of the La Plata, the Congo, the Niger, the Loire, the Rhine, the Elbe, and the great rivers of the Mediterranean and the Baltic. Murray estimates the total area of land draining to the Atlantic to be 13,432,000 square miles, or with the Arctic area nearly 20,000,000 square miles, nearly four times the area draining to the Pacific Ocean, and almost precisely four times the area draining to the Indian Ocean. Murray's calculations give the amount of precipitation received on this area at 15,800 cubic miles annually, and the river discharge from it at 3900 cubic miles.

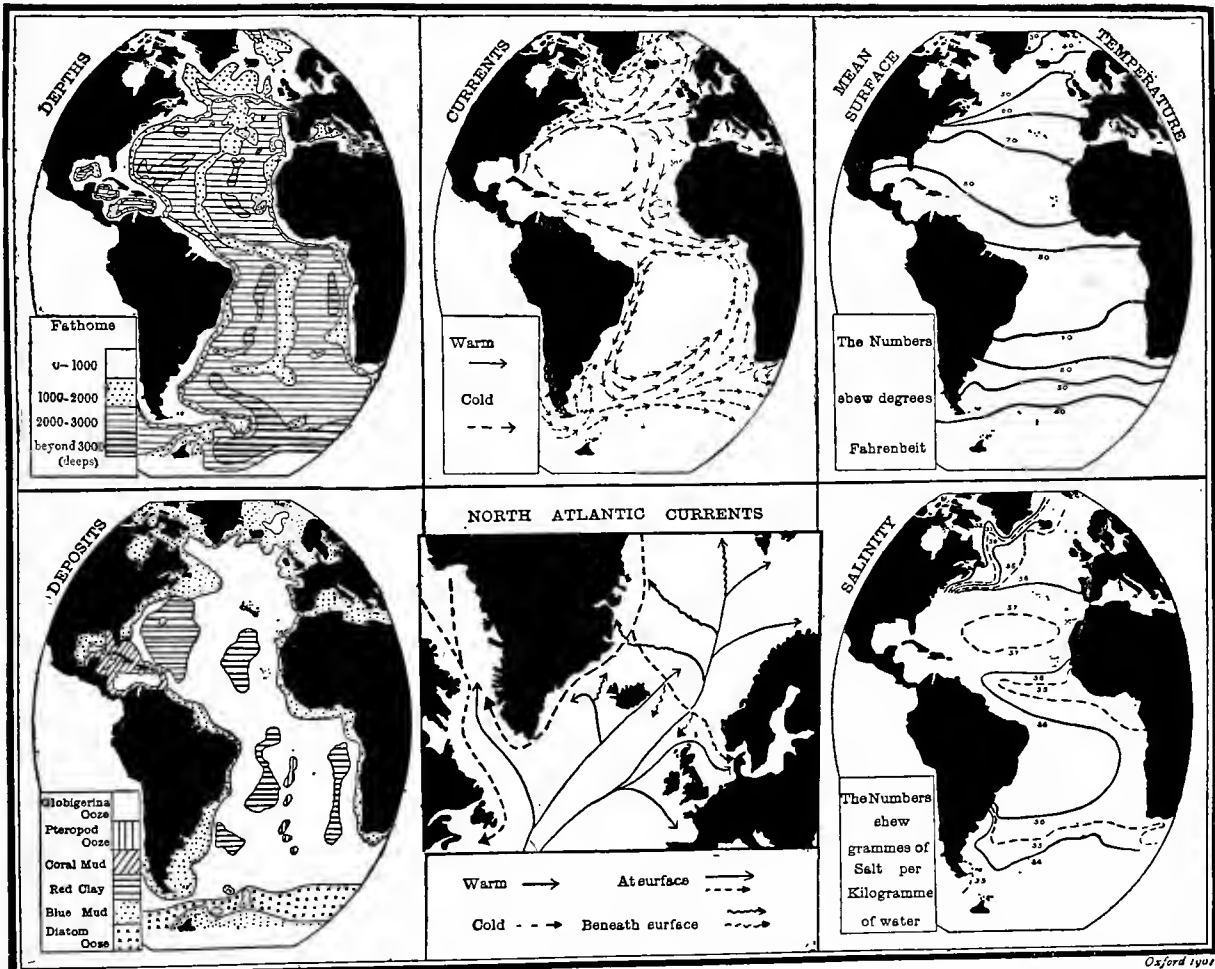

The dominant feature of the relief of the Atlantic basin is a submarine ridge running from north to south from about lat. 50° N. to lat. 40° S., almost exactly in the central line, and following the S-shape of the coasts. Over this ridge the average depth is about 1700 fathoms. Towards its northern end the ridge widens and rises to the plateau of the Azores, and in about 50° N. lat. it merges with the "Telegraph plateau," which extends across nearly the whole ocean from Ireland to Newfoundland. North of the fiftieth parallel the depths diminish towards the north-east, two long submarine ridges of volcanic origin extend north-eastwards to the south-west of Iceland and to the Faroe Islands, and these, with their intervening valleys, end in a transverse ridge connecting Greenland, through Iceland and the Faroe Islands, with North-western Scotland and the continental mass of Europe. The mean depth over this ridge is about 250 fathoms, and the maximum depth nowhere reaches 500 fathoms. The main basin of the Atlantic is thus cut off from the Arctic basin, with which the area north of the ridge has complete deep-water communication. This intermediate region, which has Atlantic characteristics down to 300 fathoms, and at greater depths belongs more properly to the Arctic Sea, commonly receives the name of Norwegian Sea. On both sides of the central ridge deep troughs extend southwards from the Telegraph plateau to the Southern Ocean, the deep water coming close to the land all the way down on both sides. In these troughs the depth is seldom much less than 3000 fathoms, and this is exceeded in a series of patches to which Murray has given the name of "Deep." In the eastern trough the *Peake deep* lies off the Bay of Biscay in 20° W. long., *Monaco deep* and *Chun deep* off the north-west of Africa, *Moseley deep* off the Cape Verde Islands, *Krech deep* off the Liberian coast, and *Buchanan deep* off the mouth of the Congo. The western trough extends northwards into Davis Strait, forming a depression in the Telegraph plateau; to the south of Newfoundland

Relief of the bed.

and Nova Scotia are *Sigsbee deep*, *Thoulet deep*, *Libbey deep*, and *Suhm deep*, each of small area; north-east of the Bahamas *Nares deep* forms the largest and deepest depression in the Atlantic, in which a sounding of 4561 fathoms was obtained (70 miles north of Porto Rico) by the U.S. ship *Blake* in 1883. Immediately to the south of Nares deep lies the smaller *Makaroff deep*; and off the coast of South America are *Tizard deep* and *Havergal deep*. South of 40° S. lat. the form of the sea-bottom changes considerably on account of the eastward trend taken by the alternate elevations and depressions. Between the southern extremity of South America and Graham Land, in the Antarctic, the depth nowhere reaches 2000 fathoms, and a plateau of less depth extends eastward to South Georgia

and the Sandwich group. In 40° S. lat., 40° W. long., the 3000-fathoms line marks an offshoot of the great *Ross deep*, which runs south-eastwards to the main depression. East of this trough the depth is, generally, over 2000 fathoms, except where a bank, on which Bouvet Island stands, suggests a south-easterly prolongation of the main central ridge, which, but for this, would appear to end at Tristan da Cunha. From the south point of Africa south-eastwards to the Crozet Islands and Kerguelen the depth is less than 2000 fathoms, an ill-defined ridge separating the eastern margin of the Ross deep from the main basin of the Indian Ocean (*q.v.*)

The foundations of our knowledge of the relief of the Atlantic basin may be said to have been laid by the work of H.M.S.

B. V. Darbishire & O. J. R. Howarth

Oxford, 1904

Challenger (1873-76), of the German ship *Gazelle* (1874-76), the French expedition in the *Travailleur* (1880), and the U.S. surveying vessel *Blake* (1877 and later). Large numbers of additional soundings have been made in recent years by cable ships, by the expeditions of H.S.H. the Prince of Monaco, and by the German *Valdivia* expedition under Professor Chun (1898); but with the exception of the last-named none of the later workers have seriously modified the contours outlined by the *Challenger* and *Gazelle*.

For the volume of the North Atlantic, Karstens gives the value 136,384,000 cubic kilometres, or 21,362,000 cubic miles, giving a mean depth of 2047 fathoms. If we include the enclosed seas, the North Atlantic has a volume of 150,415,000 cubic kilometres, or 23,560,000 cubic miles, giving a mean depth of 1800 fathoms. The South Atlantic has a total volume of 164,263,000 cubic kilometres, or 25,729,000 cubic miles, giving a mean depth of 2067 fathoms. The

following table, due to Murray, gives details of the area of the floor of the Atlantic basin, and the volume of water resting thereon, at different levels:—

Depth. Fathoms.	Area. Square Miles.	Volume. Cubic Miles.
Between 0-100	2,907,003	2,353,703
100-500	2,404,482	8,370,611
500-1000	1,840,634	9,568,637
1000-2000	5,468,015	15,816,901
2000-3000	10,928,918	8,905,287
3000-4000	1,780,012	690,123
Over 4000	5,832	2,155
	25,334,896	45,707,417

Mean depth, 1830 fathoms.

The Atlantic Ocean contains a relatively small number of islands. The only continental groups, besides some S. I. — 97

islands in the Mediterranean, are Iceland, the British Isles, Newfoundland, the West Indies, and the Falklands, and the chief oceanic islands are the Azores, Madeira, the Canaries, the Cape Verde Islands, Ascension, St Helena, Tristan da Cunha, and Bouvet Island.

The greater part of the bottom of the Atlantic is covered by a deposit of Globigerina ooze, roughly the area between 1000 and 3000 fathoms, or about 60 per cent. of the whole. At a depth of about 3000 fathoms, *i.e.*, in the "Deeps," the Globigerina ooze gradually gives place to red clay. In the shallower tropical waters, especially on the central ridge, considerable areas are covered by Pteropod ooze, a deposit consisting largely of the shells of pelagic molluscs. Diatom ooze is the characteristic deposit in high southern latitudes. The terrigenous deposits consist of blue muds, red muds (abundant along the coast of Brazil, where the amount of organic matter present is insufficient to reduce the iron in the matter brought down by the great rivers to produce blue muds), green muds and sands, and volcanic and coral detritus.

The question of the origin of the Atlantic basin, like that of the other great divisions of the hydrosphere, is still unsettled. Most geologists include the Atlantic with the other oceans in the view they adopt as to its age (see GEOLOGY and OCEANOGRAPHY); but Suess and Neumayr, while they regard the basin of the Pacific as of great antiquity, believe the Atlantic to date only from the Mesozoic age. Neumayr finds evidence of the existence of a continent between Africa and South America, which protruded into the central North Atlantic, in Jurassic times. Kossmat has shown that the Atlantic had substantially its present form during the Cretaceous period.

In describing the mean distribution of temperature in the waters of the Atlantic it is necessary to treat the northern and southern divisions separately. The heat equator, or line of maximum mean surface temperature, starts from the African coast in about 5° N. lat., and closely follows that parallel to 40° W. long., where it bends northwards to the Caribbean Sea. North of this line, near which the temperature is a little over 80° F., the gradient trends somewhat to the east of north, and the temperature is slightly higher on the western than on the eastern side until, in 45° N. lat., the isothermal of 60° F. runs nearly east and west. Beyond this parallel the gradient is directed towards the northwest, and temperatures are much higher on the European than on the American side. From the surface to 500 fathoms the general form of the isothermals remains the same, except that instead of an equatorial maximum belt there is a focus of maximum temperature off the eastern coast of the United States. This focus occupies a larger area and becomes of greater relative intensity as the depth increases until, at 500 fathoms, it becomes an elongated belt extending right across the ocean in about 30° N. lat. Below 500 fathoms the western centres of maximum disappear, and higher temperatures occur in the eastern Atlantic off the Iberian peninsula and North-western Africa down to at least 1000 fathoms; at still greater depths temperature gradually becomes more and more uniform. The communication between the Atlantic and Arctic basins being cut off, as already described, at a depth of about 300 fathoms, the temperatures in the Norwegian Sea below that level are essentially Arctic, usually below the freezing-point of fresh water, except where the distribution is modified by the surface circulation. The isothermals of mean surface temperature in the South Atlantic are in the lower latitudes of an ∞ -shape, temperatures being higher on the American than on the African side. In latitudes south of 30° S. the curved form tends to disappear, the lines running more and more

directly east and west. Below the surface a focus of maximum temperature appears off the coast of South America in about 30° S. lat., and of minimum temperature north and north-east of this maximum. This distribution is most marked at about 300 fathoms, and disappears at 500 fathoms, beyond which depth the lines tend to become parallel and to run east and west, the gradient slowly diminishing.

The Atlantic is by far the saltiest of the great oceans. Its saltiest waters are found at the surface in two belts, one extending east and west in the North Atlantic between 20° and 30° N. lat., and another of almost equal salinity extending eastwards from the coast of South America in 10° to 20° S. lat. In the equatorial region between these belts the salinity is markedly less, especially in the eastern part. North of the North Atlantic maximum the waters become steadily fresher as latitude increases until the channels opening into the Arctic basin are reached. In all of these water of relatively high salinity appears for a long distance towards the north on the eastern side of the channel, while on the western side the water is comparatively fresh. In the higher latitudes of the South Atlantic the salinity diminishes steadily and tends to be uniform from east to west, except near the southern extremity of South America, where the surface waters are very fresh. Our knowledge of the salinity of waters below the surface is as yet very defective, large areas being still unrepresented by a single observation. The chief facts already established are the greater saltiness of the North Atlantic compared with the South Atlantic at all depths, and the low salinity at all depths in the eastern equatorial region, off the Gulf of Guinea.

It is now generally admitted that the movements of the surface waters of the great oceans are primarily controlled by the winds, and the resulting circulation consists of (a) drift currents in the open sea, following the general wind directions, and (b) stream currents, which are independent of the local winds, but are due to inequalities of pressure produced by the interference of land masses with the movements of the drift currents. Quite recently Pettersson has shown that the formation and melting of polar ice must be regarded as a factor contributing a considerable portion of the energy of ocean currents, and this factor must be of great importance in the Atlantic. The wind circulation over the Atlantic is of a very definite character. In the South Atlantic the narrow land surfaces of Africa and South America produce comparatively little effect in disturbing the normal planetary circulation. The tropical belt of high atmospheric pressure is very marked in winter; it is weaker during the summer months, and at that season the greater relative fall of pressure over the land cuts it off into an oval-shaped anticyclone, the centre of which rests on the coolest part of the sea surface in that latitude, near the Gulf of Guinea. South of this anticyclone, from about the latitude of the Cape, we find the region where, on account of the uninterrupted sea surface right round the globe, the planetary circulation is developed to the greatest extent known; the pressure gradient is exceedingly steep, and the region is swept continuously by strong westerly winds—the "roaring forties." This is merely the "polar eddy," which is probably arrested by the frictional resistance of the land and the low temperatures in the higher Antarctic latitudes.

In the North Atlantic the distribution of pressure and resulting wind circulation are very largely modified by the enormous areas of land and frozen sea which surround the ocean on three sides. The tropical belt of high pressure persists all the year round, but the immense demand for air to supply the ascending currents over the heated land

Distribution of temperature.

Meteorology.

surfaces in summer causes the normal descending movement to be largely reinforced, hence the "North Atlantic anticyclone" is much larger, and its circulation more vigorous, in summer than in winter. Again, during the winter months pressure is relatively high over North America, Western Eurasia, and the Arctic regions; hence vast quantities of air are brought down to the surface, and circulation must be kept up by ascending currents over the ocean. The Atlantic anticyclone is therefore at its weakest in winter, and on its polar side the polar eddy becomes a trough of low pressure, extending roughly from Labrador to Iceland and Jan Mayen, and traversed by a constant succession of cyclones. The net effect of the surrounding land is, in fact, to reverse the seasonal variations of the planetary circulation, but without destroying its type. In the intermediate belt between the two high-pressure areas the meteorological equator remains permanently north of the geographical equator, moving between it and about 11° N. lat.

The wind circulation may shortly be described thus from north to south:—

1. "Iceland" depression—low-pressure belt, traversed by numerous cyclones, some of great intensity, in winter; abundant rainfall.

2. A belt of "westerly variables," the polar side of the Atlantic anticyclone, merging into (1).

3. Calm and dry belt, the axis of the Atlantic anticyclone—the "horse latitudes," or "calms of Cancer."

4. Belt of N.E. and E. winds. These coming from a high-pressure area are dry, hence there is little rainfall, and great evaporation from the sea surface, which attains its greatest salinity in this region; the "trade winds."

5. Equatorial belt of calms and rains; the "doldrums."

6. Belt of S.E. and E. winds—the "trade winds."

7. Tropical calm and dry belt, or "calms of Capricorn."

8. Belt of W. and N.W. winds, merging into the "roaring forties."

The part of this circulation which is steadiest in its action is the trade winds, and this is therefore the most effective in producing drift movement of the surface waters. The trade winds give rise, in the region most exposed to their influence, to two westward-moving drifts—the *equatorial currents*, which are separated in parts of their course by currents moving in the opposite direction along the equatorial belt. These last may be of the nature of "reaction" currents; they are collectively known as the *equatorial counter-current*. On reaching the South American coast, the southern equatorial current splits into two parts at Cape St Roque: one

Currents. branch, the *Brazil current*, is deflected southwards and follows the coast as a true stream current at least as far as the River Plate. The second branch proceeds north-westwards towards the West Indies, where it mingles with the waters of the northern equatorial; and the two drifts, blocked by the <-shape of the land, raise the level of the surface in the Gulf of Mexico, the Caribbean Sea, and in the whole area outside the West Indies. This congestion is relieved by what is probably the most rapid and most voluminous stream current in the world, the *Gulf Stream*, which runs along the coast of North America, separated from it by a narrow strip of cold water, the "cold wall," to a point off the south-east of Newfoundland. At this point the Gulf Stream water mixes with that from the *Labrador current* (see below), and a drift current eastwards is set up under the influence of the prevailing westerly winds: this is generally called the *Gulf Stream drift*. When the Gulf Stream drift approaches the eastern side of the Atlantic it splits into two parts, one going southwards along the north-west coast of Africa, the *Canaries current*,

and another turning northwards and passing to the west of the British Isles. Most of the Canaries current re-enters the northern equatorial, but a certain proportion keeps to the African coast, unites with the equatorial return currents, and penetrates into the Gulf of Guinea. This last feature of the circulation is still somewhat obscure; it is probably to be accounted for by the fact that on this part of the coast the prevailing winds, although to a considerable extent monsoonal, are off-shore winds, blowing the surface waters out to sea, and the place of the water thus removed is filled up by water derived either from lower levels or from "reaction" currents.

The movements of the northern branch of the Gulf Stream drift have been the object of more careful and more extended study than all the other currents of the ocean put together, except, perhaps, the Gulf Stream itself. The cruises of the *Porcupine* and *Lightning*, which led directly to the despatch of the *Challenger* expedition, were altogether within its "sphere of influence"; so also was the great Norwegian North Atlantic expedition. More recently, the area has been further explored by the German expedition in the ss. *National*, the Danish *Ingolf* expedition, and the minor expeditions of the *Michael Sars*, *Jackal*, *Research*, &c. Much has also been done by the discussion of observations made on board vessels belonging to the mercantile marine of various countries. It may now be taken as generally admitted that the current referred to breaks into three main branches. The first passes northwards, most of it between the Faroe and Shetland Islands, to the coast of Norway, and so on to the Arctic basin, which, as Nansen has shown, it fills to a great depth. The second, the *Irminger stream*, passes up the west side of Iceland; and the third goes up the Greenland side of Davis Strait to Baffin Bay. These branches are separated from one another at the surface by currents moving southwards: one, the importance of which has only recently been recognized, to the east of Iceland; the second, the *Greenland current*, skirts the east coast of Greenland; and the third, the *Labrador current* already mentioned, follows the western side of Davis Strait. Pettersson has recently shown that these cold surface currents are chiefly due to the melting of sea ice, caused by the influx of immense quantities of warm water from the Gulf Stream drift, and this result has been confirmed by Dickson, who shows, from an investigation of the seasonal changes of the circulation, that a drift of the kind described is inadequate to account for all the facts. He maintains that, just as in the case of the equatorial currents, a heaping-up of water takes place off the south-west coast of Europe and the north-west of Africa, and that this heaping-up takes place especially in summer, when the Atlantic anticyclone produces its maximum effect. The heaped-up water escapes by stream currents of the same nature as the Gulf Stream; and it is these currents, not the drifts, which are able to make their way into high latitudes, guided by the outline of the land. During winter, when the Atlantic anticyclone is at its weakest and the surface circulation is especially under the control of the cyclones of the Iceland depression, a general drift circulation is set up, large quantities of water move south-eastwards from Davis Strait, cross the Atlantic, and pass north-eastwards into the Norwegian Sea.

The development of the equatorial and the Brazil currents in the South Atlantic has already been described. On the polar side of the high-pressure area a west wind drift is under the control of the "roaring forties," and on reaching South Africa part of this is deflected and sent northwards along the west coast as the cold *Benguela current*, which rejoins the equatorial. In the central parts of the two high-pressure areas there is practically no surface

circulation. In the North Atlantic this region is covered by enormous banks of gulf-weed (*Sargassum bucciferum*), hence the name Sargasso Sea. The Sargasso Sea is bounded, roughly, by the lines of 20°-35° N. lat. and 40°-75° W. long.

The sub-surface circulation in the Atlantic may be regarded as consisting of two parts. Where water is banked up against the land, as by the equatorial and Gulf Stream drift currents, it appears to penetrate to very considerable depths; the escaping stream currents are at first of great vertical thickness, and part of the water at their sources has a downward movement. In the case of the Gulf Stream, which is not much impeded by the land, this descending motion is relatively slight, being perhaps largely due to the greater specific gravity of the water; it ceases to be perceptible beyond about 500 fathoms. On the European-African side the descending movement is more marked, because the coast-line is much more irregular, and the northward current is deflected against it by the earth's rotation; here the movement is traceable to at least 1000 fathoms. The northward movement of water across the Norwegian Sea extends down from the surface to the Iceland-Shetland ridge, where it is sharply cut off; the lower levels of the Norwegian Sea are filled with ice-cold Arctic water, close down to the ridge. The south-moving currents originating from melting ice are probably quite shallow. The second part of the circulation in the depth is the slow "creep" of water of very low temperature along the bottom. The North Atlantic being altogether cut off from the Arctic regions, and the vertical circulation being active, this movement is practically non-existent; but in the South Atlantic, where communication with the Southern Ocean is perfectly open, Antarctic water can be traced to the equator, and even beyond.

The tides of the Atlantic Ocean are of great complexity. The tidal wave of the Southern Ocean, which sweeps uninterruptedly round the globe from east to west, generates a secondary wave between Africa and South America, which travels north at a rate dependent only on the depth of the ocean. With this "free" wave is combined a "forced wave," generated, by the direct action of the sun and moon, within the Atlantic area itself. Nothing is known about the relative importance of these two waves. (H. N. D.)

Atlas Mountains.—Since the exploration of the western section by Hooker and Ball in 1878, this range has been visited and even crossed at more than one point by later travellers. Oscar Lenz, who surveyed a considerable part of the Great Atlas north of Tarudant, and determined a pass south of it in the Little Atlas in 1879-80, and penetrated thence across the Sahara southwards to Timbuktu, was followed in 1883-84 by Ch. de Foucauld, whose extensive itineraries include many districts that had never before been visited by any Europeans. Such were parts of the first and middle ranges crossed once; three routes over the Great Atlas, which was moreover traversed along both flanks nearly for its whole length; and six journeys across the Little Atlas, with a general survey of the foot of this range and several passages over the Jebel-Bani. Then came the late Joseph Thomson, who explored some of the central parts, but broke little new ground, and failed to cross the main range (1888); H. M. P. de la Martinière, who increased our knowledge of the uplands in the province of Fez (1890-91); and lastly, Walter B. Harris, who explored some of the southern slopes and crossed the Little Atlas during his expedition to the Tafilet oasis (1894). Thanks to these expeditions, and especially to De Foucauld's careful surveys, we now possess a somewhat

clear idea of the hitherto imperfectly known Atlas system in its more important western (Moroccan) section, which bears the comprehensive Berber name of *ADRAR N'DEREN*, the "Deren Mountains." Here it forms not two or three chains, as hitherto supposed, but as many as five distinct ranges, all varying in length and height, but disposed parallel to one another in the normal direction from south-west to north-east, with a slight curvature towards the Sahara. Generally speaking, the northern more or less convex slopes, being exposed to the moist Atlantic winds, are in many places well wooded, while the southern flanks, which intercept the dry Saharan winds, are mainly destitute of vegetation.

The main range, commonly known as the **GREAT ATLAS**, occupies a central position in the system, and is by far the longest and loftiest chain, terminating, not in a plateau as often asserted, but in a sharply outlined crest, and culminating between the Bibawán Pass and the Jebel Aïshin. The fall towards the Dahra district at the north-east end is gradual and continuous, but precipitous at the opposite extremity facing the Atlantic between Agadir and Mogador. At several points the crest has been deeply eroded by old glaciers and running waters, and thus have been formed a number of passes, which, however, are little utilized for peaceful intercourse, the approaches on both slopes being mostly held and blocked rather than kept open by mutually hostile Berber tribes. The Aïshin section, culminating in a peak nearly 15,000 feet high, maintains a mean altitude of 11,600 feet, and from this great mass of schists and sandstones a number of secondary ridges radiate in all directions, forming divides between the Um-er-Rébia, the Sebu, the Muluya, the Ghir, and the Draa, which flow respectively to the west, north-west, north-east, south-east, and south. Eastwards the Aïshin terminates abruptly in the steep Jebel-Terneit cliffs, which rise some 6000 feet above the surrounding plains. For a distance of 100 miles it nowhere presents any passes accessible to caravans; but south-westwards some gaps in the range afford communication between the Um-er-Rébia and the Draa basins. In the same direction the Aïshin is continued by a not yet named crest, which appears to maintain the same mean altitude of considerably over 11,000 feet, and it is this south-western extension of the Moroccan system which gives it greater average height than the European Alps, although dominated by less elevated peaks. Yet a few summits in the extreme south-west still exceed 11,000 feet in the neighbourhood of Cape Ghir. Besides huge masses of old schists and sandstones, geologists have discovered extensive limestone, marble, diorite, basalt, and porphyry formations, while granite prevails on the southern slopes of the Aïshin range. The presence of enormous glaciers in the Ice Age is attested by the moraines at the Atlantic end, and by other indications farther east. The best known passes are: (1) The Bibawán in the upper Wed-Sus basin (4150 feet according to Lenz); (2) the Tizi, *i.e.*, the "Pass" in a pre-eminent sense, giving access from Marakesh to Tarudant, rugged and difficult, but low, and utilized by Lemprière, Jackson, Lenz, and other travellers; (3) Tizi n'Tameffut, leading down to the Draa valley; (4) Tizi n'Glawi (7600 feet, Foucauld); (5) Tizi n'Telremt (7250 feet, Foucauld), leading down to the Wed-Ghir.

The **MIDDLE ATLAS**, skirting the north flank of the Great Atlas at some distance inland, is not visible from the coast, and is still but little known; but seems to run from the region north of Demnat to the Dahra district beyond Debdon, presents a somewhat regular snowy crest between the Um-er-Rébia and the Wed el-Abid valleys, and is crossed

The Great Atlas.

The secondary ranges.

by passes from 5000 to 6000 feet high. Both slopes are wooded, and its forests are the only parts of Morocco where the lion still survives.

The LITTLE or ANTI-ATLAS running parallel to and south of the main range is one of the least elevated chains in the system, having a mean altitude of not more than 5000 feet, although some peaks and even passes exceed 6000 feet. At one point it is pierced by a gap scarcely five paces wide with polished walls of variegated marbles. Although in some winters nearly free from snow, La Martinière found the Little Atlas quite covered with a white mantle in 1890-91. The Atlas system is completed by two other less important ranges—the JEBEL-BANI,

south of the Little Atlas, crossed several times by Foucauld, who describes it as a low, narrow, rocky ridge with a height of 3000 feet in its central parts; and the ULMESS RIATA, south of the middle range, not a continuous range, but a series of broken mountain masses from 3000 to 3500 feet high, and traversed by the rivers Sebu and Muluya.

ATMOSPHERIC ELECTRICITY.

§ 1. INVESTIGATION into the early history of atmospheric electricity would be the province rather of the antiquary than of the scientific man. In pre-scientific days lightning was usually regarded as the special vehicle of divine vengeance. Lucretius was perhaps the first who attempted to apply to its elucidation the scientific method; he pointed out that even temples of Jupiter had not escaped the thunderbolt, which seemed to imply an incredible degree of inefficiency in the department over which that divinity was supposed to preside. Like most modern scientific men who have considered the subject, Lucretius had a theory of his own, and he might almost be looked upon as the parent of the "electric fluid" phraseology still so prominent in popular writings. Even in 1749, when Franklin proposed the famous kite experiment to test the identity of natural and artificial electricity, the electric fluid theory was probably held by most scientific men in a fairly literal sense. The electric fluid was supposed to reside in the clouds, whence it was attracted by any sharp point held upwards. Shortly after 1750 the observations by Lemonnier and others of electric phenomena in the atmosphere in the absence of cloud led to some modification of ideas. It was only, however, with the introduction of improved methods and apparatus after the middle of the 19th century, mainly by Lord Kelvin, that there was any approach to exact measurements of atmospheric electricity. To understand the different methods employed or recommended, a brief survey of the phenomena is necessary.

§ 2. At most places in dry weather the electric potential near the ground is normally positive relative to the earth, and increases with the height. The existence of earth currents shows that the earth, strictly speaking, may not be all at one potential; but the potential differences between points on the earth's surface—say, 1 kilometre apart—are insignificant compared to the normal potential difference between the earth and a point 1 metre above it, and when considering this latter difference we may regard the earth as at a uniform zero potential. What is aimed at in ordinary observations of atmospheric electricity is the measurement of the potential difference between the earth and a point at a given height above it, or else the difference in potential between two points in the same vertical at a given distance apart.

Let a conductor—say, a metallic sphere—be supported by a metal rod of negligible capacity whose other end is earthed. Then the conductor must all be at zero potential, and consequently the sphere must have an induced charge which produces at its centre a potential equal, but opposite, to what would exist at the same spot in free air. This neglects any charge carried by the air displaced by the sphere, and assumes a statical state of conditions, and further, what in practice is

never wholly realized, that the conductor exerts no disturbing influence outside itself. Suppose now that the sphere's earth connexion is broken, and that it is carried by an insulating handle inside a building at zero potential, where its potential (relative to the earth) is determined. If this potential is $-V$ (volts), then, assuming no loss of electricity during the operations, the potential of the air at the spot occupied by the sphere was $+V$. This method under various forms was largely in use about the middle of the 19th century. It was followed for many years by Quetelet at Brussels, and in a modified form by Palmieri at Naples; in recent years it has been employed at the suggestion of Elster and Geitel on the top of the Sonnbliek.

Next, suppose that a fixed conductor is insulated from the ground, and that by some means it is kept at the potential of the air which it displaces, then the measurement of its potential is equivalent to a measurement of the potential of the air. This is the basis of various seemingly different methods. Originally the conductor took the shape of long metal wires, supported by silk or other insulating material, and no artificial means were employed to bring them to the potential of the surrounding air. The addition of sharp points was a step in advance. But the method can hardly be said to have been a quantitative one until the sharp points were replaced by either a flame (fuse, gas, lamp) or a liquid jet breaking into drops. In either case the theory is the same. The matter leaving the conductor, whether it be the products of combustion of a fuse or the drops of a liquid, supplies the means of maintaining equality of potential between the conductor and the air at the spot where the matter quits electrical connexion with the conductor. It is customary to apply the term *collector* to the flame or liquid apparatus, its function being, in popular language, to collect electricity.

§ 3. Several forms of flame-collector have been proposed, and two have been a good deal used, viz., Lord Kelvin's portable electrometer (*Papers on Electrostatics and Magnetism*, §§ 263, 277, &c.) with a fuse, and Exner's form of gold-leaf electroscope (Exner, *Wien. Sitz.* vol. xciii. (Ab. ii.), 1886, p. 222; also *Sitz.* xcv., xcvi., xcix., &c.; Elster and Geitel, *Terrestrial Magnetism*, vol. iv. p. 15, &c.) in conjunction with an oil lamp or gas flame. The latter is the instrument employed in most of the recent work done by Exner, Elster and Geitel, and others in Austria and Germany. The most obvious defect of the ordinary flame-collector is the tendency in the flame to be blown out. This prevents the use of Exner's form on windy days, but Pellat (*Soc. Franc. Phys. Bull.* June 1899; *Science Abstracts*, 1706, for 1899) has invented a form which claims to have surmounted this difficulty.

Of liquid collectors the representative is Lord Kelvin's "water-dropper." The water is contained in a tank standing on insulated supports, and the tube through which the

Instruments.

jet issues passes through a hole in a window. From the tube, or the tank, an insulated wire passes to a quadrant electrometer. Readings can be taken by eye, or a continuous photographic record can be obtained. In the latter case, light reflected from the mirror attached to the electrometer needle falls on prepared paper, which is wound round a drum driven by clockwork. Installations of this kind are, or have been, in operation at a good many observatories, including Kew, Greenwich, Lyons, Perpignan, Lisbon, and Batavia; of late years a water-dropper has been in operation during summer near the top of the Eiffel Tower. At Kew Observatory the water-dropper tube is connected to the needle of the electrometer, whose quadrants are connected, the one pair to the positive pole the other pair to the negative pole of a battery of cells, whose centre is earthed. The arrangement is shown diagrammatically in Fig. 1. The most obvious weak point in a water-dropper is the tendency to freeze in cold weather.

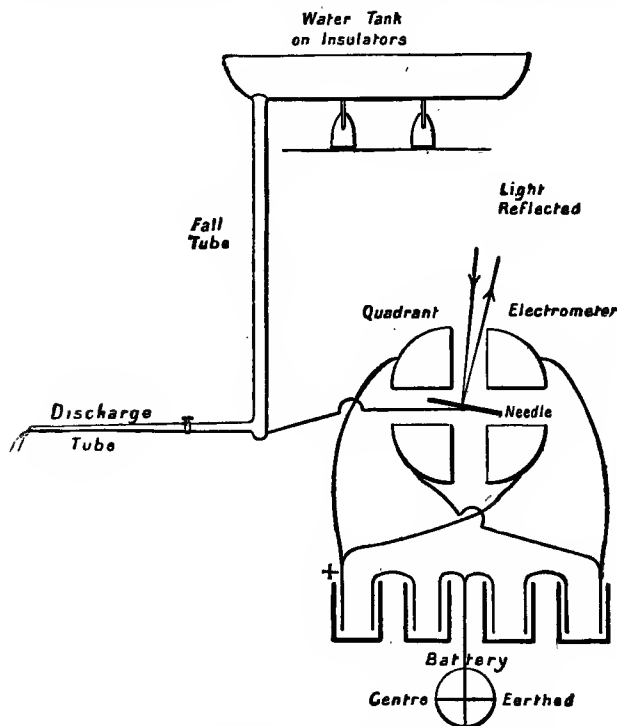

FIG. 1.—Diagram of the Water-dropper at Kew Observatory.

To remedy this, less easily frozen liquids have sometimes been employed, or the water has been heated or the tube protected. By such means water-droppers were kept in continual operation at two of the stations (Sodankylä and Cape Thorsden) of the international polar year 1882-83 during very severe cold.

§ 4. Before passing to the observational data it is expedient to refer to various sources of uncertainty. As already stated, we may in this inquiry regard the earth as at a uniform zero potential. Above a limited area of a level plain of absolutely smooth surface, devoid of houses, trees, or grass, the equipotential surfaces under normal conditions would be horizontal planes, and if we could determine the potential at a point 1 metre above the ground we should have a definite measure of the *potential gradient* at the earth's surface. The presence, however, of apparatus or observers upsets the conditions, while above uneven ground, or near a tree or a building, the equipotential surfaces cease to be horizontal. In an ordinarily moist climate a building seems to be practically at the earth's potential; near its walls the equipotential surfaces are far from being horizontal, and near a ridge they may lie very close together. The height of the walls in the various observatories possessing water-droppers, the height of the water-dropper tube above the ground, and the distance it projects from the wall, all vary largely. Again, the tube may project from the centre of a long wall or from a corner, and there may be external buildings or trees sufficiently near to influence the potential. An interesting

example of the influence of the situation is presented by Batavia Observatory. During the years 1887-90, with the water-dropper at a height of 2 metres above the ground, the mean of the potentials recorded was 79 volts; but during 1890-95, with the water-dropper at a height of 7·8 metres, the mean voltage was 967. This will show the futility of comparing the *absolute* voltages met with at two stations, unless means exist of allowing for the difference in the environments of the apparatus. This is the principal reason why Tables I. and II., p. 675, give the *ratios* borne by individual hourly or monthly values to the mean value for the day or year.

§ 5. There are other sources of uncertainty. If the shape of the equipotential surfaces near the jet is influenced by trees, shrubs, or grass, the influence will vary throughout the year. Again, in winter, the varying depth of snow or the formation of icicles may exert an appreciable influence. There are further sources of trouble in the apparatus itself. Unless the insulation is perfect, the potential recorded is not that of the atmosphere at the spot where the jet breaks. The action of the jet is opposed by the leakage through imperfect insulation, and if this is greater at one hour of the day, or at one season of the year, than at another, there may be a fictitious element in the diurnal or annual variation. A similar result may arise from variability in the pressure under which the jet issues, especially if the insulation is indifferent. The potentials that have to be dealt with are often hundreds, and sometimes thousands, of volts, and insulation troubles are more serious than is generally appreciated. As a check on the records from water-droppers, it is desirable that scale-value determinations should be regularly made, and that the curve readings should from time to time be compared with eye observations, taken with a portable electrometer or electroscopes in a fixed position, at a sufficient distance from buildings or shrubs. In interpreting the records from a water-dropper, allowance must be made for the existence of purely local phenomena. The necessity for this was shown as long ago as 1860 at Glasgow (Kelvin, *Papers on Electrostatics and Magnetism*, § 392). Two water-droppers were kept running in the university buildings, at no great distance apart but at different levels, and it was found that they often did not show pronounced changes of potential simultaneously. From this Lord Kelvin drew the conclusion—which more recent observations have only tended to confirm—that there are often electrified portions of the atmosphere in motion close to the earth. What may be regarded as accidental temporary disturbances have probably little influence on the results found for mean diurnal or annual inequalities, but this is not the case with influences such as the site of the station, whether in a valley or on a hill, near a river or the sea.

§ 6. When rain is falling the potential frequently changes rapidly. These changes are often too sudden to be satisfactorily dealt with by an ordinary electrometer, and they sometimes leave hardly a trace on the photographic paper. Again, the rain dripping from all parts of the efflux tube may materially affect the situation. For these and other reasons, it is customary at some observatories to take no account of days on which there is an appreciable amount of rainfall, or else to form separate tables for "dry" or "fine" days, and for "all" days. In other cases negative potentials are excluded from certain of the tables. Speaking generally, the exclusion of days of rain and of negative potential comes pretty much to the same thing (see, however, § 15).

Of the accompanying tables (p. 775) the first gives the mean diurnal inequality at various stations for the whole year, while the second shows diurnal inequalities for "winter" and "summer." These each include six months, except at Sodankylä and Perpignan, when three months at midwinter and three at midsummer are meant. For reasons already stated in § 4, the hourly values are expressed as percentages of the mean value for the twenty-four hours. The height h of the efflux tube above the ground, and the distance l which it projects from the building, are in metres. The hours are in most cases mean local time. In the case of Florence, however, the entry under an hour is really the mean for the previous sixty minutes. At Sodankylä apparently a correction of about twenty-seven minutes would be necessary to give local time. The data employed in calculating the tables are derived from the following sources: Cape Thorsden (*Observations faites au Cap Thorsden Spitzberg, par l'Expédition Suédoise*, tome ii. 2, par S. A. André, Stockholm, 1887); Sodankylä (*Expédition Polaire Finlandaise*, tome iii., Helsingfors, 1898); Kew Observatory (Everett, *Phil. Trans.* for 1868, p. 347, and Whipple, *Brit. Assoc. Report* for 1881, p. 443); Greenwich (annual volumes of *Greenwich Magnetical and Meteorological Observations*); Florence (*Met. Zeit.* for 1891, p. 357); Perpignan (*Met. Zeit.* for 1891, p. 113, and 1890, p. 319); Lisbon (annual volumes of *Annaes do Obs. do Infante D. Luiz*); Batavia (*Observations made at the Mag. and Met. Obs. at Batavia*, vol. xviii., 1895); Cape Horn (Hann, *Met. Zeit.* for 1889, p. 96).

§ 7. Some of the results in Table II. are shown graphically in Fig. 2, along with some corresponding

results for the Bureau Central Météorologique, the Eiffel Tower, and the Collège de France, Paris, the last based on diagrams in a paper by Chauveau (*Séances de la Soc. Franc. de Physique* for 1899, p. 91). In this paper Chauveau suggests that there are at ordinary stations two distinct types of diurnal variation, viz., a summer type

possessed of two distinct maxima and two distinct minima, and a winter type showing only one maximum (in the evening) and one minimum (in the morning), or else closely approaching this as an ideal. Arguing from the results on the Eiffel Tower and from those on a high staging at Trappes, Chauveau draws the conclusion that the afternoon

minimum in summer arises from causes peculiar to stations near the ground, and that at moderate heights the winter type of inequality applies in all latitudes throughout the entire year. It should be remarked, however, that some of the results in Tables I. and II. hardly seem to fit this theory.

Some of the irregularities in Tables I. and II. would probably disappear if more years' data were employed; this is especially true in cases where the range is small,

FIG. 2.

as at Cape Thorsden in winter. In this instance, according to the data, the inequality is almost the opposite of that usually met with, the potential being highest in the early morning hours, and at about its lowest value between 9 and 11 P.M. In summer the morning minimum is as well marked as at other places. It will be noticed that the evening maximum is decidedly less prominent at Greenwich than at Kew, especially in winter, and that the afternoon minimum in winter is distinctly present at Kew though hardly visible at Greenwich.

In considering such discrepancies it would be well to bear in mind the possibility, or rather probability, that atmospheric potential may, like thunderstorms and auroras, vary much from one year to the next. At Lisbon the summer inequality presents three fairly equal maxima. These are possibly fictitious, as the range is exceptionally small, but the phenomenon was exhibited by each of the three years included, and there is a suggestion of more than two maxima at some of the other stations. Narrowness of diurnal range is clearly no general attribute of low latitudes, for that at Batavia is most conspicuous. Some of the irregularities in the tables may be due to the interaction of conflicting agencies, of which one may be dominant at one time, another at another. Thus C. R. André (*Comptes Rendus*, 112 (1891), p. 1509), on separating quiet bright days at Lyons into two sets, according as the wind was northerly or southerly, concluded that the characteristics of the diurnal inequality were conspicuously different in the two cases. André's diagrams show two well-marked maxima and minima (with small doubtful ones) in each instance, but with southerly wind the morning maximum is much the larger, whereas with the wind northerly it is somewhat the smaller.

§ 8. The mean of the hourly ordinates of electrograms (electric potential curves) for a month gives the monthly mean, and the intercomparison of the monthly means gives the annual inequality. For reasons already indicated, Table III. gives relative not absolute values for the twelve monthly means. The data are from the same sources as those utilized in Tables I. and II.

At Sodankylä the year employed began with September 1882, at Cape Thorsden with November 1882. At the latter station there were only ten months' observations, and the results for November and December seem hardly credible. The figures suggest that the rapid fall in potential observed at Kew and Greenwich in April and May takes place later in the far north, and somewhat earlier in Florence, Perpignan, and Lisbon. At the higher level at Batavia the annual inequality seems very irregular, notwithstanding that it is a mean from six years' results.

§ 9. Diurnal and annual inequalities have been published for a variety of places, which are based on eye observations with Exner's electroscopes. Such results depend only on observations taken at certain hours of the day, sometimes only on bright days; consequently they are not directly comparable with inequalities based on the continuous records of self-recording instruments. Two examples are given in Table IV. The Wolfenbüttel data are due to Elster and Geitel (*Wien. Sitz. ci. Abth. ii.*, 1892, p. 703); the data for Ladenburg were obtained by Gockel (*Met. Zeit.* for 1897, p. 281) during the years 1892-95. The figures are the monthly means in volts of the potential at a fixed point in the atmosphere.

TABLE IV. (Annual Inequality).

	Jan.	Feb.	March.	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.
Wolfenbüttel	891	889	294	138	110	102	123	121	121	183	260	470
Ladenburg	397	587	148	66	62	60	60	..	73	116	106	184

§ 10. Table V. gives some data bearing on the question of how the amplitude of the diurnal inequality is influenced by the height of the water-dropper above the ground. The heights are

in metres, the maximum and minimum values of the potential are in volts. The data for Paris and Trappes are from the paper by Chauveau already mentioned; the others from the same sources as Tables I. and II. London is the mean of Kew (1880) and Greenwich.

TABLE V.

Station.	London.		Paris.		Trappes	Perpignan.	Batavia.	
	Year.	Summer.	Bureau Central.	Eiffel Tower.			Year.	Year.
Height . .	3		..	285	20	8.4	2	7.8
Season . .	Year.	Summer.	Summer.	Summer.	Summer.	Year.	Year.	Year.
Maximum	172	2490	372	72.8	125	1496
Minimum	102	1740	213	39.0	24	401
Max./mean	1.24	1.84	1.29	1.13	1.28	1.81	1.58	1.55
Min./mean	.85	.76	.77	.79	.70	.71	.80	.42

Perhaps all that can be said is that the results are not unfavourable to the view that the relative importance of the diurnal inequality diminishes as the height above the ground increases.

§ 11. The diurnal inequality near the ground on the top of a mountain has no necessary relationship to that above a plain at the same height above the sea. Elster and Geitel (*Met. Zeit.* for 1891, p. 321) believe that on the top of a mountain the diurnal variation is small, basing their view partly on some observations of their own on the top of the Sonnblick (3100 metres). The mean of these

for certain hours of the day, along with some corresponding date obtained by Michie Smith in January 1885 on Dodabetta (8642 feet), the highest summit of the Neilgherries in India (*Trans. R.S.E.* vol. xxxii. p. 583), are given in Table VI. (afternoon hours dashed).

TABLE VI.

Hour.	6	8	10	Noon.	2'	4'	6'
Sonnblick	200	218	240	214	224	...	220
Dodabetta	55	.67	93	108	93	69

The unit in which the potential is measured is not the same in the two cases, and the hours are not exact local mean time. Elster and Geitel's results, except that for 6 P.M., depend on three days' observations; Michie Smith's are means from five days nearly free from mist. In support of their view Elster and Geitel refer to a few observations by Exner on a hill near St Gilgen, and to a considerable number of observations made more recently, but with apparently somewhat primitive apparatus, on the Sounblick. In view of the large variation observed on Dodabetta, more experiments on the subject are clearly wanted.

§ 12. Many of the data referred to below are taken from Le Cadet's interesting book *Étude du champ électrique de l'Atmosphère*, Paris, 1898. For small heights use may be made of captive balloons, provided with a burning fuse, and carrying a wire attached to an electroscope on the ground. With such apparatus Exner (*Wien. Sitz.* xciii., 1886, p. 222) found the potential gradient nearly uniform up to heights of 30 or 50 metres above the ground. At great heights the potential differs so much from that of the earth that captive balloons are unsuitable. Accordingly, in 1885 a free balloon ascent was made at Vienna by Lecher, at Exner's suggestion. The potential gradient was found by using two water-droppers, with their jets at a difference of 2 metres in level. The mean of the few measurements taken made the potential gradient at a height of 550 metres nearly double that at the ground. More recent experiments, however, tend to show that Lecher's observations, if correct, were exceptional. Perhaps the most important of these experiments are those due to Le Cadet himself. Like Lecher he employed two collectors—either water-droppers or flame-collectors—but usually with an arrangement for altering their difference of level. Table VII. gives some of Le Cadet's results. H is the height of the balloon in metres, P the potential gradient in volts per metre.

On 11th September the value found for P at the ground was 150. The marked tendency shown in the table for P to diminish as the height increases is equally prominent in other observations by Le Cadet. Thus on 24th March 1897, at heights between 1680 and 2300 metres, P varied from 32 to 28, while its mean value at the ground as deduced from the simultaneous records of the Lyons water-dropper was 99. Similar results were observed in Germany by Baschin, during an ascent on 17th February 1894. Using two "water-droppers"—with 65 per cent. alcohol in the water—he found for P values of 49, 28, and 13, answering to the heights of 760, 2400, and 2800 metres respectively. During the ascent the value of P at the ground varied from 98 to 181 at Potsdam, and from 85 to 200 at Wolfenbüttel. In opposition to these results Tuma, during an ascent at Vienna in

1892, found P to increase as the height increased from 410 to 1900 metres; but several recent ascents (*Met. Zeit.* for 1899, p. 280, or *Wien. Sitz.*, March 1899) lead him to the same conclusion as Le Cadet, viz., that under normal conditions the potential gradient diminishes as the height increases. The possibility that a free balloon may carry off a charge as it leaves the earth has been discussed by Bornstein (*Met. Zeit.*, 1898, p. 65), who shows how such a charge could be measured if the balloon carried three water-droppers at different levels. Supposing however a charge to exist initially, it would tend, as Baschin points out, to disappear when ballast was discharged. Tuma, from experiments made on several of his recent ascents, concluded that no charge existed on the balloon.

§ 13. If V be the potential, ρ the density of free electricity at a point in the atmosphere, at a distance r from the earth's centre, we have, neglecting variations of V in horizontal directions, $r^{-2}(d/dr)(r^2 dV/dr) + 4\pi\rho = 0$.

Throughout the limited portion of the earth's atmosphere open to experiment, we may for practical purposes treat r^2 as constant in this equation, and so take $\rho = -(1/4\pi)(d/dr)(dV/dr)$. Thus ρ is positive if, as recent experiments seem to show, the potential gradient, dV/dr , diminishes as we recede from the earth.

If σ be the surface density of the charge on the earth, we have $\sigma = -(1/4\pi)(dV/dr)$ where dV/dr is the potential gradient close to the ground. As dV/dr is normally positive, the inference is that normally the earth's surface has a negative charge.

If we take a tube of force 1 cm. cross-section, and suppose it cut by the equipotential surfaces at the heights h_1 and h_2 above the ground, then under the conditions assumed above the total charge, M, included within the specified portion of the tube is given by

$$4\pi M = (dV/dr)_{r=R+h_1} - (dV/dr)_{r=R+h_2},$$

where R is the earth's radius.

Le Cadet applies equivalent formulæ to his balloon ascent of 11th September 1897, assuming the potential gradient to be 150 (volt/metre) at the ground, and 13.4 (volt/metre) at 4000 metres. Supposing a volt equal to .0033 C.G.S. electrostatic units, the charge on the ground per sq. cm. is $-(150/100) \times .0033 + 4\pi$, or approximately $-.000395$ electrostatic unit (in coulombs -13×10^{-14}). The charge in the unit tube of force between the ground and the height of 4000 metres works out at $+0.00036$ C.G.S. electrostatic unit, leaving only about $+0.000035$ electrostatic units above this level. These figures give for the average density of the charge between the height of 4 kilometres and the ground the value 9×10^{-10} electrostatic units (3×10^{-10} coulombs). This is insignificant compared with the density of the charges recently given to air by Kelvin, Maclean, and Galt (see § 17). Trabert (*Met. Zeit.*, 1898, p. 401) makes a similar calculation in discussing the probability of the existence of vertical earth-air currents of the order 17×10^{-12} amperes per sq. cm. The existence of such currents seems indicated by the researches of A. Schmidt and others, who have concluded that a portion of the earth's magnetic field cannot be accounted for by a Gaussian potential (see MAGNETISM, TERRESTRIAL, § 24). Trabert takes 130 (volt/metre) as the most probable mean value of the potential gradient at the ground. Answering to this, a calculation similar to Le Cadet's makes the surface density -11×10^{-14} coulombs per sq. cm. Thus Schmidt's hypothetical mean current would transmit in one second fully 150 times as much electricity as exists at the instant on the earth's surface. This would imply a rate of dissipation about one million times larger than that found by Linss and by Elster and Geitel in the absence of photo-electric action (see § 18).

§ 14. Elster and Geitel have attempted to measure the charge brought down by rain falling into an insulated vessel, as well as the simultaneous potential gradient in the atmosphere (*Met. Zeit.*, 1888, p. 95; *Wien. Sitz.* xcix. Abth. ii., 1890, p. 421; *Terrestrial Magnetism*, March 1899, p. 15). There are various serious difficulties—splashing of raindrops, influence of apparatus, surgings in the electrometer, &c.—and though Elster and Geitel have done their best to surmount these, they seem somewhat doubtful of their complete success. The conclusions indicated by the experiments are: (1) raindrops almost invariably carry a charge; the sign may be positive or negative, and may change repeatedly in the course of a single rainstorm; (2) the charge is more often than not opposite in sign to the simultaneous value of the potential gradient near the ground. On 11th May 1892,

during a thunderstorm, the charge brought down by the rain, when greatest, was approximately at the rate of 76×10^{-14} coulombs per second per sq. cm. of earth's surface. This was the maximum met with. In their paper in *Terrestrial Magnetism*, Elster and Geitel give graphical illustrations of their results.

§ 15. At most stations a negative potential gradient is exceptional, except during rain or fog. During rain it is a frequent but by no means invariable phenomenon, and it seldom persists long without a recurrence to positive. The alternations of sign during heavy thunderstorm rain are often both frequent and sudden, and a similar phenomenon is not unusually observed during thick fog. In some localities a negative potential gradient seems by no means uncommon, even on bright calm days. Thus Michie Smith (*Phil. Mag.* vol. xx. 1885, p. 456) observed numerous instances of negative potential at Madras during bright days in August and September. The phenomenon was quite common between 9.30 A.M. and noon, during westerly winds, which at Madras are very dry and usually dusty. The presence of dust seemed to Michie Smith a contributory cause, but dust in easterly winds was not accompanied by negative potential. At the Finnish polar station Sodankylä, in 1882-83, Lemstrom and Biese found that out of 255 observed occurrences of negative potential, 106 took place in the absence of rain or snow. The proportion of occurrences of negative potential under a clear sky was much above its average in autumn, and much below its average in spring and summer. In many cases Lemstrom and Biese observed no change of sign to follow on rain or snowfall. At Polhem, in Spitzbergen, Wijkander is reported to have observed negative potentials almost as often as positive; but the potential gradients at Polhem seem to have been abnormally low. At the polar station Godthaab, in 1882-83, negative potential seemed sometimes to be associated with aurora (Paulsen, *Bull. de l'Acad. . . de Danemarke*, 1894, p. 148).

§ 16. It has been found by Lenard, Elster, and Geitel and others, that the potential gradient is negative near a waterfall. The influence may extend to a considerable distance. Lenard (*Wied. Ann.* xvi. 1892, p. 584), who has specially investigated the matter, concludes that when pure water falls upon water the air in the neighbourhood becomes negatively charged; the presence of dust in the air is, he believes, unessential. The effect can be produced inside a closed space (Maclean and Goto, *Phil. Mag.* vol. xxx. 1890, p. 148), but under such circumstances the presence of dust seems to increase the effect. A little impurity in the water markedly diminishes the charge, and may alter its sign. More recent experiments by Kelvin, Maclean, and Galt (*Phil. Trans.* vol. xcvi. A, p. 187) have shown that when air is charged by dropping water, as in Maclean and Goto's experiments, the charge is considerably greater in the air near the level of impact of the falling water than in that at a higher level. A sensible charge still remained, however, when the influence of the splashing was eliminated. In the opinion of Kelvin, Maclean, and Galt, this property of falling water renders an ordinary water-dropper unsuitable for use indoors, at least in a small room, though it constitutes no practical objection to its use out of doors. Exner (*Wien. Sitz.* (2) 1896, p. 467) observed an electrical action in the case of breaking sea-waves, noticing the spray to be negatively electrified.

§ 17. Electrification is generally admitted to exist in the atmosphere, but some authorities have held that it is carried by dust, or by ice and water particles forming clouds. Lord Kelvin's view is that ordinary air, whether containing dust or not, can be electrified, either positively or negatively. This conclusion is supported by experiments by Kelvin and Maclean (*Proc. Roy. Soc.* vol. lvi. 1894, p. 84; *Phil. Mag.* August 1894), and by more recent experiments by Kelvin, Maclean, and Galt (*Phil. Trans.* cxci. A, p. 187). In the earlier experiments the electrification was measured by means of a water-dropper. In the more recent ones, for the reasons specified in § 16, other methods were employed, and by means of needle points attached to an electric machine a charge of density 37×10^{-5} C.G.S. electrostatic units was given on one occasion to ordinary air, while a density as great as 22×10^{-4} units was attained by means of an electrified hydrogen flame. After stopping the electric machine, the electrification gradually

disappeared, but could be detected for many minutes. In the earlier experiments little difference was observed between very dusty air and air as dustless as possible. Negative electrification seemed to disappear, when the machine was stopped, more rapidly than positive. In the later experiments it was found possible to give a small electrification to air in other ways, e.g., by shaking it up with water or solutions of various kinds, or blowing it in bubbles through water or aqueous solutions.

§ 18. Linss (*Met. Zeit.* 1887, p. 352) found that an insulated paste-board cylinder, covered with tinfoil and charged either positively or negatively, lost its charge gradually when in the free atmosphere. The potential V existing after dissipation during time t was connected with the original potential V_0 by a formula of the type $V = V_0 e^{-\alpha t}$, where q though constant on a particular occasion varied appreciably from day to day. The formula implies that the rate of fall of the potential varies as its existing value (counting the earth's potential as zero). Linss's experiments have been repeated by Elster and Geitel (*Terrestrial Magnetism*, vol. iv. 1899, p. 213). Their dissipator consisted of a hollow cylinder of blackened copper, insensitive to any direct photo-electric effect. When used out of doors, it was protected from rain, wind, and direct sunlight by an insulated hood. Regular daily observations were made for a long time, the loss during a given interval being measured for both positive and negative charges. In addition to numerous experiments at Wolfenbüttel, a considerable number were made on the Brocken and on the Alps, near Zermatt. Elster and Geitel denote the fraction of the charge lost per minute by E , distinguishing the sign of the charge by the addition of + or -. In the lowlands they found on the average $E \pm = 1.3$ per cent. In other words, positive and negative charges were lost, on the whole, equally fast, and on the average a charge of 100 units lost 1.3 units in one minute. This result agrees pretty well with that obtained by Linss. Neither wind nor mist was found to possess much influence, and, somewhat contrary to expectation, the most rapid loss of charge was observed on days when the air was specially clear and free from dust. In mountainous districts they found a change in the phenomena, as may be seen from the following typical results, obtained during the ascent of a peak near Zermatt:—

Position.	Height above Sea.	E(+).	E(-).
	Metres.	Per cent.	Per cent.
Zermatt valley . . .	1620	4.5	4.4
On level ground . . .	2600	4.4	6.8
Near end of ridge . . .	3000	2.7	7.0
Peak, Gorner Gratz . . .	3140	0.7	6.6

From these and similar observations Elster and Geitel conclude: (1) that normally in valleys high above the sea the rate of dissipation is greater than near sea-level, whilst remaining independent of the sign of the charge; (2) that on mountains, especially near peaks, a negative charge is lost much more rapidly than a positive charge.

A diametrically opposite phenomenon was observed by them near waterfalls. For instance, near a fall at Zermatt they obtained 16.2 per cent. for E(+) as against 1.9 per cent. for E(-).

They attribute the loss of charge to the existence of small positively and negatively charged masses in the atmosphere. In the lowlands or in mountain valleys the two species are equally numerous on the average, but positive masses largely predominate near mountain peaks and negative masses near waterfalls (cf. § 16).

§ 19. It has long been a disputed question whether vapour from a charged liquid carries off part of the charge; it is rather a vital point in some theories respecting atmospheric electricity, such as that of Exner. Various experimenters (e.g., Blake, Mascart, Sohnecke, Pellat) have advanced what they regarded as crucial evidence in favour of one view or the other. The question is discussed by J. J. Thomson, in his *Recent Researches in Electricity and Magnetism*, p. 54, and Traherne has treated it more recently in the *Met. Zeit.* for 1899, p. 377. Several supporters of the view that the vapour carries off a charge, e.g., Lord Kelvin (*Proc. Roy. Soc.* 31st May 1894, p. 84), have pointed out that if it be conceded that a drop of pure water can be charged and evaporated, the charge must be carried off by something which is either aqueous vapour or is unknown to science.

§ 20. In Exner's theory of atmospheric electricity aqueous vapour is the essential element. If, as before, P be the potential gradient in volts per metre, and q be the density of aqueous vapour present in the atmosphere, then, according to Exner, $P = A / (1 + kq)$, where A and k are constants. In its extreme form the theory would imply that the above formula applied with A and k absolute constants in the case of every recorded value of P on clear days. Elster and Geitel, however, in their applications of the formula, seem generally to regard P and q as answering to the mean values during a day's observations. On other occasions

they have attributed to A values differing from one series of experiments to another. Exner himself (*Wien. Sitz. xcix. Abth. ii. 1891, p. 601*) has applied his formula with $A=1400$ and $k=1.15$ to observations at Vienna, Wolfenbüttel, St Gilgen, and India. Arranging his observations in groups, each of which answers to a narrow range of vapour density, he compares the mean observed and calculated values of P for the several groups. The tendency for the mean P to be small when the mean q is large is decided. Elster and Geitel (*Wien. Sitz. ci. 1892, p. 703*) applied Exner's formula to groups of observations made by them at Wolfenbüttel on quiet, comparatively clear days. They found a fair general agreement between the observed and calculated mean values of P for the groups, but within the same vapour density group the individually observed values of P often differed conspicuously. This had been noticed previously by Exner himself. Independent critical examinations of Exner's theory have been made by Chree (*Proc. Roy. Soc. vol. lx. 1896, p. 96*), Braun (review *Met. Zeit. 1896, p. [78]*), Trabert (*Met. Zeit. 1897, p. 106*), and Gockel (*Met. Zeit. 1897, p. 281*), dealing respectively with observations at Kew, Bamberg, Meiningen, and Ladenburg. In each case the conclusion reached was that the relation between potential gradient and vapour density is not a unique and fundamental one, as Exner supposes. When observations taken at all seasons of the year are combined together, the great majority of instances of large vapour density (or of high temperature) will be found to have occurred in summer, when the potential gradient is normally low; thus there can hardly fail to be a certain amount of agreement between observation and any theory which associates low potential with high vapour density (or high temperature).

§ 21. In 1887 Hertz (*Wied. Ann. xxxi. p. 983*) found that the discharge between two poles was facilitated by the presence of ultra-violet light. Subsequent experimenters (see J. J. Thomson's *Recent Researches in Electricity*, arts. 39 to 42) found that the seat of this action was the cathode, and further, that various metallic substances—notably freshly-polished zinc—when insulated became positively electrified, or rapidly lost a negative charge when exposed to ultra-violet light from any source, including the sun. This species of dissipation is confined to negative charges, and depends principally on the material of the charged surface and the freshness of its polish; but it also depends on the nature of the surrounding gas and its pressure. The property, though prominent in potassium, sodium, and zinc, is inconspicuous in most common materials at the earth's surface; Elster and Geitel, however (*Wied. Ann. xlv. 1891, p. 722*), found sensible traces of it in fluorspar and a few other minerals. The earliest recognition of ultra-violet light as a possibly important factor in atmospheric electricity, seems due to Arrhenius (*Met. Zeit. 1888, pp. 297 and 348*). Whilst mentioning the possible effect of ultra-violet light incident on the earth or on particles in the atmosphere, he relies mainly on its making the air it traverses conduct electrolytically. Elster and Geitel, on the other hand, attach main if not exclusive importance to its action at the earth's surface. From experiments with electric light they concluded that z , the rate of loss of a negative charge by a small sphere of freshly amalgamated zinc, was connected with J , the intensity of ultra-violet light, by a linear relation $z=a+bJ$ (*Wien. Sitz. ci. Abth. ii. 1892, p. 703*). Having found a and b experimentally, they determined J from day to day from the observed rates of loss of charge in sunshine. They tried several formulæ connecting J with the potential gradient P , the simplest being of the type $P=A/(a+\beta J)$, where A , a , β , are constants. In comparing observed and calculated values of P , they followed Exner's example, arranging the observations in groups according to the value of J . Whilst some of the series of observed and calculated mean group values show a surprisingly good agreement, individual observations within the same group often differ conspicuously. More recently Brillouin and Buisson (reviewed *Met. Zeit. 1898, p. 38*) have found that dry ice is sensitive to ultra-violet light, the influence being of the order of one-tenth of that observed with zinc. As the ice surface melts, the effect rapidly diminishes, becoming vanishingly small when a complete layer of water has formed. This discovery has been questioned by Benndorf. If confirmed, it would increase the probability that ultra-violet light plays an important part in atmospheric electricity.

§ 22. Recently, owing mainly to the researches of C. T. R. Wilson, evidence has accumulated as to the existence in atmospheric air of nuclei—other than dust particles—which act as centres of condensation for water vapour, when supersaturation is produced artificially. Wilson found that ions acting as nuclei can be called into existence by Röntgen rays, Uranium rays, and ultra-violet light acting on negatively charged zinc or even on moist air. J. J. Thomson (*Phil. Mag. Dec. 1898, p. 533*) pointed out that if the positive and negative ions should differ in their power of condensing water vapour, then a cloud might form round the one set of ions, and that as the cloud particles fell under gravity, electrical separation would take place. Wilson (*Phil.*

Trans. cxcii. p. 289) has found that ions produced by Röntgen rays do really show this difference, negative ions serving as condensation nuclei under considerably less supersaturation than positive ions. He found, however, that the non-dust nuclei, always present in small numbers in the atmosphere, and the nuclei produced in moist air by ultra-violet light do not behave as free ions; and whilst there is considerable reason to believe that ionization develops in these nuclei in the process of supersaturation this remains to be proved. Supposing ions to act as condensation nuclei in the atmosphere, Wilson's experiments seem to indicate that this action would be chiefly limited to negative ions, and that the rain so formed would mainly carry down negative electricity. As he himself remarks, however, Elster and Geitel's experiments (§ 14) do not show any conspicuous preponderance of negative electricity in rainfall. Again, the supersaturation required before even negative ions act as condensation nuclei is considerable, and Aitken (*Nature, March 1900, p. 514*) believes that the number of dust particles usually present in the atmosphere is so large as to afford little opportunity for ions to act. Elster and Geitel on the other hand (*Terrestrial Magnetism, vol. iv. 1899, p. 213*) regard the action of ions, positive as well as negative, as in all probability a factor of importance.

§ 23. Everett (*Phil. Trans. 1868, p. 347*), in discussing the Kew atmospheric electricity results, specified certain points of resemblance between the diurnal variation and that of barometric pressure. The two elements agree in having two maxima and minima in their diurnal inequalities, and the times of their occurrence, at least at Kew, are fairly similar. Hann (*Met. Zeit. 1889, p. 106; 1890, p. 29; 1891, p. 113*) has dwelt on this resemblance in reviewing atmospheric electricity observations at various stations, and has further pointed out that the relative importance of the semi-diurnal as compared with the diurnal term in a Fourier analysis, in the case of electric potential as in that of barometric pressure, appears less in arctic than in temperate latitudes, and is greatest in tropical stations.

§ 24. In the papers mentioned in § 20, Chree, Braun, Trabert, and Gockel all describe a closer association of high potential gradient with low temperature than with low vapour density. Trabert seems almost disposed to regard this association as fundamental, in the absence presumably of disturbing causes such as rainfall. If this were the case, we ought to encounter exceptionally high potential gradients at arctic stations, especially at night in winter. At Cape Thorsden, however, so far as the recorded position of the water-dropper enables one to judge, the potential gradient was exceptionally low. At Sodankylä, Lemstrom and Biese found that the mean potential gradient for the colder half of the day was considerably less than that for the warmer half during winter and spring, and that for the year as a whole, the mean gradient during the warmer hours stood to that during the colder hours in the ratio 823 : 735. Again, while the chief maximum in the diurnal inequality of the potential gradient usually occurs after sunset, the principal minimum at many stations occurs before sunrise, when the temperature is at its lowest. Finally, whilst the diurnal inequality of the potential gradient usually shows two maxima and minima, that of temperature has normally but one.

§ 25. Observations by Elster and Geitel on 19th August 1887, and by Ludwig on 22nd January 1898 (*Met. Zeit. 1888, p. 27, and 1899, p. 281*), agreed in showing a diminution of potential gradient during the totality of a solar eclipse, followed by a smart rise after totality. These observations possess a certain significance in connexion with the ultra-violet light theory of Arrhenius, to which they seem opposed. Sudden changes of potential gradient are, however, so frequent, that much weight cannot be assigned to observations so limited in number. Observations under somewhat analogous conditions, but pointing to an opposite conclusion, are described by Gockel (*Met. Zeit. 1899, p. 481*). During several days' observations in a small oasis, El Mora near Biscra, he found a marked tendency in the potential gradient to rise rapidly just after sunset.

§ 26. Lemstrom (*Brit. Assoc. Report for 1898, p. 808*) has been experimenting since 1885 on the influence of artificial electric fields or currents on the growth of plants. The influence is, he says, in general highly beneficial; for instance, it shortens the time required by strawberries and raspberries to ripen, and increases the yield. It may, however, be injurious, especially during bright days, unless abundance of water is provided. Lemstrom believes atmospheric electricity to play an important part in the growth of vegetation in high latitudes, and he assigns a special rôle to the needles of fir and pine trees. E. H. Cook (*Brit. Assoc. Report for 1898, p. 809*) describes experiments somewhat similar to Lemstrom's. He observed a beneficial effect on plants grown under a pole—especially the negative pole—of a Wimshurst machine or an induction coil. Cook refers to experiments aiming at the direct utilization of atmospheric electricity.

§ 27. The beginning and ending of thunderstorms at a station are seldom very clearly defined, and the duration is very variable, so that the exact significance to be at-

tached to figures showing the diurnal inequality of thunderstorms is open to a little uncertainty. The data in Tables VIII. and IX. are all quoted by Arrhenius (*Met. Zeit.* 1888, p. 348), except those for Edinburgh, which are from a paper by Mossman (*Trans. R. S. E.* vol. xxxix. p. 63). The data for Belgium are due to Lancaster, those for Italy to Ferrari; in the latter case only storms lasting less than three hours are included. The data for the Russian empire are due to Klossousky; they are based on ten years' observations, 1870-79. In all cases the figures represent percentages of the total number, afternoon hours are dashed.

TABLE VIII.

Relative Diurnal frequency of Thunderstorms.

Interval.	0-2	2-4	4-6	6-8	8-10	10-12	0'-2'	2'-4'	4'-8'	8'-8'	8'-10'	10'-12'

South Russia	5.5	4.9	11.6	12.9	25.8	16.6	11.7	11.0
Mean	3.5	3.0	3.1	8.5	23.6	28.3	20.4	9.6

§ 28. Table X. shows how the number of thunderstorms varies throughout the year. The figures are percentages of the total number recorded. The epochs covered and the sources of the figures are as follows: Edinburgh, 1770-1896, Mossman (*Trans. R. S. E.* vol. xxxix. p. 63);

TABLE X.

Relative frequency of Thunderstorms throughout the Year.

	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.	Jan.	Feb.	Mar.
Edinburgh	8.8	12.6	20.8	28.5	18.3	7.2	2.2	0.9	0.9	1.8	1.2	1.8
London	6.6	12.7	18.8	25.5	19.2	9.3	3.1	1.7	0.9	0.6	0.5	1.6
Paris	7.5	14.9	21.8	22.0	17.0	9.9	8.5	0.4	0.4	0.2	0.4	2.8
Hungary	5.7	16.2	25.8	22.8	17.0	6.9	2.4	0.8	0.8	0.1	0.4	1.8
Batavia	10.5	7.9	5.5	4.8	8.8	5.4	8.8	12.2	10.9	10.4	9.2	11.1
West Siberia	0.8	11.5	28.0	36.4	20.1	8.0				6.2		
North Russia	0.7	7.5	27.6	32.2	24.4	5.5				2.1		
South "	8.8	14.2	27.3	28.4	15.2	8.8				5.8		
Italy	7.4	7.2	19.1	17.2	16.5	14.6				18.2		

London, 1763-1896, Mossman (*Quarterly Journal of R. Met. Socy.* vol. xxiv. 1898, p. 31); Paris (Parc St Maur), 1873-93, Renou (*Met. Zeit.* 1894, p. 277); Hungary, mean from numerous stations, 1871-95, Héjas (*Met. Zeit.* 1899, p. 219); Batavia, 1867-95 (*Mag. and Met. Observations*, vol. xviii. 1895); Russian provinces, 1870-79, and Italy (1882-83) from Arrhenius (*Met. Zeit.* 1888, p. 348). In the last-mentioned cases the data for winter are lumped together, so for convenience the year starts with April.

Alongside this last table it is instructive to place the following particulars as to the number of persons killed by lightning in different months in England and Wales during the twenty-four years 1857-80 (R. Lawson, *Quart. Journal R. Met. Soc.* vol. xv. 1889, p. 140), with corresponding data in the United States during the eight years 1891-98 (Henry, *Bull.* No. 26, U.S. Dept. of Agriculture, 1899). The six winter months October-March are grouped together.

TABLE XI.
Total deaths by Lightning.

	April.	May.	June.	July.	August.	September.	Winter.	Total.
England and Wales (24 years)	10	46	127	114	93	30	23	443
United States (8 years)	116	337	641	683	484	153	82	2496

§ 29. If we compare Tables VIII., IX., and X., with Tables I., II., and III., we see that to a certain extent high thunderstorm frequency and low potential gradient vary in parallel lines. Thus, thunderstorm frequency and intensity are greatest about midsummer, when potential gradient is least, and there is at most stations a minimum of potential gradient in the afternoon at about the same hour as the thunderstorm maximum. The connexion is, however, far from close. Thus we have the thunderstorm minimum occurring alongside of the early morning potential gradient minimum; and the diurnal and annual variations in thunderstorms appear much more accentuated than the corresponding variations in potential gradient.

§ 30. When we consider the influence of geographical position, we also find thunderstorm frequency more variable than potential gradient, at least so far as is at present known. If we accept Exner's observations of potential as representative, the mean potential gradient does indeed diminish as we pass from temperate to tropical climates, but we do not encounter such notable discrepancies as are presented in Table XII. The data are from the sources already mentioned.

TABLE XII.

Average Number of Thunderstorms in a Year.

Edinburgh, 1770-1896.	London, 1768-1896.	Paris, 1873-93.	Batavia, 1867-95.
6.4	10.7	27.3	120

It must be allowed that the drawing of safe conclusions from thunderstorm data is particularly difficult, owing to the differences between the records from stations in the same latitude. Instructive illustrations are afforded in Plate I. of the memoir by A. J. Henry, on United States thunderstorms mentioned above. In some parts of the Pacific states the average annual number is put at from 1 to 5, as against 30 to 45 in some of the central and south-eastern states. Even in some quite small areas, especially islands or coast districts containing high mountains, the differences in thunderstorm frequency are great. There is the further consideration that a great deal may depend on the observer.

§ 31. Other thunderstorm data are more independent of the imagination, but all seem attended by sources of uncertainty. An illustration is afforded by the following statistics from the paper by Lawson already mentioned, giving the average number of persons killed annually per ten million inhabitants in various districts of England and Wales. The original treats separately the epochs 1852-61, and three following decades. Table XIII. gives only the final means. The letter M denotes "midland"; N, north; S, south, &c.

TABLE XIII.

Persons killed annually per Ten Million Inhabitants.

London.	S.E.	S.M.	E.	S.W.	W.M.	N.M.	N.W.	York.	N.	Wales.
1.3	8.0	12.3	12.7	5.6	10.7	18.0	6.6	11.4	10.4	9.1

The north-midland district (Leicesters, Rutland, Lincoln, Nottingham, and Derby) showed the largest proportion of persons killed during each decade, and London (metropolitan area) the least. From what is known otherwise, there can hardly be any doubt that one would be seriously in error if one supposed the figures in Table XIII. to be an exact measure of relative thunderstorm intensity. The figures are largely influenced by the fact that persons employed indoors have much less chance of being struck by lightning than those out of doors. As emphasizing this fact, Lawson mentions that between 1852 and 1880, only 104 females were killed by lightning, as against 442 males.

§ 32. Table XIV. gives the mean annual number of thunderstorms recorded per decade at Edinburgh, London, and Tilsit.

The Edinburgh and London data are from the papers by Mossman already mentioned, those for Tilsit are due to Kassner (see *Met. Zeit.* for 1894, p. 237).

TABLE XIV.
Mean Annual Number of Thunderstorms.

Decade ending	1800	1810	1820	1830	1840	1850	1860	1870	1880	1890
Edinburgh .	4.0	4.9	5.7	7.7	6.7	5.7	6.5	5.4	10.6	9.4
London .	7.9	9.5	8.3	11.5	11.8	10.5	11.9	9.6	15.7	13.0
Tilsit	12.1	12.1	16.1	15.3	11.9	17.6	21.8

Mossman expresses the opinion that the apparent recent increase in the frequency of thunderstorms at Edinburgh and London is, to some extent at least, a true phenomenon. Unquestionably the two sets of figures show corroborative features—notably the fall in the decade 1861 to 1870—but it is difficult to feel certain that the notable extension in the limits of both cities may not have exercised an influence. The diminished intensity in the decade 1861-70 is, it may be added, in accord with Lawson's vital statistics. In Germany various authorities believe in a great recent increase in thunderstorms. Von Bezold (*Berlin. Sitz.* 1899, No. 16) has given a table showing the number per million of insured houses struck in Bavaria for each year from 1833 to 1897. Prior to 1868, the number struck in one year never exceeded 78 per million; between 1868 and 1883 it exceeded 100 per million in five, but only five, years; since 1884 it has only once been less than 100 per million, and it exceeded 200 per million in 1895, 1896, and 1897. Kassner (reviewed *Met. Zeit.* 1890, p. 385), dealing with similar insurance statistics for Central Germany, concluded that during the twenty-six years 1864 to 1889, destructive lightning strokes had increased 126 per cent. as against an increase of only 11 per cent. in houses. Von Bezold seems to accept a large increase in thunderstorm intensity in Germany as an undoubted fact, and he is disposed to associate it with the great increase in smoky factory chimneys, and in the number of wires and rails all over the country. It is possible, of course, that changes in the ordinary height or construction of buildings, or influences which only an insurance expert could assess, may have had an effect.

§ 33. Table XV. gives data based on the number of trees of different species struck by lightning during a series of recent years in the forests of Lippe, in Germany, as quoted by Henry (*l.c.*).

TABLE XV.

Species of Tree.	Oak.	Fir.	Pine.	Beech.	Larch.	Ash.	Birch.
Total struck .	159	59	20	21	7	5	4
Mean liability .	57	39	5	1

In calculating the liability, allowance is made for the relative numbers of the different species. The different years are treated separately, the liability of beech to be struck being taken as unity throughout. Prohaska (see *Met. Zeit.* 1899, p. 128) gives somewhat analogous data for Styria. He concludes that oaks, poplars, and pear trees are especially liable to be struck, while beech is exceptionally safe. Jonesco (see Henry, *l.c.*) has concluded from experiments that fresh wood, rich in starch, but poor in fatty material, possesses the greatest electrical conductivity, and that the conductivity in some species of living trees varies a good deal with the season of the year. He believes that the liability to be struck by lightning is greater the higher the conductivity. Allowance must, however, be made for the fact that different species of trees attain different heights, and that one species may be common in marshy, another on rocky ground. According to Hellman (quoted by Henry), the liability to lightning stroke on different soils in Germany may be put at: chalk 1, clay 7, sand 9, loam 22. Differences of this kind might influence the apparent liability of different species of trees to be struck.

§ 34. Luminous discharges from pointed objects are not infrequent in mountainous districts, especially during thunderstorms. On the Sonnblick, where the phenomenon is of frequent occurrence, St Elmo's fire has been found to answer to a discharge sometimes of positive, sometimes of negative electricity (Elster and Geitel, *Met. Zeit.* 1891, p. 321, and 1894, p. [68]). The colour and appearance of the light differ in the two cases, red predominating in a positive, blue in a negative discharge. Stade (*Met. Zeit.* 1898, p. 238) also describes the appearance of St Elmo's fire of different signs, as observed on the Brocken.

§ 35. A description of the more prominent features of aurora will be found in the *Ency. Brit.* vol. xvi. pp. 177, 178, 183. Table XVI. contains some statistics more recently published as to the relative frequency of auroras in different months of the year. The data for Scotland and London are from papers by Mossman (see *Met. Zeit.* 1898, p. 307), the rest are quoted by Ekholm and Arrhenius (*Kongl. Svenska Vetenskaps-Akademiens*

Handlingar, Bd. 31, No. 2, 1898). The figures are percentages of the mean number for the year.

TABLE XVI.
Relative frequency of Auroras throughout the Year.

	N.E. Scotland (122 years).	London (189 years).	Norway (1861-95).	United States (1871-98).	From 16° S. to 39° S. (1788-1894).

Table XVI. is in general agreement with the statement in the *Ency. Brit.* that auroras are most frequent near the equinoxes. In comparing winter and summer data, especially in high latitudes, it must be remembered that faint auroras are invisible in twilight.

§ 36. Table XVII. may be regarded as a continuation of one in the *Ency. Brit.* vol. xvi. p. 178. It gives Wolf's relative sun-spot numbers alongside of numbers proportional to the frequency of auroras. In the case of Edinburgh the figures are the actual number of auroras as given by Mossman (*l.c.*). The other data are from a paper by Ekholm and Arrhenius (*K. Svenska Vet.-Akad. Hand.* Bd. 31, No. 3, 1898).

TABLE XVII.

Sun-spot and Auroral Frequency.

Year.	Wolf's Number.	Auroral Frequency.		
		Edinburgh.	N. America.	16° to 39° S.
1869	73.9	5	...	3
1870	139.1	19	...	123
1871	111.2	21	408	60
1872	101.7	8	565	105
1873	66.3	12	781	8
1874	44.6	10	1443	11
1875	17.1	4	741	6
1876	11.3	0	676	2
1877	12.3	2	877	1
1878	3.4	1	258	0
1879	6.0	0	405	1
1880	32.3	12	646	5
1881	54.3	2	804	17
1882	59.6	5	860	138
1883	63.7	2	686	28
1884	63.5	3	533	0
1885	52.2	5	728	2
1886	25.4	6	974	8
1887	13.1	0	610	3
1888	6.8	1	759	9
1889	6.3	0	336	1

1892	73.8	9	614	48
1893	84.9	2	1067	9
1894	78.0	8	...	12

§ 37. During the polar year, September 1882 to September 1883, numerous aurora observations were made at many of the stations. Those at the Finnish station, Sodankylä, have been discussed by Lemstrom and Biese (*Exped. Polaire Finlandaise*, t. iii., Helsingfors, 1898). In addition to the more usual phenomena the Finnish observers noticed a variety of others. On a good many occasions, in the absence of ordinary aurora, they saw a yellowish-white illumination, showing in the spectroscope the characteristic auroral line (wave-length 5569×10^{-7} mm., according to Lemstrom). On some occasions, in the absence of any phenomenon visible to the unaided eye, Lemstrom saw the auroral line wherever he turned the spectroscope. The most outstanding phenomena, however, described by Lemstrom and Biese are artificially produced luminosities, in the shape usually of flames, but occasionally resembling auroral rays. The auroral line was usually detected, but was feeble. The apparatus consisted of a number of sharp points connected by wires carried on insulators, the whole enclosing an area of several hundred square metres on the top of one or other of a

series of hills near Sodankylä. Sometimes a Holtz machine was introduced into the wire circuit, and when worked it enhanced the effect, or even rendered it visible when previously unseen. Coloured illustrations represent the artificial phenomenon on several occasions as very prominent, and extending to a considerable height.

§ 38. At the Danish polar station, Godthaab, Paulsen saw on several occasions auroral sheets, which seemed to be suspended vertically like curtains and to sweep past with great velocity, travelling from magnetic south. At Paulsen's suggestion, Lieut. Vedel of the Ryder Arctic Expedition, 1891, 1892, kept a lookout for this phenomenon, and was able on a variety of occasions to observe the declination magnet during its occurrence. According to these observations—made on an island in Scoresby Sound, 70° 27' N. lat.—the needle moved to the west as the auroral curtain approached from the south, oscillated as the curtain passed overhead, and then moved to the east as the curtain receded towards the north (Paulsen, *Bull. de l'Acad. Roy. . . de Danemark*, 1894, p. 148). Paulsen believes the phenomenon to imply the existence of an electric current directed downwards in the space occupied, or seemingly occupied, by the auroral curtain.

§ 39. Numerous attempts have been made to determine the height of auroral displays. Simultaneous theodolite observations have frequently been made from two stations at a considerable distance apart. The calculated heights in mean latitudes have often exceeded 100 kilometres. At Godthaab the calculations of the Danish observers often put auroral arcs at heights under 10 kilometres, and occasionally under 2. From the observations at Sodankylä, Lemstrom thought it doubtful whether the objects seen from the two ends of the base were really the same. The question has been treated with great fullness of detail by Cleveland Abbe (*Terrestrial Magnetism*, vol. iii. 1898, pp. 5, 53, and 149); he seems disposed to doubt whether what the observer sees as aurora has an independent objective existence.

§ 40. The subject of lunar influence has been treated by Ekholm and Arrhenius in several papers dealing with a great mass of observations, and containing many useful references (*K. Sven. Vet.-Akad. Hand.*, Bd. 19, No. 8; Bd. 20, No. 6; Bd. 31, No. 2). In the case alike of electric potential, thunderstorms, and auroras, they find a conspicuous tropical lunar period, 27·82 days. They conclude, however, that the synodic lunar period, 29·53 days, found by Fritz in auroras is not real, arising simply from the fact that

moonlight affects the visibility of auroras. An investigation by Polis (*Met. Zeit.*, 1894, p. 230) seems to indicate a synodic lunar period in thunderstorms at Aachen. Investigations into thunderstorm data at Paris by Renou (*Comptes Rendus*, cxviii. p. 140), and into similar data at Batavia (*Batavia Observations*, vol. xviii. 1895), on the other hand, would indicate that if a lunar influence exists it is small. Ekholm and Arrhenius (*K. Sven. Vet.-Akad. Hand.*, Bd. 31, No. 3) have also examined into the existence of a period of approximately twenty-six days. They decide in favour of the existence of such a period, not merely for thunderstorms and auroras, but also for magnetic storms and for the amplitude of diurnal variation of magnetic elements. The most probable value for the period is, they find, 25·929 days. The methods and conclusions of Ekholm and Arrhenius have been critically discussed by Schuster in several papers with somewhat unfavourable results. (See MAGNETISM, TERRESTRIAL, § 14.)

(C. C.)

Atrek, a river rising in the Persian province of Horassan, enters the S.E. corner of the Caspian Sea, after a course of nearly 300 miles. In its lower course it forms the frontier between Persia and Russia.

Attleborough, a town of Bristol county in South-eastern Massachusetts, U.S.A. It has an area of 28 square miles, with a rolling surface, and contains a large rural population, with a village of considerable size, bearing the same name as the town. This has manufactures of a varied character, largely jewellery. It is on the New York, New Haven, and Hartford railway. It was incorporated in 1694. Population (1890), 7577; (1900), 11,335.

Attock, a town and fortress of British India, on the Indus, in the Rawal Pindi district of the Punjab, 47 miles by rail from Peshawar. In 1883 an iron girder bridge of five spans was opened, which carries the North-western railway to Peshawar, and which also has a subway for wheeled traffic and foot passengers. The military importance of Attock has diminished, but it still has a garrison of artillery and infantry. St Peter's Church is a fine building. Population (1881), 4210; (1891), 2654.

Atui. See COOK ISLANDS.

Aube, a department in the E. of France, watered by the Seine and its tributary the Aube.

Area 2327 square miles, with 26 cantons and 446 communes. The population decreased from 257,374 in 1886 to 251,435 in 1896. The chief towns are Troyes (52,000 inhabitants in 1896), Bar-sur-Aube, Bar-sur-Seine, Nogent, Arcis, and Romilly. Births (1899), 4547, of which 463 were illegitimate; deaths, 5641; marriages, 1693. In 1896 there were 696 schools, with 32,000 pupils. One

per cent. of the population was illiterate. The land under cultivation comprised 1,383,200 acres, of which 918,840 acres were plough-land, and 41,990 acres in vines. The wheat crop in 1899 yielded a value of £1,100,281. Rye, barley, oats, and mangold-wurzel also contribute to the agricultural wealth of the department. The production of vines in 1899 amounted to the value of £300,000. In 1899 the live stock numbered 31,220 horses, and 88,790 cattle. As it lacks both coal and iron, the department does little in the way of working metals, producing only cast-iron and steel to the value in 1898 of £60,000; but the textile industry has assumed large proportions around Troyes, where the cotton manufacture employs 24,000 looms and 70,000 spindles.

Aubervilliers-les-Vertus, a village, arrondissement of St Denis, department of Seine, France, on the canal St Denis, 2 miles from right bank of Seine and 1 mile N. of the fortifications of Paris. Near it is a fort of the 2nd line. Manufactures include chemicals, glue, cardboard, printing ink, and glass, and there are iron-works. Population (1881), 19,340; (1891), 24,757; (1896), 27,064; (comm.), 27,064.

Auburn, capital of Androscoggin county, Maine, U.S.A., situated on the Androscoggin river, which furnishes abundant water-power. It has communication by three railways, the Maine Central, the Grand Trunk, and the Portland and Rumford Falls. Its manufactures consist mainly of cotton goods and boots and shoes. Population (1880), 9555; (1890), 11,250; (1900), 12,951.

Auburn, capital of Cayuga county, New York, U.S.A., situated in 42° 55' N. lat. and 76° 35' W. long., at the outlet of Owasco lake, at an altitude of 673 feet. Though the site is hilly its plan is regular. The city is divided into ten wards, has a good water supply pumped from the lake, and most of its streets are macadam-

ized. Its manufactures are extensive, in 1890 having a value of more than \$9,000,000, and consist largely of agricultural implements and boots and shoes. The city is traversed by the New York Central and Hudson River and the Lehigh Valley railways. It was the home of William H. Seward, secretary of state during the Civil War and the period of reconstruction. Population (1880), 21,924; (1890), 25,858; (1900), 30,345.

Auch, chief town of department Gers, France, 426 miles S.S.W. of Paris, on railway from Agen to Toulouse. There are a civil and military hospital and a large asylum. Important articles of commerce are wine, corn; and wool; poultry are extensively exported, and its pâtés-de-foie (of duck) are esteemed; marble and spar are worked. Population (1881), 9560; (1891), 9273; (1896), 9313, (comm.) 11,461.

Auckland, an important seaport, on the southern shore of Waitemata harbour, Eden county, in the province of Auckland North Island, New Zealand. It is the largest and most beautiful town in New Zealand. Its public library and art gallery owe much to the generosity of Sir George Grey and other citizens. Its museum shows the best existing collection of Maori art. The extension of the city has not marred the charm of the surroundings. These, indeed, have been beautified by gardens and tree planting. The industries are substantial, among them being sugar-refining, shipbuilding, manufactures of rope and twine, bricks and tiles, while there are also timber works. The harbour accommodation is very good, and includes two graving docks, of which one (the Calliope) is 525 feet long, the other 312. The total trade in 1893 was £2,744,277; in 1896, £3,236,605; in 1899, £4,071,323. The registered tonnage of shipping in 1899 was—inwards, 311,827 tons; outwards, 214,351 tons. Population (1871), 18,000; (1881), 26,083; (1891, with suburbs), 51,287; and now estimated at 65,000.

Aude, a department in the S. of France, bordering on the Mediterranean. It is traversed by offshoots of the Pyrenees and of the Corbières, and watered by the Aude.

Area, 2448 square miles, distributed among 31 cantons and 439 communes. The population declined from 332,080 in 1886 to 310,513 in 1896. The chief towns are Carcassonne, the capital, with a population of 30,000 in 1896, Castelnaudary, Limoux, and Narbonne (30,000 inhabitants). Births in 1899, 6233, of which 232 were illegitimate; deaths, 6227; marriages, 2286. In 1896 the primary schools numbered 836, with 45,000 pupils. Four per cent. of the population was illiterate. The surface under cultivation measured 975,650 acres, of which 476,710 acres were plough-land, and 284,000 acres laid out in vines. In this latter culture Aude holds the third rank in France, in respect of extent of cultivation. In 1899 the wheat crop yielded a value of £463,203; maize is one of the cultures next in importance. In 1899 the vines gave a gross return of the value of £4,040,000. The mulberry is also grown. In 1898 the live stock numbered 25,136 horses, and 31,080 cattle. Aude produces a little iron and (1898) 8000 tons of sea salt. There is no working in metals, and the other industries, giving way before all-engrossing viticulture, are quite inconsiderable.

Audenarde. See OUDENARDE.

Audran, Edmond (1842-1901), French musical composer, was born at Lyons in 1842. He studied music at the École Niedermeyer, where he won the prize for composition in 1859. Two years later he accepted the post of organist of the church of St Joseph at Marseilles. He made his first appearance as a dramatic composer at Marseilles with *L'Ours et le Pacha* (1862), a musical version of one of Scribe's vaudevilles. This was followed by *La Chercheuse d'esprit* (1864), a comic opera, also produced at Marseilles. Audran wrote a funeral march on the death of Meyerbeer, which was performed with some success, and made various attempts to win fame as a writer

of sacred music. He produced a mass (Marseilles, 1873), an oratorio, *La Sulamite* (Marseilles, 1876), and numerous minor works, but he is known almost entirely as a composer of the lighter forms of opera. His first Parisian success was made with *Les Noces d'Olivette* (1879), a work which speedily found its way to London and (as *Olivette*) ran for more than a year at the Strand Theatre (1880-81). Audran's music has, in fact, met with as much favour in England as in France, and all save a few of his works have been given in a more or less adapted form in London theatres. Besides those already mentioned, the following have been the most undeniably successful of Audran's many comic operas: *Le Grand Mogol* (Marseilles, 1876; Paris, 1884; London, as *The Grand Mogul*, 1884), *La Mascotte* (Paris, 1880; London, as *The Mascotte*, 1881), *Gillette de Narbonne* (Paris, 1882; London, as *Gillette*, 1883), *La Cigale et la Fourmi* (Paris, 1886; London, as *La Cigale*, 1890), *Miss Hélyett* (Paris, 1890; London, as *Miss Decima*, 1891), *La Poupée* (Paris, 1896; London, 1897). Audran was one of the best of the successors of Offenbach. He had little of Offenbach's humour, but his music is distinguished by an elegance and a refinement of manner which lift it above the level of opéra bouffe to the confines of genuine opéra comique. He was a fertile if not a very original melodist, and his orchestration is full of variety, without being obtrusive or vulgar. Many of his operas, *La Mascotte* in particular, reveal a degree of musicianship which is rarely associated with the ephemeral productions of the lighter stage. He died 17th August 1901.

(R. A. S.)

Auerbach, Berthold (1812-1882), German novelist, was born on 28th February 1812, at Nordstetten in the Black Forest. His parents were Jews, and he was intended for the priesthood; but becoming estranged from Jewish orthodoxy by the study of Spinoza, he devoted himself to literature, and made a fortunate beginning in a romance on the life of Spinoza (1837), so interesting in itself, and so close in its adherence to fact, that it may be read with equal advantage as a novel or as a biography. A translation of Spinoza's works followed in 1841, and Auerbach turned to the class of fiction which has made him famous: the *Dorfgeschichten*, or stories of peasant life in the Black Forest, in which, as well as in *Barfüssele*, *Edelweiss*, and other novels of greater compass, he depicts the life of the south German peasant as Jeremias Gotthelf had painted the peasantry of Switzerland, but in a much less realistic spirit. When this vein was exhausted Auerbach returned to his first phase as a philosophical novelist, producing *Auf der Höhe*, *Das Landhaus am Rhein*, and other romances of profound speculative tendencies, turning on plots invented by himself. These were no exception to the general wearisomeness of long German novels, and Auerbach's fame will continue to rest upon his *Dorfgeschichten*, impaired as the celebrity of even these has been by the growing demand for a more uncompromising realism. Auerbach died at Cannes, 8th February 1882.

(R. G.)

Auersperg, Anton Alexander, COUNT (1806-1876), after Grillparzer the most celebrated modern Austrian poet, was born at Laibach, 11th April 1806. Born to an ample fortune, he took a prominent part in public life, which became more active as the grip of absolutism gradually relaxed. At first the object of persecution and suspicion for his Liberal tendencies, he was in 1860 summoned by the Crown to represent Carinthia in the Diet, and was made a peer for life in the following year. His subsequent course was that of a determined opponent of federalism, but the current of events was too strong for him. He died at Gratz, on 12th September 1876. As a

poet Auersperg gained great reputation by the anonymous *Walks of a Vienna Poet* (1831), a collection of lyrics displaying the humour, tender feeling, and power of natural description which continued to characterize him, and which excited especial attention by so pronounced a hostility to Metternich's despotic system that the author was obliged to print them at Hamburg. Subsequent volumes under the pseudonym of "Anastasius Grün" were no less successful, and in 1850 Auersperg further endeared himself to his countrymen by an epic of popular life, *Der Pfaff von Kahlenberg*. If not the greatest of Austrian poets, he is the most typically national. Among his works is a version of the English ballads of the Robin Hood cycle. (R. G.)

Augier, Guillaume Victor Émile (1820-1889), French dramatist, who with Dumas *fils* and Sardou may be said to have held the French stage during the second empire, was born at Valence in Drôme on the 17th September 1820. He received a good education and studied for the bar. In 1844 he wrote a play in two acts and in verse, *La Ciguë*, refused at the Théâtre Français, but produced with considerable success at the Odéon. This settled his career. Thenceforward, at fairly regular intervals, either alone or in collaboration with some well-known writer—Musset, Sandeau, Labiche—he produced plays which were in their way eventful, and in the case of the *Fils de Giboyer*—which was regarded as an attack on the clerical party in France, and only brought out by the direct intervention of the emperor—caused some political excitement. His last comedy, *Les Fourchambault*, belongs to the year 1878. After that date he wrote no more, restrained by an honourable fear of producing inferior work. The Academy had long before, on the 28th January 1858, elected him to be one of its members. He died in his house at Croissy on the 25th October 1889. Such, in briefest outline, is the story of a life which Augier himself describes as "without incident"—a life in all senses honourable. The man respected himself and his art, and his art on its ethical side—for he did not disdain to be a teacher—has high qualities of rectitude and self-restraint. Uprightness of mind and of heart, generous honesty, as M. Jules Lemaître well said, constituted the very soul of all his dramatic work. Nor are exemplifications far to seek. In the *Mariage d'Olympe* (1855) the courtesan is shown as she is, not glorified as in Dumas's *Dame aux Camélias*. In *Gabrielle* (1849) the husband, not the lover, is the sympathetic, poetic character. In the *Lionnes pauvres* (1858) the wife who sells her favours comes under the lash. Greed of gold, social demoralization, lust of power, these are satirized in *Les Effrontés* (1861), *Le Fils de Giboyer* (1862), *Contagion* (1866), *Lions et Renards* (1869)—which, with the *Gendre de M. Poirier*, reach the high-water mark of Augier's art; while in *Jean de Thommeray* (1873), brought out after the great reverses of 1870, the regenerating note of patriotism rings high and clear. But it would be unfair to suggest that Augier was a preacher only. He was a moralist in the great sense, the sense in which the term can be applied to Molière and the great dramatists—a moralist because of his large and sane outlook on life. Nor does the interest of his dramas depend on elaborate plot. It springs from character and its evolution. His men and women move as personality, that mysterious factor, dictates. They are real, several of them typical. Augier's first drama, *La Ciguë*, belongs to a time (1844) when the romantic drama was on the wane; and his almost exclusively domestic range of subject scarcely lends itself to lyric outbursts of pure poetry. But his verse, if not that of a great poet, has excellent dramatic qualities, while the prose of his prose dramas is admirable for directness, alertness, sinew, and a large and

effective wit. Perhaps it wanted these qualities to enlist laughter on his side in such a war as he waged against false passion and false sentiment. (F. T. M.)

Augsburg, a town and episcopal see of Bavaria, Germany, chief town of the district of Swabia, on the river Lech, 39 miles W.N.W. from Munich by rail. The newer buildings, all in the recently built W. quarter of the city, include law courts, theatre, and municipal library, with 150,000 vols. Augsburg is particularly well provided with special and technical schools. It has become a centre of the acetylene gas industry of Germany, and the number of artisans engaged in its various works now exceed 19,000. Population (1885), 65,905; (1900), 89,109.

Augusta, a fortified seaport of the province of Syracuse, Sicily, Italy, on an island on the S. side of Cape Santa Croce, on the E. coast of the island, 19 miles by rail N. from Syracuse. It is connected with the mainland by a bridge, and has a spacious harbour, fortified, with a small foreign and some coasting trade. The people cure fish, crush out olive oil, quarry chalk, burn lime, and extract salt. Population, about 14,000. The town was founded in 1232 by the emperor Frederick II., and is memorable for the defeat (1676) of the Dutch admiral De Ruyter by the French under Duquesne, in which De Ruyter was mortally wounded.

Augusta, capital of Richmond county, Georgia, U.S.A., in 33° 29' N. lat. and 81° 51' W. long., on the west bank of the Savannah, at the head of navigation and at the falls in the river. These afford a magnificent water-power, which is extensively utilized in manufactures. The city stands at 143 feet above sea-level, is divided into five wards, is well drained and lighted, and is supplied with water from the Savannah. It is the most important cotton-manufacturing centre of the south. In 1890 the cotton factories employed 4500 hands, and their annual product was valued at over \$6,000,000. The assessed valuation of real and personal property in 1899 was \$18,780,076, the net debt \$1,896,469, and the tax rate \$24.76 per \$1000. Population (1880), 21,891; (1890), 33,300; (1900), 39,441, of whom 995 were foreign-born and 18,487 were negroes.

Augusta, capital of Kennebec county and of the state of Maine, U.S.A., on the Kennebec, at the head of tide and navigation. Its site is hilly, the land rising sharply from the river on both sides. The city is regularly laid out, and is entered by the Maine Central railway. Few of the streets are paved, and the drainage system is incomplete. There is a fine public library, and the state-house, a beautiful structure, stands on an eminence in the southern outskirts. It has considerable manufactures, chiefly in cotton, wool, and lumber, the falls in the river at this point furnishing water-power. It was settled under the name of Cushnoc in 1754, was afterwards a part of Hallowell, was incorporated as the town of Augusta in 1797, was made the capital in 1827, and received a city charter in 1849. Population (1880), 8665; (1890), 10,527; (1900), 11,683.

Augusta, Marie Louise Catherine, QUEEN OF PRUSSIA and GERMAN EMPRESS (1811-1890), born at Weimar on the 30th of September 1811, was the second daughter of Charles Frederick, grand-duke of Saxe-Weimar-Eisenach, son of Karl August, the patron of Goethe and Schiller. In 1829 she married Prince William, second son of Frederick William III. of Prussia; her elder sister, Princess Marie, had two years before married Charles, the third son of the king of Prussia, and

was the mother of Prince Frederick Charles, the famous general. There were two children of the marriage, Frederick (*q.v.*), the future emperor, and Louise (*b.* 1838), who married the grand-duke of Baden. In 1840, on the death of his father, Prince William, who, as his elder brother was childless, was now heir-presumptive, took the title of Prince of Prussia; in 1858 he became Prince Regent, and in 1861 succeeded to the throne. In 1871 he assumed the title of German emperor. The princess brought with her from Weimar a keen interest in art and literature; she continued to correspond with Goethe till his death. She also gave considerable attention to political affairs and was (again a tradition of the court of Weimar) more favourable to constitutional government and political liberty than was quite consistent with the usual tone of the Prussian court. After 1840 she and her husband generally lived at Coblenz, which always remained her favourite place of residence; but when in Berlin, especially after 1848, she became to some extent the centre of a Liberal opposition to the Government. This attitude she continued after Prince William had become king, and her influence was generally unfavourable to the policy and person of Bismarck, who in his posthumous memoirs has left a record of the difficulties which he sometimes experienced from her opposition. She was greatly interested in works of charity and benevolence and took an active part in the organization of the Red Cross Society and the Good Samaritans, established for the relief of sufferers in time of war. The old Weimar traditions continued to influence her to her latest years, and she had little sympathy with the military spirit which prevailed at the Prussian court or with the exaggeration of national feeling which became common after the great war. After 1870 again her dislike of Bismarck's policy was increased by his struggle with the Church, for though a Lutheran she always showed much interest in the Roman Catholic Church as in the worship of other religious denominations, especially that of the Anglican Church, in the ministrations of which she found much comfort in her declining years. She died in Berlin on the 7th of January 1890. (J. W. H.E.)

Augustowo, a district town of Russian Poland, 135 miles S. of Suwalki, on the canal of the same name (65 miles), connecting the Vistula with the Niemen by means of the Netta, Czernoganza, and several lakes. It has a considerable export trade to the Baltic Sea. Population (1897), 12,746.

Aulie-ata, a small district town and fort of Russian Turkestan, province of Syr-daria, 260 miles N.E. of Tashkent on the highway to Yvernyi, situated on the Talas river at the western end of the high Alexandrovskiy range, its altitude being 5700 feet. The inhabitants of the town are mostly Sarts and Tajiks trading in cattle, horses, hides, &c. The population in 1897 was 12,006.

Aumale, Duc d'. See ORLEANS.

Aundh, a native state of India, in the Deccan division of Bombay, ranking as one of the Satara Jagirs. Its area is 447 square miles; its population (65,146 in 1891) was 63,933 in 1901; its gross revenue in 1897-98 was Rs.1,89,311, of which Rs.31,779 was expended on public works; the number of police was 65; the boys at school numbered 998. The chief, whose title is Pant Pratinidhi, is a Brahman by caste. The state has suffered severely from plague, the number of deaths down to July 1898 having been 661. The town of Aundh is situated in 17° 32' N. lat. and 74° 22' E. long., 26 miles south-east of Satara. Population, about 3500.

Aurangabad, a town and district of India, in the north-west division of the dominions of the Nizam of Haidarabad, on the river Kaum. It is a railway station on the Haiderabad-Godaveri line, 435 miles from Bombay. In 1891 the population, with military cantonments, was 33,887; in 1901 it was 26,165, showing a decrease of 23 per cent. It has a cotton mill, with 184 looms and 16,500 spindles, and employing 722 hands. The district of Aurangabad has an area of 6176 square miles. The population (1891) was 1,094,601, being 152 persons per square mile; in 1901 it was 984,700, showing a decrease of 13 per cent., due to the famine of 1899-1900. It contains the famous caves of Ajanta, and also the battlefield of Assaye.

Auray (Breton *Alrae*), a town of France, department of Morbihan, in the arrondissement of Lorient, 12 miles W. of Vannes by rail. Iron manufacture and oyster culture are the chief industries; mine props are sent to England. Population (1881), 5064; (1891), 5071; (1896), 5193, (comm.) 6099; (1901), 6485.

Aurette de Paladines, Louis Jean Baptiste d' (1804-1877), French general, was born at Malzieu, Lozère, on the 9th of January 1804, was educated at St Cyr, and entered the army as sub-lieutenant of foot in 1824. He served with distinction in Algeria against the Arabs between 1841 and 1848 (lieut-colonel, officer Legion of Honour); took part in the Roman campaigns of 1848 and 1849 (colonel); and served as general of brigade throughout the Crimean War of 1854-56 (general of division, commander Legion of Honour). During the campaign in Lombardy in 1859 he commanded the ninth division at Marseilles, and superintended the despatch of men and stores to the seat of war (grand officer Legion of Honour). Placed on the reserve list in 1869, he was recalled to the Marseilles command on the outbreak of the Franco-German war of 1870-71. The revolution of the 4th September obliged him to leave Marseilles, but after the defeat of de la Motterouge and capture of Orleans by the Germans, he was appointed by the Government of National Defence, in November 1870, to the command of the army of the Loire. He was at first very successful against Von der Tann, winning the battle of Coulmiers and compelling the Germans to evacuate Orleans, but the capitulation of Metz had set free additional German troops to oppose him, and, after his defeat at Beaune la Rolande and subsequent unsuccessful fighting near Orleans, resulting in its recapture by the Germans in December, Aurette retreated into the Sologne and was superseded. After the armistice he was elected to the National Assembly by the departments both of Allier and Gironde. He sat for Allier and was one of the fifteen officers chosen to assist in the peace negotiations. He was decorated with the grand cross of the Legion of Honour, and was given the command at Bordeaux, but retired in 1872. Elected a life senator in 1875, he supported the monarchical majority of 1876. He died at Versailles on the 17th of December 1877. He was the author of *La Première Armée de la Loire*, published in 1872. His fine qualities as a soldier were marred by indecision. (R. H. V.)

Aurillac, chief town of department Cantal, France, 366 miles S. of Paris by rail. There is a bronze statue (1883) of General Delzons. Its manufactures comprise copper wares, chemical products, umbrellas, goloshes, and sabots. Population (1881), 11,655; (1891), 12,587; (1896), 13,531, (comm.) 14,578; (1901), 17,459.

Aurora, a city of Kane county, Illinois, U.S.A., situated in 41° 46' N. lat. and 88° 17' W. long., on the Fox river, 39 miles W.S.W. of Chicago, at an altitude of

648 feet. Its plan is somewhat irregular, and it is divided into seven wards. Excellent railroad connexions are afforded by the Chicago, Burlington, and Quincy, the Chicago and North-Western and the Elgin, Joliet, and Eastern railways. Agricultural tools and machines are the chief manufactures. The shops of the Chicago, Burlington, and Quincy railway, employing upwards of 2000 hands, are situated here. The silver-plate works are also one of the largest industries in the city. It was settled in 1834. Population (1880), 11,873; (1890), 19,688; (1900), 24,147.

Aurora, a city of Lawrence county, Missouri, U.S.A., on the St Louis and San Francisco railway, at its junction with a branch of the Kansas City, Fort Scott, and Memphis railway, in the neighbourhood of a lead and zinc mining region. Population (1890), 3489; (1900), 6191.

Aurora polaris. See ATMOSPHERIC ELECTRICITY.

Aussig (Czech *Oustí nad Labem*), the chief town of a government district in Bohemia, Austria; a considerable river port on the Elbe. Population in 1890, 23,723; in 1900, 40,000; almost exclusively German and Catholic (2 per cent. Czech, 5 per cent. Protestant, and 2 per cent. Jewish). The adjoining communes of Kletsche and Schön-priesen were incorporated in 1899. In 1857 there were only 6404 inhabitants. All branches of industry and trade show great progress. The port, which was extended in 1891, was entered in 1896 by 1700 passenger and 1776 freight steamers, together with 7800 sailing vessels and towed barges. The principal articles forwarded are lignite, coal, sugar, stone and stoneware, corn, fruit, flour, cotton, rice, oil, fat, salt, and petroleum. In addition to the important textile, chemical, and boat-building industries, &c., its manufactures now comprise paraffin, oils, tar, colouring stuffs, machinery, glass, pianos, leather, malt, &c. Aussig was the birthplace of the painter Raphael Mengs (1728-79).

Austin, capital of Mower county, Minnesota, U.S.A., on the Red Cedar river, at an altitude of 1200 feet. The plan is quite regular, and the city is on the Chicago and Great Western, and the Chicago, Milwaukee, and St Paul railways. Population (1880), 2305; (1890), 3901; (1900), 5474.

Austin, capital of Travis county, and of the state of Texas, U.S.A., in 30° 16' N. lat. and 97° 43' W. long., on the north bank of the Colorado. The river is not navigable. The city is divided into eleven wards; the site is level and the plan regular. The surrounding country is a rich agricultural region, producing cotton as its principal crop. The finest building is the capitol, which the state obtained by bartering 3,000,000 acres of land in the "Pan Handle." It is said to have cost \$4,500,000. The city contains a number of state institutions; among them the Lunatic Asylum, the Deaf and Dumb Asylum, the Blind Asylum, and the University of Texas. The last had 65 instructors and 800 students in 1899. Austin has three railways—the Houston and Texas Central, the International and Great Northern, and the Austin and North-Western. It received its name from Stephen Austin, a prominent man in the early history of Texas. Its site was selected, and the city built to serve as the capital, work on it having been commenced in 1839, immediately after the separation of Texas from Mexico. Population (1880), 11,013; (1890), 14,575; (1900), 22,258.

Austin, Alfred (1835—), English Poet-laureate, was born at Headingley, near Leeds, 30th May 1835. His father, Joseph Austin, was a merchant of the city of

Leeds; his mother, a sister of Joseph Locke, M.P. for Honiton. Mr Austin was educated at Stonyhurst, Oscott, and London University, where he graduated in 1853. He was called to the bar four years later, and practised as a barrister for a short time; but in 1861, after two comparatively false starts in poetry and fiction, he made his first noteworthy appearance as a writer with a satire called *The Season*, which contained incisive lines, and was marked by some promise both in wit and observation. In 1870 he published a volume of criticism, *The Poetry of the Period*, which was again conceived in a spirit of satirical invective, and attacked Tennyson, Browning, Matthew Arnold, and Mr Swinburne in no half-hearted fashion. The book aroused some discussion at the time, but its judgments were extremely uncritical. In 1881 Mr Austin returned to verse with a tragedy, *Savonarola*, to which he added *Soliloquies* in 1882, *Prince Lucifer* in 1887, *England's Darling* in 1896, and *The Conversion of Winckelmann* in 1897. For several years he edited *The National Review*, and has written many leading articles in the columns of *The Standard*. On Tennyson's death in 1892 it was felt that none of the then living poets, except Mr Swinburne or Mr William Morris, who were disqualified on other grounds, was of sufficient distinction to succeed to the laurel crown, and for several years no new Poet-laureate was nominated. In the interval the claims of one writer and another were much canvassed, but eventually, in 1896, Mr Austin was appointed. Since then he has written several occasional poems, suggested by contemporary events (in particular, the Jameson Raid), which have not escaped criticism. The chief characteristic of Mr Austin's poetry, as of the best of his prose, is a genuine and intimate love of nature. His prose idylls, *The Garden that I love* and *In Veronica's Garden*, are full of a pleasant, open-air flavour, which is also the outstanding feature of his *English Lyrics*. His lyrical poems are wanting in spontaneity and individuality, but many of them possess a simple, orderly charm, as of an English country lane. He has, indeed, a true love of England, sometimes not without a suspicion of insularity, but always fresh and ingenuous. In dramatic poetry he is less successful. His laureate poems have been considerably below the level of his earlier achievements; but it was a very unenviable task to assume the laurel in succession to two poets whose work is among the richest in English literature.

Australasia, a term used by English geographers in a sense nearly synonymous with the *Oceania* of Continental writers. It thus comprises all the insular groups which extend almost continuously from the south-eastern extremity of Asia to more than half-way across the Pacific. Its chief divisions are *Malaysia* with the *Philippines*; *Australia* with *Tasmania* and *New Zealand*; *Melanesia*, that is, New Guinea, New Britain, New Ireland, and York, the Solomons, New Hebrides, Santa Cruz, Fiji, Loyalties, and New Caledonia; *Micronesia*, that is, the Ladrões, Pelew, and Carolines, with the Marshall and Gilbert groups; lastly, *Polynesia*, that is, Samoa, Tonga, Cook, Tahiti, the Marquesas, Ellice, Hawaii, and all intervening clusters. The term is so far justified in that it harmonizes better than *Oceania* did with the names of the other continents, and also embodies the two essential facts that it is a south-eastern extension of Asia, and that its central and most important division is the great island-continent of Australia. In a more restricted sense the term *Australasia* corresponds to the large division including Australia, Tasmania, and New Zealand.

See *Australasia*, 2 vols. Stanford Compendium Series, new issue. London, 1893-94.

AUSTRALIA.

PHYSICAL GEOGRAPHY.

AUSTRALIA is the only continent entirely in the southern hemisphere. A mostly unbroken coast-line faces the sea in majestic and stately curves, giving the whole land a character of compactness, which likens it in some way to portions of the African continent. Quite one-half of its area is drained towards the interior. There are, however, no rivers like the Congo or Nile, and no snow-capped mountains to act as feeders. The average height of the land is not more than 300 feet, the highest point, Mount Kosciusko, being only 7328 feet above sea-level, and well below the limits of perpetual snow. Australia lies between $10^{\circ} 39'$ and $39^{\circ} 11\frac{1}{2}'$ south lat., and between meridians of $113^{\circ} 5'$ and $153^{\circ} 16'$ east long. Its greatest length is 2400 miles from east to west, and the greatest breadth 1971 miles from north to south. The area is, approximately, 2,946,691 square miles, with a coast line measuring about 8850. This is equal to one mile to each 333 square miles of land, the smallest proportion of coast shown by any of the continents. The salient features of the Australian continent are its compact outline, the absence of navigable rivers communicating with the interior, the absence of active volcanoes or snow-capped mountains, its isolation from other lands, and its antiquity. Some of the most profound changes that have taken place on this globe in lifting mountains such as the Alps and the Himalayas, have taken place in Mesozoic times. Rocks high up on the shoulders of these great ranges were formed beneath the sea at a time when a great portion of the Australian continent was already dry land. Vast tracts of Europe and Asia have been submerged in Tertiary times. Australia has been for the most part above the sea since the period anterior to the great earth movements named. In this sense Australia has been rightly referred to as one of the oldest existing land surfaces. It has been described as at once the largest island and the smallest continent on the globe. While in one sense a large island, it conforms in general to the continental model. The general contours exemplify the law of geographers, as to having a high border around a depressed interior, and as to having the highest mountains on the side of the greatest ocean. The main dividing range of Eastern Australia looks out upon the greatest and deepest water mass on the globe, the Tasman Sea and the South Pacific.

Australia stands up from the ocean depths in three fairly well marked shelves. The basal plain of these terraces is the bed of the Pacific, having an average depth of 15,000 feet. From this profound foundation rise Australia, New Guinea, and Melanesia, in varying slopes. The first ledge rising from the ocean floor has a depth averaging 8000 feet below sea-level. The outer edge of this basal ledge is roughly parallel to the coast of West Australia, and more than 150 miles from the land. Round the Australian Bight it continues parallel to the coast, until south of Spencer Gulf (the basal ledge still averaging 8000 feet in depth) it sweeps southwards to lat. 55° , and forms a submarine promontory 1000 miles long. The edge of the abyssal area comes close to the eastern coasts of Tasmania and New South Wales, approaching to within 60 miles of Cape Howe. The terrace closest to the land, known as the continental shelf, has an average depth of 600 feet, and connects Australia, New Guinea, and Tasmania in one unbroken sweep. Compared with other continents, the Australian continental shelf is extremely narrow. There are points on the eastern coast where the land plunges down to oceanic depths with an abruptness rarely paralleled. Off the Queensland coast the shelf broadens, its outer edge being lined by the seaward face of the Great Barrier Reef. From Torres Strait to Dampier Land the shelf spreads out, and connects Australia with New Guinea and the Malay Archipelago. An elongation of the shelf to the south joins Tasmania with the mainland. The vertical relief of the land above the ocean is one of the chief factors in determining the climate as

well as the distribution of the fauna and flora of a continent. The land mass of Australia rises to a lesser mean height than that of any other continent. The chief mountain systems are parallel to, and not far from, the coast-line. Thus, taking the continent as a whole, it may be described as a plateau, fringed by a low-lying well-watered coast, with a depressed, and for the most part arid, interior. A great central plain covers quite 500,000 square miles of the continent. Although termed the Central Plain, it is situated a little to the east of a meridional line bisecting the continent. The vast bulk of this plain is situated to the south of the 22^{nd} degree, but portions of it reach very close to the low-lying flats south of the Gulf of Carpentaria. The contour of the continent in the latitude of the Richmond River is as follows:—A short strip of coastal plain; then a sharp incline rising to a mountain range 4000 feet above sea-level, at a distance of 40 miles from the coast. From this a gently-sloping plateau keeps deepening until nearly down again to the sea-level, in a line due north of Spencer Gulf. Then there is a gentle rise to the Low Steppes, much of which country is spinifex desert 500 to 1000 feet above sea-level. A further gentle rise in the High Steppes leads to the mountains of the West Australian coast, and another strip of low-lying coastal land to the sea. The Great Central Plain is certainly Australia's most notable inland feature. Comparatively little of the rainfall over its vast extent ever reaches the sea by any known river system. Indeed the river systems as shown on maps leave a false impression as to the actual condition of things. The absence of rivers connecting the coast-line with the interior has already been noticed. In keeping with this is the solid outline of the coast generally. On the north and north-west some notable indentations lead to the Fitzroy, the Victoria, the Daley, and the Roper rivers.

The network of streams forming the tributaries of the Darling and Murray system give an idea of a well-watered country. The so-called rivers have running water only after heavy rains, and very few of these tributaries ever reach the main drainage line. Flood waters disappear often within a distance of a few miles, being absorbed by porous soil, stretches of sand, and sometimes by the underlying bed-rocks. The waters even of the Macquarie do not usually reach the Darling, but break up into innumerable gutters, and spread out over vast flats. In flood times only, the river overflows its banks, and flooding the flat country for miles around, reaches the Darling. Oxley went down the Lachlan, 1817, during one of these periods of flood, and the great plains appeared to him to be the fringe of a vast inland sea. As a matter of fact, they are an alluvial deposit spread out by the same flood waters. The great rivers of Australia, draining inland for the most part, carve out valleys, dissolve limestone, and spread out their deposit over the plains when the waters become too sluggish to bear their burden farther. From a geological standpoint, the Great Australian Plain and the fertile valley of the Nile have had a similar origin. Taking the Lachlan as one type of Australian river, we find it takes its rise amongst the precipitous and almost unexplored valleys of the Main Dividing Range. With the help of its tributaries it acts as a denuding agent for 14,000 square miles of country, and carries its burden of sediment westwards. A point is reached about 200 miles from the Dividing Range, where the river ceases to act as a denuding agent, and the area of deposition begins. But the river is still about 1000 miles from the sea. The Darling is reckoned amongst the longest rivers in the world, for it is navigable, part of the year, from Walgett to its confluence with the Murray, 1758 miles, and then to the sea, a further distance of 587 miles,—making in all 2345 miles of navigable water. But this gives no correct idea of the true character of the Darling, for it can hardly be said to drain its own watershed. From the sources of its various tributaries to the town of Bourke, the river may be described as draining a watershed. But from Bourke to the sea, 550 miles in a direct line, the river gives rather than receives water from the country it flows through.

The annual rainfall and the catchment area afford no data whatever as to the size of a river in the interior of Australia. In Europe it has been estimated that from 20 per cent. to 50 per cent. of the rainfall flows away in rivers. The discharge of the Darling River at Bourke does not amount to more than 10 per cent. of the rainfall of its catchment area. It was this startling fact which first led to the idea that, as the rainfall could not be accounted for either by evaporation or by the river discharge, much of the unaccounted-for 90 per cent. must in part sink into the ground, and in part be absorbed by some underlying bed-rock. All Australian rivers depend entirely and directly on the rainfall. They are flooded after rain, and in seasons of drought become dry water-courses. Springs which equalize the discharge of rivers by continuing to pour water into their beds, long after a rainy season,

seem entirely absent in the interior. Neither are there any snow-fields to feed rivers, as in the other continents. More remarkable still, over large tracts of country the water seems disposed to flow away from, rather than to, the river-beds. As the low-lying plains are altogether an alluvial deposit, the coarser sediments accumulate in the regions where the river first overflows its banks to spread out over the plains. The country nearest the river receiving the heaviest deposit becomes in this way the highest ground, and so continues until a "break-away" occurs, when a new river-bed is formed, and the same process of deposition and accumulation is repeated. As the general level of the country is raised by successive alluvial deposits, the more ancient river-beds become buried, but being still connected with the newer rivers at some point or other, they continue to absorb water. This underground network of old river-beds underlying the great alluvial plains must be filled to replenition before flood waters will flow over the surface.

Outside the great alluvial plain there is a vast tract of country

extending from the Musgrave Ranges west and north. This may be considered a plateau without any of the features of the plains. The bed-rock is nowhere far from the surface, thus forming a strong contrast with the great alluvial plain where the bed-rock is buried many hundred feet below the surface. Over the entire western half of Australia there is no leading drainage system, and we have here an area that is almost unique in the features of a continent. There is no high mountain, and probably over an expanse of 400,000 miles not a drop of the scanty rainfall ever reaches the sea.

The term desert applied to the Australian interior is somewhat misleading. Sand-hills there are, and vast stretches of sandy country. But much of the so-called desert will support animal life to some extent. Sturt's "Stony Desert" is not at all what the name would suggest. Peculiar water-worn and glazed boulders cover much of the surface, but there is also grass, and in good seasons the "gibber land" disappears under a waving carpet of meadow. Part of Sturt's "Stony Desert" is now a sheep-run,

SKETCH MAP OF AUSTRALIA.

with one sheep to 10 to 12 acres, but growing excellent wool. Genuine desert exists in the spinifex country. On the outskirts are shady baubinia trees and bright-looking desert-apple trees. The treacherous spinifex, too, looks fair enough from the distance, and often puts on a coat of enticing verdure when the plains and downs are parched and withered. It will grow almost on the surface of a hard rock, and in most parts of the desert the bed-rock is covered with but a shallow coating of soil. The result is like a thousand knitting-needles thrown into a confused kind of tangle, with all the points sticking upwards, and this tangle grows larger and more formidable every year, until a bush fire happily sweeps it away and a new growth starts. Much of this part of the continent is now known as the Australian Steppes. The Lower Steppes extend over an area corresponding mostly to the extent of the Cretaceous formation. Their prevailing aspect is characterized by flat and terraced hills, capped by desert sandstones, with stone-covered flats stretching over long distances. The country round Lake Eyre, where some of the land is actually below sea-level, comes under this heading. The Higher Steppes, as far as they are known, consist of Ordovician and Cambrian rocks, with an average elevation of 1500 to 3000 feet above sea-level. Over this country water-courses are shown on maps. These run in wet seasons, but in every instance for a short distance only, and

sooner or later they are lost in sand-hills, where their waters disappear and a line of stunted gum-trees (*Eucalyptus rostrata*) is all that is present to indicate that there may be even a soakage in these supposed rivers.

Another notable feature of the interior is the so-called lake area, a district stretching to the north of Spencer Gulf. These lakes are expanses of brackish waters that spread or contract as the season is one of drought or rain. In seasons of drought they are hardly more than swamps and mud flats, which for a time may become a grassy plain, or desolate coast encrusted with salt. The country around is the dreariest imaginable, the surface is a dead level, there is no heavy timber and practically no settlement. Lake Torrens is sometimes 100 miles in length. To the north stretches Lake Eyre, and to the west of Torrens Lakes, Lake Gairdner. Some of these depressions are at, or slightly below, sea-level, so much so that a very slight depression of the land would connect much of the interior with the Southern Ocean.

Along the entire coast there extends a succession of mountain ranges from Cape Howe to Cape York. These constitute a Cordillera stretching 1700 miles from north to south. Several points rise to heights of from 4000 to 5000 feet, mostly as isolated peaks. Towards the south-eastern corner of the continent the peaks come closer, clustering around

Mountain ranges.

Mount Kosciusko (7328 feet), and are here known as the Australian Alps. North of Kosciusko the Main Divide merges into the Blue Mountains and Liverpool Range. The high land continues roughly parallel to the coast, and with generally diminishing altitude through Queensland to Cape York. Near the Queensland border Mount Lindsay rises to a height of 5500 feet. In the latitude of Brisbane the chain swerves inland; no other peak north of this reaches higher than Mount Bartle Frere in the Bellenden Ker Range (5438 feet). The Southern Ocean system of the Victorian Dividing Range hardly attains to the dignity of high mountains. An eastern system in South Australia touches at a few points a height of 3000 feet; and the Stirling Range, belonging to the south-western system of South Australia, reaches to 2340 feet. There are no mountains behind the Great Australian Bight. On the west the Darling Range faces the Indian Ocean, and extends from Point d'Entrecasteaux to the Murchison River. North of the Murchison, Mount Augustus and Mount Bruce, with their connecting highlands, cut off the coastal drainage from the interior; but no point on the north-west coast reaches a greater altitude than 4000 feet. Several minor ranges, the topography of which is little known, extend from Cambridge Gulf, behind a very much broken coast-line, to Limmen Bight on the Gulf of Carpentaria. Nothing is more remarkable than the contrast between the aspect of the coastal ranges of the north-east, and on the south-east of the continent. The higher Australian peaks in the south-east just look what they are, the worn and denuded stumps of mountains, standing for untold ages above the sea. Their shoulders are lifted high above the tree-line. Their summits stand out gaunt and lonely in an unbroken solitude. Having left the tree-line far behind him, nothing is visible to the traveller for miles around but barren peaks and torn crags in indescribable confusion. A verdure of herbage clothes the valleys that have been scooped from the summits downwards. But there are no perpetual snow-fields, no glaciers creep down these valleys, and no alpine hamlets ever appear to break the monotony. The mountains of the north-east, on the contrary, are clothed to their summits with a rich and varied flora. Naked crags, when they do appear, lift themselves from a sea of green, and a tropical vegetation, quite Malaysian in character, covers everything.

The absence of active volcanoes in Australia is a state of things, in a geological sense, quite new to the continent. Some of the volcanoes of the western districts of Victoria have been in eruption probably subsequent to the advent of the black-fellow. In some instances the cones are quite intact, and the beds of ash and scoriæ are as yet almost unaffected by denuding agencies. As late as 1859 an observer wrote in the *Quarterly Journal of the Geological Society* that, with one doubtful exception, Australia was a non-volcanic continent. The exception referred to is Mount Wingen. But even here there is nothing in the least resembling volcanic conditions. Some coal seams have been burning for years, giving out much smoke and steam. Mount Wingen was, in the eyes of the settlers, as it was in fact, a "burning mountain." Late in the Tertiary period vast sheets of lava poured from many points of the Great Dividing Range of eastern Australia. But it is notable that all recent volcanic action was confined to a wide belt parallel to the coast. No evidences of recent lava flows can be found in the interior over the Great Alluvial Plain, the Lower, or the Higher Steppes. Nor has the continent, as a whole, in recent times been subjected to any violent earth tremors; though in 1873, to the north of Lake Amadeus, in central Australia, Giles records the occurrence of earthquake shocks violent enough to dislodge considerable rock masses.

The Barrier Reef forms the prominent feature off the north-east coast of Australia. Ranging for a length of 1200 miles, it is the

Barrier Reef. greatest of coral reefs, ancient or modern. The channel between the reef and the coast is in places 70 miles in width and 60 fathoms deep. Flinders described the

Barrier Reef in his *Voyage to Terra Australis*; and the Admiralty charts give much information as to soundings, &c. Our knowledge of the fauna of this richest of hunting grounds for the naturalist is very incomplete. Interest naturally centres in the coral polyp and its stony structure. Photographs have shown us what the physical features of the reefs are. The Hon. R. Abercromby's photographs, taken at Fiji, were probably the first; but Saville Kent, Agassiz, and other observers, have made us fairly well acquainted with the conditions presenting themselves on this great tract of growing land. The first point to strike a visitor to the Barrier Reef is the abundance of soft coral, or branching polyparies without a stony nucleus, and the abundance of nullipores and other plant-like organisms. Much of the pink and lilac-coloured patches that catch the eye prove on examination to be nullipores or coralline seaweeds. There are patches of pebbles and boulders and fine sand everywhere, but each particle is part of a living thing. The patches of coral grow more or less after the manner of fairy rings—the outer edges flourishing and the inner dying and breaking into coral debris. The leading forms amongst the coral masses exposed at very low tides are the branching

madrepores, the rounded masses of brain coral (meandriua), and porites. A field of madrepores is suggestive of miniature shrubbery, with plants, having the aspect of young pines. The coral is of every hue and colour, and not a little is added to the splendid scene by brilliant-hued fishes and bright and gaily-coloured sea-anemones (actinia), the latter often being more than 18 inches in diameter. The beautiful *distichopora coccinea* resembles somewhat the true red coral and is very abundant; but the red coral itself is not to be found. *Heliopora cœrulea*, the beautiful blue coral, is not rare. This remarkable species has the stony framework of a bright blue, the colouring matter of most corals being confined to the "fleshy" covering. On the reef there is always to be found a great abundance of shells, living and dead. In appearance, the living specimens of many of the handsome species are disappointing, but the crabs, star-fishes, and great clam shells are conspicuous. Sea-cucumbers abound, so much so that the bêche-de-mer fisheries bring in more than £20,000 a-year. These interesting holothurians are collected by hand at low water, and sent to the Chinese markets after being cured by drying and smoking. "Rock oysters," too, are plentiful, and the blocks thrown up by the waves are soon encrusted with the well-known and delicate species *ostrea glomerata*.

There is nothing to be seen on or around the Great Barrier Reef that might be urged as a serious objection to Darwin's well-known subsidence theory. Any facts noted as inconsistent with prolonged steady subsidence might have been caused by a very slight upheaval. The few clear openings in the whole length of the outer rampart of the Great Barrier Reef are opposed to large estuaries. But being 30 to 90 miles away, they are not, in all probability, caused by fresh water from the land. Such breaks, however, are strong evidence in favour of subsidence. The old river channels, already referred to as being below sea-level, as well as the former land-connexion with New Guinea, all point to the conditions assumed by Darwin.

EXPLORATION.

By the end of the year 1873 the whole of the eastern portion of Australia had been explored, the unknown part of the continent being confined to the interior of West Australia and those districts of South Australia north of the Macdonnell Range and west of the overland telegraph line. Several attempts had been made to cross the colony of West Australia in the direction of east and west, but even Major Warburton's expedition, the most successful of these, had failed in the important particular of determining the nature of the country through which it passed. Major Warburton had virtually raced across from the Macdonnell Range in South Australia to the head waters of the Oakover river on the north-west coast, without allowing himself sufficient time to note the characteristics of the country. The next important expedition was differently conducted. John Forrest was despatched by the Perth Government with general instructions to obtain information regarding the immense tract of country out of which flow the rivers falling into the sea on the northern and western shores of West Australia. Leaving Yewin, a small settlement about lat. 28° south, long. 116° east, Forrest travelled north-east to the Murchison river, and followed the course of that river to the Robinson Ranges; thence his course lay generally eastward along the 26th parallel. Forrest and his party safely crossed the entire extent of West Australia, and entering South Australia struck the overland telegraph line at Peake station, and, after resting, journeyed south to Adelaide. Forrest traversed seventeen degrees of desert in five months, a very wonderful achievement, more especially as he was able to give a full report of the country through which he passed. His report destroyed all hope that pastoral settlement would extend to the spinifex region; and the main object of subsequent explorers was to determine the extent of the desert in the direction of north and south. Ernest Giles made several attempts to cross the Central Australian Desert, but it was not until his third attempt that he was successful. His journey ranks almost with Forrest's in the importance of its results and the success with which the appalling difficulties of the journey were overcome. Through the generosity of Sir Thomas Elder, of Adelaide, Giles's expedition was equipped with camels. It started on the 23rd May 1875 from Port Augusta. Working westerly along the line of the 30th parallel, Giles reached Perth in about five months. After resting in Perth for a short time, he commenced the return journey, which was made for the most part between the 24th and 25th parallels, and again successfully traversed the desert, reaching the overland telegraph line in about seven months. Giles's journeys added greatly to our knowledge of the characteristics of West and South Australia, and he was able to bear out the common opinion that the interior of Australia west of 132° E. long. is a sandy and waterless waste, entirely unfit for settlement.

The list of explorers from 1875 to 1900 is a long one; but after Forrest's and Giles's expeditions the main object ceased to be the

discovery of pastoral country: a new zest had been added to the cause of exploration, and most of the smaller expeditions concerned themselves with the search for gold. Amongst the more important explorations may be ranked those of Tietkins in 1889, of W. Lindsay in 1891, of Wells in 1896, of Hübbe in 1896, and of the Hon. David Carnegie in 1896-97. Lindsay's expedition, which was fitted out by Sir Thomas Elder, the generous patron of Australian exploration, entered West Australia about the 26th parallel south lat., on the line of route taken by Forrest in 1874. From this point the explorer worked in a south-westerly direction to Queen Victoria Springs, where he struck the track of Giles's expedition of 1875. From the Springs the expedition went north-west and made a useful examination of the country lying between 119° and 115° meridians and between 26° and 28° south lat. Wells's expedition started from a base about 122° 20' east and 25° 54' south, and worked northward to the Joanna Springs, situated on the tropic of Capricorn and near the 124th meridian. From the springs the journey was continued along the same meridian to the Fitzroy river. The country passed through was mostly of a forbidding character, except where the Kimberley district was entered, and the expedition suffered even more than the usual hardships. The establishment of the gold-fields, with their large population, caused great interest to be taken in the discovery of practicable stock routes, especially from South Australia in the east, and from Kimberley district in the north. Alive to the importance of the trade, the South Australian Government despatched Hübbe from Oodnadatta to Coolgardie. He successfully accomplished his journey, but had to report that there was no practicable route for cattle between the two districts.

One of the most successful expeditions which traversed West Australia was that led and equipped by the Hon. David Carnegie, which started in July 1896, and travelled north-easterly until it reached Alexander Spring; then turning northward, it traversed the country between Wells's track of 1896 and the South Australian border. The expedition encountered very many hardships, but successfully reached Hall Creek in the Kimberley district. After a few months' rest it started on the return journey, following Sturt Creek until its termination in Gregory's Salt Sea, and then keeping parallel with the South Australian border as far as Lake MacDonald. Rounding that lake the expedition moved south-west and reached the settled districts in August 1897. The distance travelled was 5000 miles, and the actual time employed was eight months. This expedition put an end to the hope, so long entertained, that it was possible to obtain a direct and practicable route for stock between Kimberley and Coolgardie gold-fields; and it also proved that, with the possible exception of small isolated patches, the desert traversed contained no auriferous country.

GEOLOGY.

All the great formations familiar in the northern hemisphere are represented in the geology of Australia, which is in no way exceptional, either in the character of the rocks or in the zones of life that characterize them. The oldest rocks are of pre-Cambrian age, but little of their life-history is known. If differences, rather than resemblances, be dwelt on, there are many points concerning Australian geology in strong contrast to much that European geologists have been accustomed to. As has already been said, there are no volcanoes on the continent, and all over the vast interior there is a general absence of igneous rocks other than granites. Basalt is almost unknown except on an outside belt of the country roughly parallel to the coast. There are no solfataras, fumeroles, or geysers, and very few hot springs. There is no such thing as perpetual snow, even on the highest mountain, no glaciers or glacier lakes, and not a single mountain range with an Alpine structure. There is a notable absence of magnesian limestones, and phosphate-bearing rocks are unknown. There is an equivalent of the red sandstones, but no salt beds and no gypsum. There is evidence of glacial action in Permo-Carboniferous times, during which period a great ice-sheet extended over a considerable portion of Australia, and evidences of recent glaciation at Mount Kosciusko are most pronounced. In the matter of folding we find the Australian, Cambrian, Silurian, and Devonian, all giving evidence of earth movements. The Silurian rocks in particular have been so folded and so intensely compressed that we usually find them over wide areas, vertical or highly inclined, and almost invariably with a meridional strike. All over the continent other formations laid down subsequent to those named are spread out in vast sheets, never showing a high angle or dip, and nowhere resting at any great height above sea-level. The Carboniferous rocks are also folded, but to a lesser degree than the Devonian, and of course in a degree not to be compared with the Silurian. The intense folding of the Silurian, taken together with the lithological character of its sediments, separates it at once from every other "formation" in the Australian geological column. So marked is this that throughout Australia rocks may be safely classed as Silurian if they show over consider-

able areas a "slaty" structure, a high angle of dip, and a meridional strike.

Against these facts may be placed others showing strong resemblance between Australian and European geology. The physical geography and the life of the Palæozoic and Mesozoic periods are in wonderful accord with those of other continents. The great development of coal in the Upper Palæozoic conforms to the northern conditions. The general types that characterize Cretaceous rocks are also present, plesiosaurs and chambered shells, such as ammonites, being as characteristic of the Australian Cretaceous as they are of the European. The forms of life, too, that occur in the Triassic of Europe, and even North America, find their counterpart here. In the shales round Sydney, which are admittedly of Triassic age, the remains of a giant labrinthodon have been unearthed, and, associated with it, fishes and plants quite in keeping with forms familiar in the European Triassic.

In using such terms as "Permian" or "Eocene" there is reason to suppose that these periods in Australia might not have been quite synchronous with the European equivalents. Indeed it is not desirable to correlate too minutely Australian and European stratified rocks. We may even go further and say that it is improbable that any single life zone was laid down exactly at the same time that a similar life zone was being built up in northern Europe. One particular horizon in the Silurian is characterized by the interesting chain coral (halysites). No one would contend that the chain coral "reefs" in Australia and in Europe were exactly contemporaneous. But the relative position of the halysites zone in the geological column is the same in Europe and in Australia, and the physical conditions that surround the growing coral are precisely similar.

Some reference is made under the heading Fauna to the presence of "living fossils" in Australia. Certain characteristic types, long extinct in the northern hemisphere, still linger in the Australasian area. The Trigonina and the Heterodontus, the Marsupials, Myrmecobius, Ceratodus, and certain conifers and cycads are examples. One genus of cycad (*Zamia*) is exceedingly common over all the mountain and coastal regions of eastern Australia. It is a near ally of one of the most characteristic forms of the fossil flora of the Oolitic and Lias. In the well-known "dirt bed" of the Portland quarries, Dorsetshire, the stems of these cycads are to be found in great abundance.

The last feature of general import is the distribution of metamorphosed rocks. The lower series of the Palæozoic show a certain amount of metamorphism in conjunction with their highly inclined position. The mesozoic rocks are much less altered from their original plane of deposition, and any metamorphism notable is of a limited and entirely local character. Certain sandstone beds of Cretaceous age have been much altered by the deposition of secondary silica. No great alteration approaching to metamorphism is known to have taken place amongst Tertiary rocks. Schistose structure is confined altogether to the Lower Palæozoic.

PRINCIPAL AUSTRALIAN SEDIMENTARY FORMATIONS, WITH SOME CHARACTERISTIC FOSSILS.

CAINOZOIC, OR TERTIARY.	POST-TERTIARY.	RECENT	Human bones and implements; remains of plants and animals of living species; Dinornis, Aptornis, Ornithorhynchus.
		PLEISTOCENE	Diprotodon, Macropus, Thylacoleo, Thylacinus, Nothosaurus, Megalania, Dromornis, Echidna, Melolania, Palorchestus, Dromæus, Mytilus, Siphonalia.
	TERTIARY.	PLIOCENE	Phascocolumys, Procoptodon, Macropus, Thylacinus, Thylacoleo, Diprotodon.
		MIOCENE	Spondylostrombus, Wilkinsonsia, Pentene, and other fossil fruits, in old "lesde."
Eocene		Nassa, Marginella, Ancilla, Cancellaria, Natica, Leispyraga, Nucula, Trigonina, Chione, Mercia, Tellina, Plabellum, Placotrochus, Terebratulina, Cucullæa, Coruhia, Nassa, Voluta, Marginella, Atrix, Murex (upwards 80 sp.), Triton, Mitra, Fusus, Natica, Cerithium.	
MESOZOIC, OR SECONDARY.	TRIAS-JURA.	CRETACEOUS	Ichthyosaurus, Plesiosaurus, Ammonites, Belemnites, Cidarid, Avicula, Trigonina, Belemnites, Otodus, Citralosaurus, Mactra, Inoceramus, Maccovells.
		JURASSIC	Taxites, Tæniopteris, Thinnfeldia, Podozamites, Sphenopteris, Leptolepis, Coccolepis, Aphnelepis.
		TRIASSIC OR TRIAS-JURA	Tæniopteris, Sagenopteris, Cycadopteris, Alethopteris, Macroteniopteris, Sphenopteris, Pecopteris, Jeanpsalis, Podozamites, Equisetum, Clethrionidium, Ocellia, Schizoneurus, Gingko, Zamites, Thinnfeldia, Phyllochea, Platycarpus, Unionella, Ectheria, Tremanotus, Palæoniscus, Myriolepis, Mestodonosaurus, Unio, Prietisomus, Clethrolepis.

PALÆOZOIC, OR PRIMARY.	PERMO-CARBONIFEROUS	Glossopteris, Phyllothea, Vertebraria, Sphenopteris, Annularia, Spirifer, Pechydomus, Productus, Orthoceras, Copularia, Martinopsis, Eurydesma, Platyceras, Leala, Gangamopteris, Aviculopecten, Notomya, Sanguinolites.
	CARBONIFEROUS	Rhacopteris, Lepidodendron, Calamites, Archæopteris, Sigillaria, Loxonema, Euouphalus, Spirifer, Orthis, Leptens, Phyllothea, Fenestella.
	DEVONIAN	Lepidodendron, Cyclostigma, Spirifer, Rhynchonella, Atrypa, Orthis, Orthoceras, Asterolepis, Pteronites, Murchisonia.
	SILURIAN	Atrypa, Pentamerus, Halysites, Graptolites, Phacops, Bronteus, Calymene, Cyathophyllum, Spirifer, Didymograptus, Lingularia, Mucophyllum, Stromatopora, Favosites, Heliophyllum, Phillipsastrea, Rhizophyllum, Columnaria, Petralia, Lichas, Syringopora, Cyclo-nema, Bellerophon, Palæaster, Niso, Trochus, Asaphus, Beyrichia, Cyphaspis.
	CAMBRIAN	Conocephalites, Dolichometopus, Dikelocephalus, Dinesus, Olenellus, Salterella, Orthisina, Leperditia.

TABLE, SHOWING THE GENERAL SUCCESSION OF AUSTRALIAN STRATA.

PERIOD.	SYSTEM.	SOME TYPICAL EXAMPLES.
POST-TERTIARY.	RECENT	Raised beaches.—Victoria and West Australia have sand loams for forming these.
	PLISTOCENE	Alluvial flats and great plains of the interior. Raised beaches of the north-west coast, Tasmania. Large area in the south-east of South Australia. Limestone creek beds, south-west Victoria, containing about 80 per cent. of living mollusca. Volcanic ash beds of Mount Gambier. Mammaliferous sandy clays containing diprotodon, &c., Mammaliferous cave deposits of New South Wales and Victoria; freshwater limestones of the Geelong district. Newer basalts at Werribee, Geelong, and Camperdown, Victoria.
CAINOZOIC, OR TERTIARY.	PLIOGENE	Marine sands of the Dry Creek and Croydon bores, South Australia. Oyster beds of the Murray river cliffs and Aldinga Bay, South Australia. Calcareous sands and clays of Jeunmy's Point, Gippsland, and the upper beds at Murray Creek, near Hamilton, West Victoria.
	MIOCENE	Generally—limestones, clays, and sands from the Snowy river, Gippsland, to the Great Australian Bight; also from Geraldton to Shark Bay, Western Australia; and Table Cape, Tasmania (all marine). Plant beds of Emmaville, New South Wales.
MESOZOIC, OR SECONDARY.	EOCENE	No marine beds of Eocene, Miocene, or Pliocene age are known east of the Main Dividing Range in New South Wales or Queensland.
	CRETACEOUS	Upper Cretaceous.—Desert sandstone of Queensland.
		Lower Cretaceous.—Rolling Downs formation of Queensland. Artesian water-bearing beds of north-western New South Wales. Kennedy Range and Gascoyne river, West Australia.
	JURASSIO	Beds with fossil fish, Talbragar river, New South Wales. Oolitic limestone of Champion Bay district, West Australia.
	TRIASSIC, OR TRIAS-JURA	The Hawkesbury sandstones and associated shales of New South Wales.
Lower Mesozoic rocks of the Clarence river. The Ipswich and Burrum beds of Queensland with <i>Tanopteris</i> . The Upper Coal Measures of Tasmania, and the Collie Creek Coal Measure of West Australia are considered to be of Mesozoic age.		
PALÆOZOIC, OR PRIMARY.	PERMO-CARBONIFEROUS	Coal Measures of New South Wales, Newcastle, Illawarra, and Lithgow, with <i>Glossopteris</i> . Upper and Middle Bowen river formations, Queensland. Collie river and Irwin river, West Australia. Tasmanite beds, Mersey and coast about the estuary of the Derwent, Tasmania.
	CARBONIFEROUS	Port Stephens district, New South Wales. Gympie, Lower Bowen, and Star formations, Queensland. Also the Lower Coal Measures of Tasmania.
	DEVONIAN	Mount Lambie sandstones, Rydal, New South Wales. Avon river and Mount Tumbo beds, Victoria. Burdekin beds, Queensland. Sandstones and grits, Kimberley, West Australia. Fingal slates, Tasmania.
	SILURIAN	Highly-inclined clay slates and talcose slates, New South Wales, South Australia, and West Australia and Victoria. Graptolite beds of Victoria. Yass and Molong limestones, New South Wales. "Larapintine" limestones, Macdonnell ranges. Queen river schists and slates, and the Gordon river group, Tasmania.
	CAMBRIAN	<i>Olenellus</i> and <i>Salterella</i> beds of Kimberley, West Australia. Ardrossan beds of South Australia. Magog and Caroline creek groups, Tasmania. Yorke's Peninsula series, South Australia. Kimberley, West Australia. Heathcote, Victoria.
PRE-CAMBRIAN	Quartzite and some metamorphic rocks of Tasmania. Mount Lofty Ranges, South Australia.	

embryonic. We cannot here, any more than elsewhere, work back far enough to get near to the beginnings of life. The animals on the Cambrian sea-shores were graded and grouped no less exactly and definitely than the invertebrate fauna of the present coast-line. Mammals, birds, reptiles, and fishes are, of course, absent; but it must strike one as remarkable that foraminifera, sponges, corals, hydrozoans, entomostraca, trilobites, brachiopods, lamellibranchs, gasteropods, and pteropods, should be present in that far-off epoch pretty much as we see them to-day. Cambrian rocks are known in Yorke's Peninsula, South Australia, and near Leigh's Creek, 300 miles to the north of Adelaide. Cambrian rocks have been described in the Kimberley district of West Australia containing such world-wide forms as *Salterella* and *Olenellus*. The Macdonnell ranges of Central Australia are considered also of Cambrian age, and, like all the Australian Cambrian, are of marine origin. Some of the Cambrian beds were laid down in shallow waters, as ripple-marked quartzites and current-bedded sandstones are known to occur. No contemporaneous igneous rocks are known. The Cambrian shows evidence of much folding, and it is evident that the earth movements giving rise to the folds took place before the deposition of the succeeding Silurian. The Macdonnell Range, usually regarded as Cambrian, consists of conglomerates, limestones, and slates, and these conglomerates are the first evidence of the existence of any land in Australia.

The Silurian system is well represented over Australia. Quite one-thirtieth of the area of the continent is covered by rocks of this age. In the colony of Queensland, however, the Silurian is not developed to any considerable extent. The Australian Silurian consists of sandstones, mud-stones, conglomerates (rare), "slates," and limestones. Over a great area of the country highly inclined mud-stones are known as Silurian "slates." The cleavage of these rocks corresponds to the bedding planes, and they are, therefore, not true slates. Nowhere has the Australian Silurian been subjected to such intense metamorphism as to develop cleavages across the deposition planes. The Silurian beds have been tilted, folded, and broken; but the conditions necessary for the production of rocks resembling, say, the Bangor slates, were not present. The mud-stones of Victoria have yielded an abundance of Graptolites, and these interesting fossils have also been found in New South Wales. The richest fauna, however, has been discovered in the limestones. European forms, made familiar by text-books, are well represented, as, for instance—*Halysites*, *Favosites*, *Syringopora*, *Phillipsastrea*, amongst the corals; *Phacops*, *Bronteus*, and *Calymene*, amongst the trilobites. *Receptaculites* is also known, together with *Pentamerus*, and a number of Spirifers. So far as is known, the Silurian beds are marine. No contemporaneous igneous rocks have been discovered. In Victoria the Upper and Lower Silurian have an aggregate thickness of 35,000 feet. In New South Wales a section has been measured at Molong showing a thickness of 3000 feet. The "slates" of Silurian age are often seen to rest directly on granite, their bedding planes standing vertically and rising directly from the granite. The granite is not, therefore, the original bed-rock on which the slates were laid down. There is abundant evidence to show that much of the granite was intruded amongst the "slates" after the latter were left highly inclined by intense folding. These granites are therefore younger than Silurian, and, as they do not intrude on the Carboniferous higher up in the series, they are probably of Devonian age.

Some interesting caves have been discovered in the limestones of this age. The Australian black-fellow has left us no history in connexion with them. Certain rock shelters have been used by the aboriginals, but of the limestone caves they evidently made no use. The living aboriginal avoids even their vicinity. The Wellington caves of New South Wales have been eroded through limestones of Silurian age. Breccias accumulated through openings from the surface, and yielded a series of most interesting giant marsupials, first drawn attention to by Sir Richard Owen. In fact, the whole importance of these caves lies in the scientific value attached to the fossils referred to. From a scenic point the caves are uninteresting. The Jenolan caves of New South Wales are also eroded from limestones of the same age. They have yielded no fossils of especial interest, but are widely known for their beauty. Geologically, the existence of the caves depends on the fact that a bar of limestone runs almost directly across a deeply eroded valley,—water, the giant sculptor of mountains, having found it easier to make for itself a passage by dissolving the limestones than by eroding them to the valley level.

In Australia there is a great development of stratified rocks up to 23,000 feet in thickness, unconformable to the older Silurian and the overlying Carboniferous. The life of the period is also clearly distinct from that of the preceding and the succeeding rocks. Here for the first time in the geological record we meet with contemporaneous igneous rocks. The Snowy river porphyries of Victoria and certain felsites in the Braidwood district, New South Wales, must be considered the results of volcanic outbursts in Devonian times. In Queensland, Devonian

Of the seven sub-kingdoms of living things, no less than five are represented in the Australian Cambrian. If we except vertebrates, we have therefore at the very dawn of life representatives of the animal world as we know it to-day,—types which are in no sense

rocks quite 20,000 feet in thickness have been measured, forming one unbroken series. Devonian rocks are developed largely in Western Australia. There is one belt 200 miles long, from the Saw Ranges to the Lubbock Range. Interbedded igneous rocks, breccias, and ash-beds are known, up to 100 feet in thickness. In the Kimberley district of the same colony there are grits, conglomerates, and limestones and slaty shales of Devonian age, 1100 feet in thickness. The earliest land plant indicating a land flora for Australia is *Dicranophyllum Australicum* from the middle Devonian of Queensland. Remnants of old land areas which supported a land flora are also preserved near Mansfield in Victoria, also near Twofold Bay, and at Rydal in New South Wales. Rocks with a thickness of quite 10,000 feet are developed at Rydal (New South Wales). They contain the well-known fossils, *Spirifera disjuncta* and *Rhynchonella pleurodon*, occurring mostly in quartzites. The series is made up for the most part of reddish and purple shales, mud-stones, grit, and conglomerates. These show a strong unconformability with the underlying Silurian. The occurrence of *Lepidodendron* is remarkable, being found as it is exactly in the same horizon as the *Spirifer* named.

The Carboniferous of Europe is remarkable for the great development of workable coal-seams in the series. In Australia the greatest accumulation of coal is found in a subsequent series of rock known as the Permo-Carboniferous. The Australian Carboniferous is characterized by such forms as *Lepidodendron*, *Rhacopteris*, *Cordiatas*, *Archaeopteris*, *Sphenopteris*, and *Palæontiscid* fish, and also by well-marked marine shells. The rocks are therefore partly marine and partly freshwater, and evidence of contemporaneous igneous activity is left by a great variety of rocks ranging from felsites to basalt. Carboniferous beds rich in fossil plants can be traced from Queensland through New South Wales. The Carboniferous rocks of Queensland are conveniently divided into (1) Gympie series, which has been measured up to 21,000 feet in thickness, on the Hodgkinson gold-field. The chief fossils are the marine forms—*Protoretepora ampla*, *Productus cora* and *Martinia subradiata*—associated with *Lepidodendron*: (2) the Star formation, made up of slates, conglomerates, sandstones, and a thin band of limestone—the whole reaching up to a thickness of 1353 feet. *Lepidodendron* is also abundant, and *Cyclostigma*, with the marine forms, *Phillipsia dubia* and *Rhynchonella pleurodon*. The Carboniferous rocks of West Australia consist of limestone beds interbedded with shales, layers of gypsum, and traces of rock salt 1000 to 1300 feet in thickness, and a series of freshwater sandstones, with a thickness of 1800 feet.

The Silurian, Devonian, and Carboniferous, with their associated igneous rocks, are the sources of all the metalliferous deposits in Australia, the alluvial leads being of course derived from the wearing down of these formations. The well-known Mount Morgan mine may perhaps be noted as an exception, for we have here a geyser deposit, of Upper Mesozoic or Tertiary age, in a Permo-Carboniferous area. No rocks newer than the Carboniferous are known to have had metalliferous deposits in the shape of lodes formed amongst them.

Permo-Carboniferous is a term originally proposed by Mr Robert Etheridge, jun., for a formation "distinguished by a copious marine fauna partaking of a Carboniferous and Permian nature, and a flora from which lycopodiaceous plants were almost entirely absent." Anyone familiar with the Carboniferous rocks of Europe will remember that the most characteristic fossil plant is *Lepidodendron*. This is absent in the Coal Measures of Eastern Australia; and in its place we find plants, and one form in particular, with quite a Mesozoic aspect. The fern referred to is *Glossopteris*. This beautiful fossil plant is found associated with workable Coal Measures over great areas of the continent. The Permo-Carboniferous rocks of Eastern Australia are quite 10,000 feet in thickness. The lower beds contain coarse conglomerates in great abundance and a very distinctive marine fauna. The upper beds are made up for the most part of finer materials and are of freshwater origin. The whole series is thus divided in the type district, Newcastle, as follows:—

PERMO-CARBONIFEROUS.	UPPER COAL MEASURES	The seams of coal worked at Newcastle belong to the Upper Coal Measures. The best known in the NEWCASTLE COAL MEASURES are, in descending order—(1) Parbury's seam; (2) Great Northern seam; (3) Burwood seam; (4) Dirty seam; (5) Yard seam; (6) Borehole seam. <i>Glossopteris</i> is abundant. The DEMPSEY SERIES, 2000 feet in thickness, separate these coal seams from the underlying TOMAGO COAL MEASURES.
	UPPER MARINE SERIES	The UPPER MARINE BEDS are about 5000 feet in thickness. The following divisions are recognized in descending order:—(1) Beds with <i>Crinoids</i> and <i>Sanguinolites</i> ; (2) beds with abundance of <i>Spirifers</i> ; (3) Murr's rock; (4) conglomerates.
	LOWER COAL MEASURES	GERTA COAL MEASURES, with no marine shells. Fossil plants abundant. <i>Glossopteris</i> is common.
	LOWER MARINE SERIES	The LOWER MARINE SERIES is about 2000 feet in thickness. <i>Burydsema cordata</i> is characteristic.

Quite fifteen seams of workable coal, with an aggregate thickness of 150 feet, have been opened up around Newcastle, New South Wales. It has been estimated that at the present rate of consumption the known coal beds would last 3000 years. The same series with similar fossils is known to occur in West Australia, Tasmania, and Queensland. A considerable amount of volcanic activity manifested itself at many points over what is now East and West Australia in Permo-Carboniferous times.

Jurassic beds are said to underlie the Cretaceous to the north of Champion Bay, West Australia. Oolitic limestones, grits, sandstones, and clay ironstones make up the series. Some fossils have been described from Shark Bay, where they occur in ferruginous and variegated limestones, clays, and ironstones, not unlike rocks of the same age occurring in England. These interesting stratified rocks are all of marine origin. In other parts of Australia freshwater deposits containing abundant plant remains are classed as Jurassic. A remnant of rocks of this age occurs near Gulgong (New South Wales). Here some yellow ferruginous shales were found to contain abundant fish remains. The fish belonged for the most part to the *Leptolepidae*, and on the same slab could be seen land-shells, and impressions of *Tæniopteris*. The fossiliferous shales are *in situ*, being laid down in an eroded hollow in the Hawkesbury sandstone.

The type district for Triassic rocks in Australia is immediately around Sydney. Here the rocks are divided into three groups: (1) Wianamatta shales, 700 feet; (2) Hawkesbury sandstone, 1000 feet; (3) Narrabeen shales, 1600 feet. The whole series is characterized by the absence of marine fossils and an abundant and decided Mesozoic flora. Fish remains have also been discovered. Much of the beauty of Sydney as a city is due to the excellent building material supplied by the Hawkesbury sandstone. Ascending from Permo-Carboniferous to Triassic rocks we at once lose the characteristic Coal Measures fossil, *Glossopteris*. Quite another fern characterizes Triassic rocks—*Tæniopteris*. In searching for artesian water in Western New South Wales, *Tæniopteris* beds have been discovered (underlying Cretaceous). After boring through these beds abundant supplies of artesian water were struck. The presumption, therefore, is that Triassic rocks, and not Cretaceous, are the source of artesian water, if not in Queensland, certainly in New South Wales.

Queensland has a great series of coal-bearing rocks, known as the Burrum formation. The lower Burrum coalfield extends along the eastern coast-line from Point Cartwright on the south, to Littabella Creek on the north, and stretches inland for an average distance of 25 miles. Its area is estimated at 3000 square miles. The Coal Measures of this formation contain several workable coal-seams, of excellent quality for steaming purposes. No marine fossils have been discovered, but plants of the usual Mesozoic aspect are plentiful. Newer than the Burrum is the Ipswich, also classed as Trias-Jura. This formation occupies an area of quite 12,000 square miles in the southeastern corner of Queensland. The Ipswich formation contains excellent coal-seams. These beds contain no marine fossils, the whole being laid down under freshwater conditions. There is an abundant flora, prominent forms being—*Equisetum*, *Sphenopteris*, *Thinnfeldia*, and *Tæniopteris*; but *Glossopteris*, so characteristic of the Newcastle Coal Measures, is absent. The Collie Creek Coal Measures of West Australia may be provisionally classed here. There is an important series of rocks in Tasmania, undoubtedly of Mesozoic age, composed mainly of variegated sandstones, shales, and blue and white clays. The series frequently contains seams of coal of good thickness and fair quality. There are no marine fossils but a great abundance of plant remains with a decidedly Mesozoic aspect. Mr R. M. Johnstone considers that these beds probably cover the whole period from the close of the upper Paleozoic Coal Measures to the beginning of the Tertiary period. Some of these beds are probably of the same age as the Trias-Jura of Queensland. Certain beds in Victoria, about Cape Paterson, Barabool Hills, and a series known as the Bellarane beds, consisting of sandstones, coal, and carbonaceous shales, may belong to this series. They contain an abundant fossil flora, but no marine fossils. The leading forms are *Tæniopteris*, *Alethopteris*, and *Zamites*. These rocks occupy four distinct areas, and contain all the known coal-bearing rocks in Victoria. They cover, at least, 4000 square miles.

The Cretaceous rocks cover an immense area in New South Wales, Queensland, North, West, and Central Australia. They may be grouped into three series—the lower, developed chiefly in Western Australia; the middle, in North-Western New South Wales; and the upper, in Queensland and over Central Australia generally. The Upper Cretaceous, to which belongs the widely-spread formation known as desert sandstone, must have covered more than one-fourth of the whole continent. This sandstone, it has been remarked, is a monument of the power of denudation. It is now found only in isolated fragmentary table-lands. Taken as a whole, the desert sandstones

vary greatly in composition, in texture, and in general appearance; but individual beds preserve their characteristics over very large areas. In Western New South Wales deposits of excellent opal have been found in marls of Cretaceous age. These marls are undoubtedly of marine origin. The opal is found filling in seams in the marls; but reptilian bones, wood, gasteropod shells and belemnites are also found converted into noble opal of first quality. The silica of the opal is probably derived from diatomaceous and radiolarian tests in the marls. The Lower Cretaceous rocks of Queensland are believed to be sources of artesian water. The Cretaceous rocks of New South Wales were also supposed to yield artesian water. More recent investigation has shown that, although the artesian bores are in many instances put down through Cretaceous rocks, the water-bearing strata belong to the underlying Triassic. The lower beds form the country known as the Rolling Downs. They consist of shales, Cretaceous sandstones, with no great development of calcareous rocks or limestones. The presence of ammonites and belemnites indicates a marine origin for these beds. Cretaceous rocks cover probably more than 300,000 square miles. It is estimated that the desert sandstone at one time covered an area of 500 square miles, but has now been reduced by denudation to isolated table-lands. The most striking feature in connexion with the Queensland Cretaceous rocks is their horizontal bedding, and their occurrence in flat-topped, step-cut hills. The desert sandstone plains present a most desolate appearance, and form some of the poorest, the driest, and the most inhospitable territory of the continent. The Cretaceous rocks have been very little disturbed by the intrusion of the igneous materials.

Marine beds of Eocene, Miocene, and probably Pliocene age occupy a large extent of country on the southern shores of the continent, extending from Gippsland away round to West Australia. Marine Tertiary must cover at least 20,000 square miles, and near Melbourne very considerable thicknesses of Eocene rocks have been found. The Croydon boring near Adelaide shows a thickness of fully 2300 feet of pre-Pliocene Tertiary strata. They reach inland to the south-western corner of New South Wales, where they are overlain by alluvial deposits of Pleistocene age. Tertiary marine beds are also known on the north coast of Tasmania. Quite a different set of beds occur inland in New South Wales, Victoria, and Queensland. There are also rocks of Tertiary age, but they were laid down under inland and fresh water conditions. Some of the beds contain in abundance fossil plants strongly suggestive of some of the earlier Tertiary European flora. Sufficient is known now of the marine Tertiary beds of Australia to separate them into Eocene, Miocene, and Pliocene.

Tertiary.

Eocene.—Eocene rocks are particularly rich in fossils—the Eocene beds of Aldinga and Adelaide being notable for gasteropods, lamellibranchs, echinoderms, and corals. The Eocene beds at Muddy Creek, West Victoria, are even more prolific, 649 species of molluscs having been recorded. The Eocene beds are made up of clays, calcareous limestones, sandstones, bands of pebbles and grits, and shelly limestones. The proportion of living species of mollusca in Australian Eocene rocks nowhere exceeds $3\frac{1}{2}$ per cent., and the percentage is usually under two.

Miocene.—Miocene beds occur overlying Eocene rocks in the river Murray cliffs. At Aldinga bay and Hallett's Cove, on the east side of St Vincent Gulf, Miocene beds rest directly on the Eocene—in both cases the newer rocks lying on the eroded surface of the older. At Muddy Creek, in Western Victoria, Miocene beds are also found overlying the Eocene, and near the Gippsland Lakes they flank an Eocene escarpment. The Australian Eocene contains 15 per cent. of living forms. The rocks consist of blue clays, mottled sands, calciferous sandstones, and sandy clays.

Pliocene.—Bores put down at Dry Creek in South Australia show the existence of strata with a fauna comprising 210 species, of which 150 are gasteropods, and 60 lamellibranchs. As the beds contain about 27 per cent. of living species, Professor Tate provisionally called these beds Older Pliocene, "though in this case the percentage system does not fully indicate the strong modern facies exhibited in this collection of fossils." The Croydon bore, near Adelaide, passed through 406 feet of stratified rocks, some of which are of Pliocene Age. Some beds occurring in the south-west of Victoria, at Limestone Creek, have yielded an abundant fauna—the proportions of recent forms being 80 per cent.—and are considered late-Pliocene. These rocks are wholly marine. Towards the centre of the continent, however, a totally different set of beds were laid down, mostly of lacustrine or alluvial origin. In Pliocene times much of the present arid interior was a well-watered country, supporting a luxuriant vegetation. The fauna of this period included many animals of astonishing proportions and most remarkable structural characteristics. These larger forms were all marsupials, and are now extinct. Species of diprotodon, nototherium, phascalomys, macropus, and protomnodon must have been plentifully distributed. To account for the existence of such huge herbivores, we must suppose a well-watered country, with a luxuriant vegetation, in place of the present desolate and arid region

of Central Australia. The lakes of the interior of Australia, which are for the most part simply dead levels of white salt, must in Pliocene times have been magnificent sheets of water, set amidst rich tropical forests. Herds of giant marsupials, birds as large as the New Zealand moa, saurians 15 feet in length (*Nothosaurus*), and gigantic monitors tenanted the country. Amongst the marsupials, *Diprotodon* was the most notable, with a head 3 feet in length. A kangaroo, with a skull as large as that of an ox, (*Palorchestes azael*) was the largest known member of the kangaroo family. *Nototherium*, another great marsupial, almost rivalled the diprotodon. The remains of a large extinct wombat, equalling a tapir in size, have also been described. Associated with these was a skull with extraordinary adze-shaped teeth. Their long chisel-like form suggested the name *Sceparnodon*. There was also an animal (*Koalemus*) probably the ancestral form of the living "native bear." The existing bear is an animal about 2 feet long, with a body made to look more clumsy by the almost complete absence of a tail. The bear of to-day weighs about 20 lb. The bear of Pliocene and post-Pliocene times was a similar animal, more clumsy and more unwieldy, if such can be pictured. The fossil form was many times as large as the "native bear," and would turn the scale at 500 to 600 lb. The *Sarcophilus*, or "Tasmanian devil," is now extinct on the mainland, but its remains are very common in Pliocene and post-Pliocene drifts, from Victoria to Queensland. Another animal that lived in the days of the diprotodon, is *Thylacoleo*, a gigantic ally of the phalangers. The skull measured nearly a foot in length. Various theories have been advanced to explain the extinction of forms so vast and varied. The drying up of the lacustrine area had no doubt much to do with the change. Pliocene conditions continued into post-Pliocene times. The absence of marine beds of this age over the continent makes our subdivisions of this portion of the geological record somewhat arbitrary. The great alluvial plains are the work of rivers in post-Pliocene times, and much of the drifts and "leads" containing gold and tin-stone are of the same age. All the evidences of the presence of man are confined to recent deposits. But although, geologically considered, man is a recent arrival, yet measured in years his existence is one of vast antiquity on the Australian continent.

Granites may be said to be well represented, and are almost everywhere associated with the older stratified rocks.

Over the whole of the interior, there is a notable absence of basalt or recent lavas, and even of such intrusive rocks as diorites. Vast tracts of Cretaceous and Tertiary country show no igneous rocks for many hundreds of square miles. The Kosciusko plateau consists for the most part of gneissic granite, cut through sparingly by igneous dykes, and in one instance, by what seems to be a volcanic neck. The bulk of the Australian granites seem to have been intruded into Silurian and Devonian, and perhaps even into Carboniferous, but they are older than the Permo-Carboniferous. The first manifestations of igneous outpourings are noted as having occurred in Devonian times. In the succeeding Carboniferous and Permo-Carboniferous, volcanic activity was also very manifest, and is shown by many hundred feet of interstratified volcanic products. In Triassic times there is very little sign of volcanic action. The Cretaceous period, too, was one of quietude. The next outburst of volcanic fires occurred in the Tertiary, and this continued down almost to the advent of the aboriginals. In the western district of Victoria some remarkably fine craters remain quite fresh and very little cut into or denuded by atmospheric agencies. Here quite eight of the points of eruption have been counted which poured out the floods of basalt known in Victoria as newer volcanic.

As regards the distribution of recent volcanic rocks, New South Wales shows excellent types of trachytes in the Warrumbungle mountains, and also in the Canoblas, a point of eruption near Orange, about one hundred miles west of Sydney. Along the slopes of the Main Dividing Range, there is much basalt of the typical basic character. Many of the "leads" that have yielded so much alluvial gold are old river-beds buried under this basalt. Flat-topped basalt-covered hills are a marked character of the western slopes of the eastern Dividing Range. These are remnants of lava streams that flowed from long-extinct, but geologically recent, volcanoes. Basalt in these instances filled the old valleys, and the surrounding country rock being worn away, the basalt now remains above the general level. Thus the lines of the old rivers, once the lowest part of the country, now stand out as the highest ground. Water-worn pebbles, sand, and shingle—in other words, old river-drifts—are invariably found under these cappings. A leucite basalt of Tertiary age occurs in three different localities in New South Wales. No nephelin basalts have been discovered anywhere on the continent. Serpentine is well represented, in one case evidently derived from an olivine-bearing rock. Basaltic dykes are extremely common, cutting up through the whole geological series as high as the Triassic. In formations of a later age, dyke rocks are not so common. Rhyolites and true Andesites are rare as products of recent volcanic action in Australia.

FLORA.

To understand the distribution of plants in Australia, one must always bear in mind that the central valleys and plateaux are surrounded by physical conditions totally different from those prevailing on the coastal plains, and that the northern part of the continent has been invaded by a number of plants characteristically Melanesian. This element was introduced *via* Torres Strait, and spread down the Queensland coast, and also round the gulf of Carpentaria, but has never been able to obtain a hold in the more arid interior. Judging by the plants alone, and to a great extent by the animals, nobody could tell, when in a Queensland coast-jungle, whether he were in Australia or New Guinea. Travellers often describe the wonderful wealth of plant life in the eastern coast-line, but this must not be taken as indicating the nature of the flora inland in the same latitude. In the interior there is little change in the general aspect of the vegetation, from the Australian Bight to the region of Carpentaria when the exotic element begins. Behind the luxuriant jungles of the Queensland coast, once over the Main Range, we find the purely Australian flora with its apparent sameness and sombre dullness. Physical surroundings rather than latitude determine the character of the flora. The contour lines showing the heights above sea-level are the directions along which species spread to form zones. Putting aside the exotic vegetation of the north and east coast-line, the Australian bush gains its peculiar character from the prevalence of the so-called gum-trees (*Eucalyptus*) and the acacias, of which last there are 300 species. But the eucalypts above all are everywhere. Stunted eucalypts fringe the tree limit on Mount Kosciusko, and the soakages in the parched interior, which pass on maps for rivers, are indicated by a line of the same trees, stunted and straggling. Over the vast continent from Wilson's Promontory to Cape York, north, south, east, and west—where anything can grow—there will be found a gum-tree. The eucalypts, so typical of the Australian bush, are remarkable for the oil secreted in their leaves, and the large quantity of astringent resin of their bark. This resinous exudation (Kino) somewhat resembles gum, hence the name "gum" tree. It will not dissolve in water as gums do, but it is soluble in alcohol, as resin usually is. Many of the gum-trees throw off their bark, so that it hangs in long dry strips from the trunk and branches, a feature familiar in "bush" pictures. The bark, resin, and "oils" of the eucalyptus are well known as commercial products. As early as 1866, tannic acid, gallic acid, wood spirit, acetic acid, essential oil and eucalyptol, were produced from various species of eucalyptus. The genus eucalyptus numbers more than one hundred and fifty species, and provides some of the most durable timbers known. The iron-bark of the eastern uplands is well known (*Eucalyptus sideroxylon*), and is so called from the hardness of the wood, the bark not being remarkable except for its rugged and blackened aspect. Samples of this timber have been studied after forty-three years' immersion in sea water. Portions most liable to destruction, those parts between the tide marks, were found perfectly sound, and showed not the slightest sign of the ravages of marine organisms. The well-known Jarrah (*Eucalyptus marginata*) of West Australia is one of the most durable of timbers; 14,000 square miles of country are covered with this species. This tree has been known to grow to 10 feet in diameter and 120 feet in height. The timber is nearly impervious to the attacks of the teredo. There is good evidence to show that, exposed to wear and weather, or placed under the soil, or used as submarine piles, the wood remained intact after nearly fifty years' trial. The following figures show the high density of Australian timber:—

Australian Timber.	Specific Gravity.	Australian Timber.	Specific Gravity.
Jarrah	1.12	Tallow wood	1.23
White iron-bark	1.17	Mahogany	1.20
Red iron-bark	1.22	Grey gum917
Forest oak	1.21	Red gum995
European Timber.	Specific Gravity.	European Timber.	Specific Gravity.
Ash753	Ebony	1.19
Beech690	British oak99
Chestnut535		

Various "scrubs" characterize the interior, differing very widely from the coastal scrubs. "Mallee" scrub occupies large tracts in South Australia and Victoria, covering probably an extent of 16,000 square miles. The mallee is a species of eucalyptus growing 12 to 14 feet high. The tree breaks into thin stems close to the ground, and these branch again and again, the leaves being developed umbrella-fashion on the outer branches. The mallee scrub appears like a forest of dried osier, growing so close that it is not always easy to ride through it. Hardly a leaf is visible to the height of one's head; but above, a crown of thick leather-like leaves shuts out the sunlight. The ground below is

perfectly bare, and there is no water. Nothing could add to the sterility and the monotony of these mallee scrubs. "Mulga" scrub is a somewhat similar thicket, covering large areas. The tree in this instance is one of the acacias, a genus distributed through all parts of the continent. Some species have rather elegant blossoms, known to the settlers as "wattle." They serve admirably to break the sombre and monotonous aspect of the Australian vegetation. Two species of acacia are remarkable for the delicate and violet-like perfume of their wood—myall and yarran. Proteaceous plants, although not exclusively Australian, are exceedingly characteristic of Australian scenery, and are counted amongst the oldest flowering plants of the world. The order is easily distinguished by the hard, dry, woody texture of the leaves and the dehiscent fruits. They are found in New Zealand and also in New Caledonia, their greatest developments being on the south-west of the Australian continent. Proteaceæ are found also in Tierra del Fuego and Chile. They are also abundant in South Africa, where the order forms the most conspicuous feature of vegetation. The range in species is very limited, no one being common to eastern and western Australia. The chief genera are banksia (*honeysuckle*), and hakea (*needle bush*).

The well-known Moreton Bay pine (*Araucaria Cunninghamii*) is reckoned amongst the giants of the forest. The genus is associated with one long extinct in Europe. Moreton Bay pine is chiefly known by the utility of its wood. Another species, *A. Bidwillii*, or the bunya-bunya, afforded food in its nut-like seeds to the aborigines. A most remarkable form of vegetation in the north-west is the gouty-stemmed tree, one of the Malvaceæ. It is related closely to the famous baobab of tropical Africa. The "grass-tree" (*Xanthorrhæa*) of the uplands and coast regions, is peculiarly Australian in its aspect. It is seen as a clump of wire-like leaves, a few feet in diameter, surrounding a stem, hardly thicker than a walking-stick, rising to the height of ten or twelve feet. This terminates in a long spike thickly studded with white blossoms. The grass-tree gives as distinct a character to an Australian picture as the agave and cactus do to the Mexican landscape. With these might be associated the gigantic lily of Queensland (*Nymphæa gigantea*), the leaves of which float on water, and are quite eighteen inches across. There is also a gigantic lily (*Doryanthes excelsa*) which grows to a height of 15 feet. The "flame tree" is a most conspicuous feature of an Illawarra landscape, the largest racemes of crimson red suggesting the name. The waratah or native tulip, the magnificent flowering head of which, with the kangaroo, is symbolic of the country, is one of the Proteaceæ. The natives were accustomed to suck its tubular flowers for the honey they contained. The "nardoo" seed, on which the aborigines sometimes contrived to exist, is a creeping plant, growing plentifully in swamps and shallow pools, and belongs to the natural order of Marsiliaceæ. The spore-cases remain after the plant is dried up and withered. These are collected by the natives, and are known over most of the continent as nardoo.

No speculation or hypothesis has been propounded to account satisfactorily for the origin of the Australian flora. As a step towards such hypothesis it has been noted that the Antarctic, the South African, and the Australian floras have many types in common. There is also to a limited extent a European element present. One thing is certain, that we have in Australia a flora that is a remnant of a vegetation once widely distributed. Heer has described such Australian genera as Banksia, Eucalyptus, Grevillea, and Hakea from the Miocene of Switzerland. Another point agreed upon is that the Australian flora is one of vast antiquity. We have here genera so far removed from every living genus that many connecting links must have become extinct. The region extending round the south-western extremity of the continent has a peculiarly characteristic assemblage of typical Australian forms, notably a great abundance of the Proteaceæ. This flora, isolated by arid country from the rest of the continent, has evidently derived its plant life from an outside source, probably from lands no longer existing.

FAUNA.

More than a hundred marsupials, or about two-thirds of the known species, are natives of Australia. The kangaroo (*Macropus*), emblematic of the island continent, lives in droves in the open grassy plains of the interior. Several smaller forms of the same general appearance are known as wallabys, and are common everywhere. Other terrestrial marsupials are the wombat (*Phascolomys*), a large clumsy burrowing animal, not unlike a pig, which attains a weight of from 60 to 100 lb; the bandicoot (*Perameles*), a rat-like creature whose depredations annoy the agriculturist; the native cat (*Dasyurus*), noted robber of the poultry yard; the Tasmanian wolf (*Thylacinus*), which preys on large game; and the recently-discovered *Notoryctes*, a small animal which burrows like a mole in the desert of the interior. Arboreal species include the well-known opossums (*Phalanger*); the extraordinary tree-kangaroo of the Queensland tropics; the flying-squirrel, which expands a membrane between the legs and arms, and by its aid makes long sailing

jumps from tree to tree; and the native bear (*Phascogale*), an animal with no affinities to the bear, and having a long soft fur and no tail. More lowly organized than the foregoing are the two monotremes, the Platypus, and *Echidna* or native porcupine; the former is famous for seeming "half bird, half beast," and is much sought after for its exquisite fur. The dugong lives in the sheltered inlets of the Queensland coast, and is systematically hunted for its oil by natives and whites. Three kinds of seals occur upon the south coast.

The mammals of Australia are with a few exceptions marsupials; that is, they differ profoundly in structure from all other mammals and are lower in the scale of organization. The marsupials of Australia have been isolated from the rest of the world from a period antedating the appearance of higher mammals in other lands. By this isolation they are spared those contests with stronger mammals which resulted in the extermination of the marsupials of other continents, with the exception of the opossums of America. We notice, however, a wonderful development of "groups," parallel with the development of the higher mammals in other lands:—

Placentals of Europe.	Marsupials of Australia.
1. Rodents.	1. Wombat and allies.
2. Carnivora.	2. Native "cats."
3. Insect-eaters.	3. Bandicoots.
4. Hoofed beasts.	4. Kangaroos.
5. Sloths and ant-eaters.	5. Native "bear" and echidna.
6. Mole.	6. Marsupial mole.

The geographical limits of the marsupials are very interesting. The opossums of America are marsupials, though not showing anomalies as great as kangaroos and bandicoots (in their feet), and myrmecobius (in the number of teeth). Except the opossums, no single living marsupial is known outside the Australian zoological region. The forms of life characteristic of India and the Malay peninsula come down to the island of Bali. Bali is separated from Lombok by a strait not more than 15 miles wide. Yet this narrow belt of water is the boundary line between the Australasian and the Indian regions. The zoological boundary passing through the Bali Strait is called "Wallace's line," after the eminent naturalist who was its discoverer. He showed that not only as regards beasts, but also as regards birds, these regions are thus sharply limited. Australia, he pointed out, has no woodpeckers and no pheasants, which are widely-spread Indian birds. Instead of these it has mould-making turkeys, honey-suckers, cockatoos, and brush-tongued lorries, all of which are found nowhere else in the world.

The *Myrmecobius* of Western Australia is a bushy-tailed ant-eater about the size of a squirrel, and from its lineage and structure of more than passing interest. It is, Mivart remarks, a survival of a very ancient state of things indeed. It had ancestors in a flourishing condition during the Secondary epoch. Its congeners even then lived in England, as is proved by the fact that their relics have been found in the Stonesfield oolitic rocks, the deposition of which is separated from that which gave rise to the Paris Tertiary strata by an abyss of past time which we cannot venture to express even in thousands of years.

Australia is rich in snakes, and has more than a hundred different kinds. Most of these are venomous, but all are not equally dreaded. Five rather common species are certainly deadly—the death adder, the brown, the black, the superb, and the tiger snakes. During the colder months these reptiles remain in a torpid state. No certain cure has been or is likely to be discovered for their poison, but in less serious cases strychnine has been used with advantage. In tropical waters a sea snake is found, which, though very poisonous, rarely bites. Among the inoffensive species are counted the graceful green "tree snake," which pursues frogs, birds, and lizards to the topmost branches of the forest; also, several species of pythons, the commonest of which is known as the carpet snake. These great reptiles may attain a length of 10 feet; they feed on small animals, which they crush to death in their folds. In the estuaries of the Northern Queensland rivers crocodiles abound. Some aged examples reach a length of 25 feet, and such are most dangerous. A small and inoffensive species is found near Port Darwin. Lizards occur in great profusion and variety. A monitor is popularly known as the "goanna," a name derived from iguana, an entirely different animal. The "frilled lizard" is a most remarkable creature. When brought to bay it stands erect on its hind-legs, extends an umbrella-like frill around its neck, and at the same time opens wide its jaws. The horned lizard of Western Australia (*Moloch horridus*) is reputed the ugliest of existing animals, being covered all over with sharp spines, which give it a vicious and repulsive appearance; really, however, it is most inoffensive. Frogs of many kinds are plentiful, the brilliant green frogs being especially conspicuous and noisy.

Two other creatures may be ranked with myrmecobius, as of more than passing interest to the naturalist. The "mud-fish" of

Queensland (*Ceratodus Forsteri*) belongs to an ancient order of fishes—the Dipnoi, only a few species of which have survived from past geological periods. The Dipnoi show a distinct transition between fishes and amphibia. For many years only two species were known to science; *Lepidosiren paradoxa* of South America and *Lepidosiren (Protopterus) annectens* of Africa. Recently, however, the Australian mud-fish has been referred to the Dipnoi,—for it was seen that it was provided with a gill-like breathing apparatus, and also true lungs. The blood circulation is in a sense intermediate between that of frogs and fishes. The heart has one ventricle and two auricles. So far the mud-fish is known only from the Mary and the Burnett rivers. Hardly of less scientific interest is the Port Jackson shark (*Heterodontus*). It is a harmless helmeted ground-shark, living on molluscs, and almost the sole survivor of a genus abundant in the Secondary rocks of Europe. One of its remarkable characteristics is the pavement of crushing teeth with which the mouth is lined. The beautiful *Trigonia* shell, so plentiful in Sydney harbour, is another genus originally believed to be extinct. The first descriptions were published from fossil forms. It was a welcome discovery to find *Trigonia* still surviving in Australian seas. There are only about five species living to-day, and even these are not plentiful. In the Secondary period, however, they must have been extremely abundant; they swarmed in Oolitic seas.

Another link connecting the present fauna of Australia with that of Secondary Europe has recently been discovered. For a considerable time a peculiar group of herrings (*Diplomystus*), characterized by a row of scutes on the back, resembling those found in other types on the opposite aspect of the body, have been known from Cretaceous and early Tertiary rocks, their range including Brazil, Wyoming, and the Isle of Wight. Until recently these herrings were considered to be extinct, but they have now been found alive in certain rivers of New South Wales.

The origin of the fauna and flora of Australia has of late attracted considerable attention. Much accumulated evidence, biological and geological, has pointed to a southern extension of India, an eastern extension of South Africa, and a western extension of Australia into the Indian Ocean. The comparative richness of protaceous plants in Western Australia and South Africa first suggested a common source for these primitive types. Dr H. O. Forbes drew attention to a certain community amongst birds and other vertebrates, invertebrates, and amongst plants, on all the lands stretching towards the South Pole. A theory was therefore propounded that these known types were all derived from a continent which has been named Antarctica. The supposed continent extended across the South Pole, practically joining Australia and North America. Just as we have evidence of a former mild climate in the Arctic regions, so a similar mild climate has been postulated for Antarctica. Modern naturalists consider that many of the problems of Australia's remarkable fauna and flora can be best explained by the following hypothesis:—The region now covered by the Antarctic ice-cap was in early Tertiary times favoured by a mild climate; here lay an Antarctic continent or archipelago. From an area corresponding to what is now South America there entered a fauna and flora, which, after undergoing modification, passed by way of Tasmania to Australia. These immigrants then developed, with some exceptions, into the present Australian flora and fauna. This theory in the course of a decade has advanced from the position of a disparaged heresy to acceptance by leading thinkers. The discovery as fossil, in South America, of primitive or ancestral forms of marsupials has given it much support. One of these, *Prothylacynus*, is regarded as the forerunner of the marsupial wolf of Tasmania. An interesting link between divergent marsupial families, still living in Ecuador, the *Cænolestes*, is another discovery of recent years. On the Australian side the fact that Tasmania is richest in marsupial types indicates the gate by which they entered. It is not to be supposed that this Antarctic element, to which Professor Tate has applied the name *Euronotian*, entered a desert barren of all life. Previous to its arrival Australia doubtless possessed considerable vegetation and a scanty fauna, chiefly invertebrate. At a comparatively recent date Australia received its third and newest constituent. The islands of Torres Strait have been shown to be the denuded remnant of a former extension of Cape York peninsula in North Queensland. Previous to the existence of the strait, and across its site, there poured into Australia a wealth of Papuan forms. Along the Pacific slope of the Queensland Cordillera these found in soil and climate a congenial home. Among the plants the wild banana, pepper, orange, and mangosteen, rhododendron, epiphytic orchids, and the palm; among mammals the bats and rats; among birds the cassowary and rifle birds; and among reptiles the crocodile and tree snakes, characterize this element. The numerous facts, geological, geographical, and biological, which, when linked together, lend great support to this theory, have been well worked out in Australia by Mr Charles Hedley of the Australian Museum, Sydney.

STATISTICS.¹

Climate.—The tropic of Capricorn divides Australia into two parts. Of these the northern or inter-tropical portion contains 1,145,000 square miles, comprising half of Queensland, the Northern Territory of South Australia, and the north-western divisions of West Australia. The whole of New South Wales, Victoria, and South Australia proper, half of Queensland, and more than half of West Australia, comprising 1,801,700 square miles, are without the tropics. In a region so extensive very great varieties of climate are naturally to be expected, but it may be stated as a general law that the climate of Australia is milder than that of corresponding lands in the Northern Hemisphere. During July, which is the coldest month in southern latitudes, one half of Australia has a mean temperature ranging from 45° to 61° and the other half from 62° to 80°. The following are the areas subject to the various average temperatures during the month referred to:—

Temperature Fahr.	Area in Square Miles.
45°-50°	18,800
50°-55°	596,300
55°-60°	681,800
60°-65°	834,400
65°-70°	515,000
70°-75°	275,900
75°-80°	24,500

The temperature in December ranges from 60° to above 95° Fahr., half of Australia having a mean temperature below 84°. Dividing the land into zones of average summer temperature, the following are the areas which would fall to each:—

Temperature Fahr.	Area in Square Miles.
60°-65°	67,800
65°-70°	63,700
70°-75°	352,300
75°-80°	439,200
80°-85°	733,600
85°-90°	570,600
90°-95°	584,100
95° and over	135,400

Judging from the figures just given, it must be conceded that a considerable area of the continent is not adapted for colonization by European races. The region with a mean summer temperature in excess of 95° Fahr. is the interior of the Northern Territory of South Australia north of the 20th parallel; and the whole of the country, excepting the seaboard, lying between the meridians of 120° and 140°, and north of the 25th parallel, has a mean temperature in excess of 90° Fahr.

Recent observations confirm the earlier opinions as to the dryness of the Australian climate, and it may be taken that nearly 40 per cent. of the area of the continent has not a greater annual rainfall than 10 inches. This dry area is shaped like a flattened oval lying between the 117th and 142nd meridian east and the parallels of 21° and 32° south. Very little of Queensland and New South Wales and no part of Victoria lie within this area. The following table shows the rainfall zones in square miles:—

Rainfall.	Rainfall Areas in Square Miles.
Under 10 inches	1,219,600
10 to 20 "	843,100
20 to 30 "	399,900
30 to 40 "	225,700
40 to 50 "	140,300
50 to 60 "	47,900
60 to 70 "	56,100
Over 70 "	14,100
Total	2,946,700

¹ These statistics refer only to the continental states of the Federation, not to Tasmania.

Population.—The Australian people are mainly of British origin, only 5 per cent. of the population of European descent being of non-British race. It is certain that the aborigines are very much less numerous than when the country was first colonized, but their present numbers can be given for only a few of the states. At the census of 1891, 38,879 aborigines were enumerated, of whom 8280 were in New South Wales, 565 in Victoria, 23,789 in South Australia, and 6245 in West Australia. It has been asserted by the Queensland authorities that there are 70,000 aborigines in that state; but this is a crude estimate, and may be far wide of the truth. In South Australia and the Northern Territory a large number are outside the bounds of settlement, and it is probable that they are as numerous there as in Queensland. The census of West Australia included only those aborigines in the employment of the colonists; and as a large part of this, the greatest, of the Australian states, is as yet unexplored, it may be presumed that the aborigines enumerated were very far short of the whole number of persons of that race in the state. Taking all things into consideration, the aboriginal population of the continent may be set down at something like 200,000. The Chinese number about 36,000, and are chiefly found in New South Wales and Queensland; South Sea Islanders and other coloured races number probably about 16,000, and are to be found principally in Queensland. On the 1st January 1900 the population of Australia was 3,535,430, but this figure is exclusive of aborigines living outside the boundaries of settlement. The increase of population since 1870 was as follows:—1870, 1,549,706; 1880, 2,130,686; 1890, 3,013,790. The expansion has been due mainly to the natural increase; that is, by reason of excess of births over deaths. Immigration to Australia has not been on a large scale since the first gold discoveries. The distance from Europe and the cost of the passage tend to prevent the flow of population, but added to this there has been lately a disinclination on the part of the Australian Governments, except those of Queensland and West Australia, to encourage immigration, and provide for the welfare of the immigrants on their arrival. During the last ten years the inflow of population has not averaged more than four or five thousand a year, and in 1899 there was an actual excess of emigrants to the number of 5189. The natural increase of population is about 14 per thousand, a ratio very little higher than in Great Britain, where the excess of births over deaths is about 12 per thousand, and far below the average obtaining in these states a few years ago. In 1899 the births numbered 95,964 and the deaths 45,425, showing a ratio per thousand equal to 27.25 and 12.90 respectively. In 1891 the births numbered 105,215 and the deaths 45,187, giving the ratios of 34.42 and 14.78 per thousand respectively. There has been a very great falling-off in the proportion of births to marriages, to such an extent indeed that the rate of Australia, which was formerly very high, has now dropped to the European level. This change has taken place since 1884. On the other hand there has been an improvement in the death-rates. The marriages in 1899 numbered 24,811, which gives a proportion of 7.05 per thousand inhabitants. This ratio is below the normal, and may be expected to be increased to about 7.50 per thousand, which was about the average for the years 1886 to 1890. The decline in the Australian marriage-rate was largely due to the bank failures which occurred in 1893, and from which the states have made a very slow recovery.

Australia contains only four cities whose population exceeds 100,000, and fifteen with over 10,000. The principal cities and towns are Sydney (pop. 489,000), Newcastle,

Broken Hill, Parramatta, Goulburn, Maitland, Bathurst, Grafton, Albury, and Orange in New South Wales; Melbourne (pop. 494,000), Ballarat, Bendigo-Geelong, Warrnambool, Castlemaine, and Stawell in Victoria; Brisbane (pop. 120,000), Rockhampton, Maryborough, Townsville, Gympie, Ipswich, and Toowoomba in Queensland; Adelaide (pop. about 162,000, including Port Adelaide) in South Australia; Perth (pop. 44,000) and Fremantle in West Australia.

ABORIGINES.

The aborigines of Australia are a single race throughout the whole continent. They are far removed in character from any other peoples, and have evidently been isolated from the rest of the human race from prehistoric times. Although their physical and mental characters stamp them as one, it is generally accepted now that the race is a blend of two or three different elements, introduced into Australia probably when the continent was still connected by dry land with New Guinea. If the aboriginal races be divided, as they conveniently may, into three classes, class A would be characterized as follows:—Hunters and fishers who dig for tubers, build crude canoes, have implements of rude design, have no fixed abode and no buildings. Class B would comprise hunters of a higher class, having finer-finished weapons, showing skill in carving, dressing neatly, and having habitations. Class C would include a higher grade, namely, those with fixed habitations, some rude method of agriculture, and some form of government. The Australian aborigines undoubtedly belong to the first or lowest class. They are typical hunters, "in this respect unapproached by the Canadian trapper, the South African bushman, or any other people, savage or civilized." Although in physical appearance the natives vary considerably, still they are clearly differentiated from any other race. The colour of the skin ranges from dusky copper to black. Muscle is usually not well developed; the legs in particular being notably destitute of calves. The physique of the aborigines of the central and more arid portions of the continent is not, as might be expected, up to that of the favoured tribes living on the coast or coastal uplands. Except in the arid interior the Australian black-fellow averages 5 feet 6 inches in height, while savages standing 6 feet are not uncommon. There is usually an abundance of hair on the face and breast; but towards the northern portions of the continent it has been noted that the aboriginal has a less luxuriant beard. The hair of the head is raven black and wavy; this is somewhat modified where Papuan influence has been felt, the hair then being quite curly and frizzly. The peculiarities about the aboriginal's head are very marked. The skull is abnormally thick and the cerebral capacity small. The head is long and somewhat narrow, and the forehead recedes in a marked degree. He has usually excellent teeth, and the hands and feet are not strikingly large. The black-fellow's carriage is graceful and erect; he walks with the head well thrown back, and his senses are always on the alert. His powers in tracking, stalking his prey, and hurling his spear are proverbial. His implements, offensive and defensive, have been well described by standard authors, but little or no light has been thrown on the origin of that wonderful weapon, the boomerang. Some writers have taken the trouble to show that the boomerang was in use ages ago in Africa and in India; but if we define the boomerang as an instrument which when projected into the air returns to its thrower, it may be safely said that we have no proof that any other race ever knew of such an implement. The boomerang that returns to the thrower is rarely if ever used for fighting purposes. The stone implements of the aborigines may be said to be crude in the extreme. But any good collection of their implements will show—(1) flakes; (2) knives, in many varieties; (3) spear-heads; (4) chisels; (5) scrapers; (6) needles or awls; (7) hammers; (8) anvils; and (9) grinding stones. Tomahawks showing a high finish are sometimes found, but they were evidently rare. There is nothing specially distinctive about the stone implements to distinguish them from those of other primitive peoples.

Closer study has not improved on previous estimates as to the paradoxical moral code of the aborigines. A wife will be beaten without mercy for unfaithfulness to her husband; but the same wife will have had to submit to the first-night promiscuity, a widespread revel which Roth shows is a regular custom in North-west Central Queensland. A husband claims his wife as his absolute property, but he has no scruple in handing her over for a time to another man. There is no proof that anything like community of women or unlimited promiscuity exists anywhere. It would be wrong, however, to conclude that moral considerations have led up to this state of things. Of sexual morality, in the everyday sense of the word, there is none. Although not invariably cannibals, the aboriginal relishes human flesh. In his treatment of women the aboriginal may be ranked lower than even the Fuegians. Early in

life the young girls are subjected to horrible mutilation (introcision), which is in some obscure way associated with quite a different operation, "the terrible rite" or male introcision, to which young men are subjected. The operation may be said to be confined to the tribes of Central and North-central Australia. The Tasmanians knew nothing of the rite, or of circumcision, and they are believed to represent the original stock that spread over the continent, and, being the most isolated, advanced but little.

The following description by Mr W. A. Horn will apply with little modification to the black-fellow over the whole continent:—"The Central Australian aboriginal is the living representative of a stone age, who still fashions his spear-heads and knives from flint or sandstone, and performs the most daring surgical operations with them. His origin and history are lost in the gloomy mists of the past. He has no written records and few oral traditions. In appearance he is a naked, hirsute savage, with a type of features occasionally pronouncedly Jewish. He is by nature light-hearted, merry and prone to laughter, a splendid mimic, supple-jointed, with an unerring hand that works in perfect unison with the eye, which is as keen as that of an eagle. He has never been known to wash. He has no private ownership of land, except as regards that which is not over-carefully concealed about his person. He cultivates nothing, and lives entirely on the spoils of the chase; and although the thermometer frequently ranges from 15° to over 90° F. in twenty-four hours, and his country is by no means devoid of furred game, he makes no use of the skins for clothing, but goes about during the day and sleeps in the open at night perfectly nude. He builds no permanent habitation and usually camps where night or fatigue overtakes him. He can travel from point to point for hundreds of miles through the pathless bush with unerring precision, and track an animal over rocks and stones, where a European eye would be unable to distinguish a mark. He is a keen observer, and knows the habits and changes of form of every variety of animal or vegetable in his country. Religious belief he has none, but is excessively superstitious, living in constant dread of an Evil Spirit which is supposed to lurk around his camp at night. He has no gratitude except that of the anticipatory order, and is as treacherous as Judas. He has no traditions, and yet continues to practise with scrupulous exactness a number of hideous customs and ceremonies which have been handed down from his fathers, and of the origin or reason of which he knows nothing. Ofttimes kind and even affectionate to those of his children who have been permitted to live, he yet practises, without any reason except that his father did so before him, the most cruel and revolting mutilations upon the young men and maidens of his tribe."

Every traveller on the Queensland coast must have noticed that, directly a boat puts off for the shore, smoke signals ascend from point to point as far as the eye can reach. It is now ascertained that information of a varied character can be conveyed over long distances by smoke signals. For the purpose of signalling, the Queensland blacks use a complicated system based on the following signals:—(1) The slender column of light-coloured smoke; (2) a heavy column of smoke; (3) a slender column of black smoke; (4) interrupted or intermittent columns of smoke; (5) groups or columns of smoke columns. Much attention has been given to the instrument known as "bullroarer," as being one of the few instruments used by the Australian aboriginal and far-distant primitive peoples. A flat piece of wood is attached at one end to a string and rapidly whirled in sling fashion. Vibrations are set up resulting in a roar, which has an extraordinary effect upon the hearer. Women and children are never allowed to see the instrument; and when in the absolute stillness of the forest the buzzing of the roar rises and falls, people unable to account for such weird sounds are awed beyond measure. Mr A. W. Howitt, writing on the subject, remarks: "The universality of its use, and under the same conditions, in world-wide localities, is one of the most puzzling questions in this branch of anthropology, and can only, as it seems to me, point to its extreme antiquity."

The most cursory observer of the aboriginal will notice that he makes no visible acknowledgment of a Supreme Being. He has no altar and no form of sacrifice. The fear of any future punishment or the hope of any future reward is neither a deterrent nor an incentive. If he has a religion, it is something completely apart from morals. There is no evidence to show that a black-fellow is guided or influenced in any action by the knowledge of a Supreme Power to whom he is responsible.

The route by which the blacks arrived in Australia has not yet been placed beyond question. If the Tasmanians be accepted as the nearest approach to the primitive type, then we have a race that had neither a boomerang nor a shield. Their whole belongings consisted of stone tomahawks and a few crude spears. If this represents the stage to which primitive man had reached when the blacks first peopled Australia, then their coming must be placed far back in the early history of mankind. That they have been isolated for long ages may be taken for granted. They have derived

little or nothing from the present races to the north of Torres Strait. Certainly the blacks of North Australia seem somewhat in advance of the aborigines generally. But no clear connexion exists either in language, or manners, or customs with Malays or Papuans. The sunny and playful disposition of the aboriginal points to Papuan rather than Malay blood, but the probability is that the natives were in possession long before the present distribution of Papuan and Malay. The blacks on parts of the north coast use an outrigger to their canoes—an idea evidently introduced from beyond Torres Strait. The bow and arrow are not known among the aborigines of Australia. The question arises as to whether they were ever acquainted with their use. Had they ever known such weapons, it is hardly likely that the knowledge of them could ever have been lost. Depending, as the Australian black-fellow did, on the chase, nothing could be better fitted for his wants. The absence of these implements points conclusively to the fact that the ancestors of these people reached Australia before the bow and arrow became what they are now, the first-comers in use by almost all races. It is not necessary that the first-comers should have been skilful navigators. Possibly there was land connexion between Australia and New Guinea in post-Tertiary times, by means of which the aborigines made their way.

The study of the languages of the various tribes has so far yielded nothing of exceptional importance. As an instance of how a spoken tongue may vary in a short time the following is of interest:—In 1893 a wild tribe of natives was discovered in the Wentworth district of New South Wales. This tribe originated through a black-fellow hiding in some little-known country with a few gins for some thirty years. In that time the tribe had grown to thirty—men, women, and children. The country they were concealed in is known as mallee scrub, the most wretched kind of land known in the state. The tribe lived as only black-fellows can on kangaroo, wild cat, and ant eggs. They used water bags made from the skins of kangaroo legs. They produced fire in the old way by rubbing two sticks together, and their only weapons were spears, which were merely stems of mallee, roughly pointed and barbed. The remarkable fact is that the station blacks had considerable difficulty in making the wild tribe understand them, although thirty years before they must have spoken the same language.

For purposes of comparison the aboriginal character, habits, and customs may be summed up as follows:—

Moral, Mental, and Social.—No moral code. A clear idea of individual ownership in property. A wife is held as property. No idea of a Supreme Being. Unable to grasp abstract ideas. No idols, no altar, and no form of sacrifice. No form of prayer or supplication. Not in any way guided in their actions by the hope of future reward or future punishment. No written language. Build no houses. No pottery. No weaving. No idea of moral justice. No art, save the making of some plaited bags. Very fearful of unseen dangers and in constant dread of witchcraft. No ownership in land, but the tribes have a well-understood limit to their hunting-grounds. Reached only to the "binary stage" in counting. Have a gesture speech, more or less perfected in various tribes, and often a complete code of smoke signals. In all that concerns hunting and the chase, their senses are far keener than those of civilized man.

Customs, &c.—Circumcision practised over most of the continent. The rite of male and female intocision practised in a horrible manner by many tribes. Some tribes force the young women to submit to promiscuity after the operation, but this is a thing quite apart from "communal marriage" or general promiscuity. Mutual avoidance of mother-in-law and son-in-law. A complicated marriage relationship. No marriage ceremony. A wife is procured by purchase, as a gift from her parents, or occasionally by forcible abduction. Polygamy is recognized. Infanticide practised. Cannibalism common. Typical hunters, but do not use the bow and arrow. Most tribes have a chief or head man, but his office is not hereditary, neither is a chief elected.

Implements, &c.—Stone chisels, hammers, and tomahawks. Barbed spears. The boomerang. A throwing stick for spears. Various clubs, and fighting boomerangs not made to return to the thrower. Make crude canoes and plait twine nets, bags, and armlets.

It is right to add that the black-fellow, when unspolled by aggression and bad treatment, is docile, capable of kindness, and even of great affection. But even here he is inconstant. The early explorers found them an inoffensive people; and even at the date of writing the tribes who practise the dreadful mutilations referred to are seldom hostile, and, when their womenfolk are not taken from them, they are disposed to be friendly.

Religion.—There is no state church in Australia, nor is the teaching of religion in any way subsidized by the state. The Church of England claims as adherents 39 per cent. of the population, and the Roman Catholic

Church 22 per cent.; next in numerical strength are the Wesleyans and other Methodists, numbering 12 per cent., the various branches of the Presbyterians 11 per cent., Congregationalists 2 per cent., and Baptists 2 per cent. At the beginning of the year 1900 it was estimated that there were in Australia 1,374,000 adherents of the Church of England, 783,000 Roman Catholics, 385,000 Presbyterians, 79,000 Congregationalists, and 81,000 Baptists.

Instruction.—Education is very widely distributed, and in every state it is compulsory for children of school ages to attend school. The statutory ages differ in the various states:—in New South Wales and West Australia it is from 6 to 13 years, in Victoria 6 to 12 years, in Queensland 6 to 11 years, and in South Australia 7 to 12 years inclusive. Religious instruction is not imparted by the state-paid teachers in any state, though in certain states persons, duly authorized by the religious organizations, are allowed to give religious instruction to children of their own denomination where the parents' consent has been obtained. According to the returns for 1899 there were 6357 state schools, with 13,462 teachers and 585,556 pupils, and the average attendance of scholars was 411,331. Besides state schools there were 2454 private schools, with 7778 teachers and 140,285 scholars, the average number of scholars in attendance being 109,389. The census of 1891 showed that about 76 per cent. of the whole population and more than 88 per cent. of the population over five years of age could read and write. There was, therefore, a residue of 12 per cent. of "illiterates," most of whom were not born in Australia. The marriage registers furnish another test of education. In 1899 only thirteen persons in every thousand married were unable to sign their names, thus proving that the number of illiterate adults of Australian birth is very small.

Public Finance.—The public revenues and expenditures of the various Governments for the year ending June 1900 were:—

	Revenue.	Expenditure.
New South Wales	£9,973,736	£9,811,402
Victoria	7,450,676	7,318,945
Queensland	4,588,207	4,540,418
South Australia	2,853,329	2,936,619
West Australia	2,875,396	2,615,675

The chief sources of revenue are customs taxation, railways, postal receipts, &c., and public lands. There are direct taxes on land and incomes in New South Wales, Victoria, and South Australia. The sums obtained during 1900 from the various sources named were:—

Customs and Excise	£7,180,907
Other Taxation	2,320,076
Railways, &c.	10,440,347
Postal and Telegraphs	2,148,335
Public Lands	3,430,641
Other sources	2,221,038

The expenditure may be grouped as follows:—

Railways and Working Expenses	£6,397,686
Postal and Telegraphs	2,095,810
Public Instruction	1,760,207
Interest and Charges on Debts	7,274,923
All other services	9,694,433

The public debt of the states on 30th June 1900 was £186,813,712, thus distributed:—

New South Wales	£85,332,993
Victoria	49,324,885
Queensland	34,349,414
South Australia	26,131,780
West Australia	11,674,640

About 80 per cent. of the whole public debt has been incurred for the purpose of constructing public works yielding a direct revenue; but the proportion varies in each state, and the details of the debt will be found under

the head of each particular state. The area of Australia is 2,946,691 square miles, or 1,885,882,240 acres; of this area the states have sold or otherwise parted with nearly 107,000,000 acres, and have under lease 779,000,000 acres. The bulk of the best land has been sold, the area neither leased nor sold, which amounts to about 1,000,000,000 acres, being chiefly in West and South Australia, and for the most part outside the region of regular rainfall.

Defence.—Practically there is no standing army in Australia, as the total number of paid soldiers is only 1571. This small permanent force is supported by a partially-paid force of 14,066, and an unpaid or strictly volunteer force of 6063 men. There are in each state, besides the land forces, small corps of naval volunteers capable of being employed as light artillery land forces or upon the local war vessels. Although the regular military force of the states is very small, Australasia (including New Zealand) was able to despatch 8300 troops for service in South Africa, and of these 6310 belonged to Australia proper. The naval defence of Australia is entrusted to the Imperial Navy, and Sydney, the headquarters of the fleet, ranks as a first-class station.

Fisheries.—The only deep-sea fisheries now carried on to any extent in Australia are the pearl fisheries in Queensland and West Australia. At one time whaling was an important industry on the coasts of New South Wales and Tasmania, and afterwards on the Western Australian coasts. The industry gravitated to New Zealand, and finally died out, chiefly through the wasteful practice of killing the calves to secure the capture of the mothers. Of late years whaling has again attracted attention, and a small number of vessels prosecute the industry during the season. The diving for pearl shell is actively carried on in Torres Strait, and has become an important industry, giving employment to nearly 2000 men, and the take in 1899 was 1200 tons of shell, valued at £130,105. Besides shell some *bêche-de-mer* and tortoise-shell is obtained. The pearl shell industry of West Australia is chiefly carried on along the north-west coast and in Shark Bay, but the production now shows a large falling-off owing to the exhaustion of the inshore banks. The value of pearls and pearl shell raised in 1899 amounted to £96,000, the banks at Shark Bay yielding only £3824, compared with £16,043 in 1890.

Timber Industry.—The timber industry is prosecuted on a large scale in West Australia and New South Wales, especially in the first-named state, where very extensive forests of splendid hardwoods exist. In 1899 the value of timber exported was—from West Australia £553,198, and New South Wales £102,218, the combined exports of the other three states only reaching £17,000. These figures do not indicate the whole value of the industry, especially in New South Wales, where a larger quantity is consumed locally than is exported.

Grazing and Agriculture.—The continent is essentially a pastoral one, and in 1899 depastured 72,625,000 sheep, 9,678,000 cattle, 1,639,000 horses, besides large numbers of swine; the figures show a great falling-off from previous years, for in 1891 there were 104,800,000 sheep and 10,860,000 cattle depastured. The butter industry is making great progress, and there were, in 1899, 1,102,000 head of dairy cattle, and the butter made was little short of 100,680,000 lb. Next to the pastoral industry agriculture is the principal source of Australian wealth. In 1900 the area devoted to tillage was 8,441,000 acres, namely, wheat, 5,550,000 acres; maize, 336,000 acres; oats, 325,000 acres; other grains, 121,000 acres; hay, 1,454,000 acres; potatoes, 112,000 acres; sugar-cane, 133,000 acres; vines, 61,000 acres; and other crops, 349,000 acres. The chief wheat lands are in Victoria, South Australia, and

New South Wales; the yield averages about 9 bushels to the acre, and is lowest in South Australia. Maize and sugar-cane are grown in New South Wales and Queensland. The vine is cultivated in all the states, but chiefly in South Australia, Victoria, and New South Wales. Australia produces abundant quantities and nearly all varieties of fruits; but the kinds exported are chiefly oranges, pine-apples, bananas, and apples. Tobacco thrives well in New South Wales and Victoria, but kinds suitable for exportation are not largely grown. Compared with the principal countries of the world, Australia does not take a high position in regard to the gross value of the produce of its tillage, but in value per inhabitant it compares fairly well; indeed, some of the states show averages which surpass those of many of the leading agricultural countries. For 1900 the total value of agricultural produce estimated at the place of production was £17,000,000 sterling, or about £4, 16s. 7d. per inhabitant.

Mineral Production.—Australia is one of the great gold producers of the world, and its yield in 1899 was about £14,334,000 sterling, and the total value of its mineral production was approximately £19,663,000. Gold is found throughout Australia, and the present prosperity of the states is largely due to the discoveries of this metal, the development of other industries being, in a country of varied resources, a natural sequence to the acquisition of mineral treasure. From the date of its first discovery, up to the close of 1899, gold to the value of £368,160,000 sterling had been obtained in Australia. Victoria, in a period of forty-eight years, contributed about £254,000,000 to this total, and is still a large producer, its annual yield being about 736,000 oz., 29,000 men being engaged in the search for the precious metal. Queensland's annual output is 705,000 oz.; the number of men engaged in gold-mining is 10,000. In New South Wales the greatest production was in 1852, soon after the first discovery of the precious metal, when the output was valued at £2,660,946; the production in 1899 was about 496,000 oz., valued at £1,752,000. Until recently West Australia was considered to be destitute of mineral deposits of any value, but it is now known that a rich belt of mineral country extends from north to south. The first important discovery was made in 1882, when gold was found in the Kimberley district; but it was not until a few years later that this rich and extensive area was developed. In 1887 gold was found in Yilgarn, about 200 miles east of Perth. This was the first of the many rich discoveries in the same district which have made West Australia the chief gold-producer of the Australian group. At the present time there are eighteen goldfields in the state, and it is estimated that over 20,000 miners are actively engaged in the search for gold. In 1899 the production amounted to 1,644,000 oz., as compared with 30,310 oz. in 1891. Of all the Australian states South Australia has produced the smallest quantity of gold, the total output from the commencement of mining operations being valued at little more than £2,213,000 sterling. The following table gives the value of gold raised from the commencement of mining to the close of the year 1899:—

State.	Value Produced.
New South Wales	£27,546,000
Victoria	254,157,000
Queensland	47,338,000
South Australia	2,213,000
West Australia	16,906,000

The production of gold, which had been declining steadily for many years, reached the lowest point in 1886. Since then there has been a marked revival. The production of gold in each state in 1899 is given below:—

State.	Weight. Oz.	Value of Gold.
New South Wales	496,196	£1,761,815
Victoria	854,500	3,418,000
Queensland	946,894	2,838,119
South Australia	23,123	79,041
West Australia	1,643,877	6,246,733

The following shows the number of miners at work:—

State.	Minors Employed.
New South Wales	19,300
Victoria	30,100
Queensland	9,800
South Australia	2,000
West Australia	21,000

The greatest development of quartz reefing is found in Victoria, some of the mines being of great depth. There are seven mines in the Bendigo district over 3000 feet deep, and fourteen over 2500 feet deep. In Lansell's 180 Mine a depth of 3352 feet has been reached, and in Lazarus Mine 3424 feet. In the Ballarat district a depth of 2520 feet has been reached in the South Star Mine.

Silver has been discovered in all the states, either alone or in the form of sulphides, antimonial and arsenical ores, chloride, bromide, iodide, and chloro-bromide of silver, and argentiferous lead ores, the largest deposits of the metal being found in the last-mentioned form. The leading silver mines are in New South Wales, the returns from the other states being comparatively insignificant. The fields of New South Wales have proved to be of immense value, the yield of silver during 1899 being £2,070,400, and the total output to the end of the year named £28,000,000. The Broken Hill field, which was discovered in 1883, extends over 2500 square miles of country, and has developed into one of the principal mining centres of the world. It is situated beyond the river Darling, and close to the boundary between New South Wales and South Australia. The lodes occur in Silurian metamorphic micaceous schists, intruded by granite, porphyry, and diorite, and traversed by numerous quartz reefs, some of which are gold-bearing. The Broken Hill lode is the largest yet discovered. It varies in width from 10 feet to 200 feet, and may be traced for several miles. Although indications of silver abound in all the other states, no fields of great importance have yet been discovered. Up to the end of 1899 Australia has produced silver to the value of £29,559,000, of which nearly £28,000,000 was obtained from the fields of New South Wales.

Copper is known to exist in all the states, and has been mined extensively in South Australia, and on a much smaller scale in New South Wales and Queensland. The low quotations which have ruled for a number of years have had a depressing effect upon the industry, and many mines once profitably worked have now been closed. The discovery of copper had a marked effect on the fortunes of South Australia at a time when the young colony was surrounded by difficulties. The first important mine, the Kapunda, was opened up in 1842. It is estimated that at one time 2000 tons were produced annually, but the mine was closed in 1879. In 1845 the celebrated Burra Burra Mine was discovered. This mine proved to be very rich, and paid £800,000 in dividends to the original owners. For a number of years, however, the mine has been suffered to remain untouched, as the deposits originally worked were found to be depleted. For many years the average output was from 10,000 to 13,000 tons of ore, yielding from 22 to 23 per cent. of copper. For the period of thirty years during which the mine was worked the production of ore amounted to 234,648 tons, equal to 51,622 tons of copper, valued at £4,749,924. The Wallaroo and Moonta mines, discovered in 1860 and 1861, proved to be even more valuable than the Burra Burra, the Moonta mines employing at one time upwards of 1600 hands. The dividends paid by these mines amounted to about £1,750,000 sterling. The satisfactory price obtained during recent years has enabled renewed attention to be paid to copper mining in South Australia, and the production of the metal in 1899 was valued at £406,000. The copper mining industry in New South Wales reached its highest point in 1883, when the production was valued at £472,982. The principal deposits of copper are found in the central part of the state between the Macquarie, Darling, and Bogan rivers. Deposits have also been found in the New England and Southern districts, as well as at Broken Hill, showing that the mineral is widely distributed throughout the state. The more important mines are those of Cobar, where the Great Cobar Mine produced, in 1899, 3794 tons of refined copper, valued at £265,580. In Northern Queensland copper is found throughout the Cloncurry district, in the upper basin of the Star river, and the Herberton district. The returns from the copper fields in the state are at present small, owing to the lack of suitable fuel for smelting pur-

poses, which renders the economic treatment of the ore difficult; the development of the mines is also greatly retarded by the want of easy and cheaper communication with the coast. In West Australia copper deposits have been worked for some years. Very rich lodes of the metal have been found in the Northampton, Murchison, and Champion Bay districts, and also in the country to the south of these districts on the Irwin river. As in the other copper-producing states, there has been a revival of the industry in West Australia, the production in 1899 being valued at £36,000. The total value of copper produced in Australia up to the end of 1899 was £29,402,000 sterling, £21,936,000 having been obtained in South Australia, £5,019,000 in New South Wales, and over £2,032,000 in Queensland.

Tin was known to exist in Australia from the first years of colonization. The wealth of Queensland and the Northern Territory of South Australia in this mineral, according to the reports of Dr Jack, late Government geologist of the former state, and the late Rev. J. E. Tenison-Woods, appears to be very great. The most important tin mines in Queensland are in the Herberton district, southwest of Cairns; at Cooktown, on the Annan and Bloomfield rivers; and at Stanthorpe, on the border of New South Wales. Herberton and Stanthorpe have produced more than three-fourths of the total production of the state. During the past few years the production has greatly decreased in consequence of the low price of the metal, but in 1899 a stimulus was given to the industry, and the production was valued at £77,000. In New South Wales lode tin occurs principally in the granite and stream tin under the basaltic country in the extreme north of the state, at Tenterfield, Emmaville, Tingha, and in other districts of New England. The metal has also been discovered in the Barrier Ranges, and many other places. The value of the output in 1899 was set down at £90,000. The yield of tin in Victoria is very small, and until lately no fields of importance have been discovered; but towards the latter end of 1890 extensive deposits were reported to exist in the Gippsland district—at Omeo and Tarwin. In South Australia tin mining is unimportant. In West Australia the production from the tin fields at Greenbushes was valued in 1899 at £25,000. The value of tin produced in Australia is about £100,000 per annum, and the total production to the end of 1899 was valued at £11,743,000, of which £6,383,000 was obtained in New South Wales and £4,526,000 in Queensland.

Iron is distributed throughout Australia, but for want of capital for developing the fields this industry has not progressed. In New South Wales there are, together with coal and limestone in unlimited supply, important deposits of rich iron ores suitable for smelting purposes; and for the manufacture of steel of certain descriptions abundance of manganese, chrome, and tungsten ores are available. The most extensive fields are in the Mittagong, Wallerawang, and Rylstone districts, which are roughly estimated to contain in the aggregate 12,944,000 tons of ore, containing 5,853,000 tons of metallic iron. Magnetite, or magnetic iron, the richest of all iron ores, is found in abundance near Wallerawang in New South Wales. The proximity of coal-beds now being worked should accelerate the development of the iron deposits, which, on an average, contain 41 per cent. of metal. Magnetite occurs in great abundance in West Australia, together with hæmatite, which would be of enormous value if cheap labour were available. Goethite, limonite, and hæmatite are found in New South Wales, at the junction of the Hawkesbury sandstone formation and the Wianamatta shale, near Nattai, and are enhanced in their value by their proximity to coal-beds. Near Lithgow extensive deposits of limonite, or clay-band ore, are interbedded with coal. Some samples of ore, coal, and limestone, obtained in the Mittagong district, with pig-iron and castings manufactured therefrom, were exhibited at the Mining Exhibition in London and obtained a first award.

Antimony is widely diffused throughout Australia, and is sometimes found associated with gold. In New South Wales the principal centre of this industry is Hillgrove, near Armidale, where the Eleanor Mine, one of the richest in the state, is situated. The ore is also worked for gold. In Victoria the production of antimony gave employment in 1890 to 238 miners, but owing to the low price of the metal, production has almost ceased. In Queensland the fields were all showing development in 1891, when the output exhibited a very large increase compared with that of former years; but, as in the case of Victoria, the production of the metal seems to have ceased. Good lodes of stibnite (sulphide of antimony) have been found near Roebourne, in West Australia, but no attempt has yet been made to work them.

Bismuth is known to exist in all the Australian states, but up to the present time it has been mined for only in three states, viz., New South Wales, Queensland, and South Australia. It is usually found in association with tin and other minerals. The principal mine in New South Wales is situated at Kingsgate, in the New England district, where the mineral is generally associated with molybdenum and gold.

Manganese probably exists in all the states, deposits having

been found in New South Wales, Victoria, Queensland, and West Australia, the richest specimens being found in New South Wales. Little, however, has been done to utilize the deposits, the demands of the colonial markets being extremely limited. The ore generally occurs in the form of oxides, manganite, and pyrolusite, and contains a high percentage of sesquioxide of manganese.

Platinum and the allied compound metal Iridosmine have been found in New South Wales, but so far in inconsiderable quantities. Iridosmine occurs commonly with gold or tin in alluvial drifts.

The noble metal Tellurium has been discovered in New South Wales at Bingara and other parts of the northern districts, as well as at Tarana, on the western line, though at present in such minute quantities as would not repay the cost of working. At many of the mines at Kalgoorlie, West Australia, large quantities of ores of telluride of gold have been found in the lode formations.

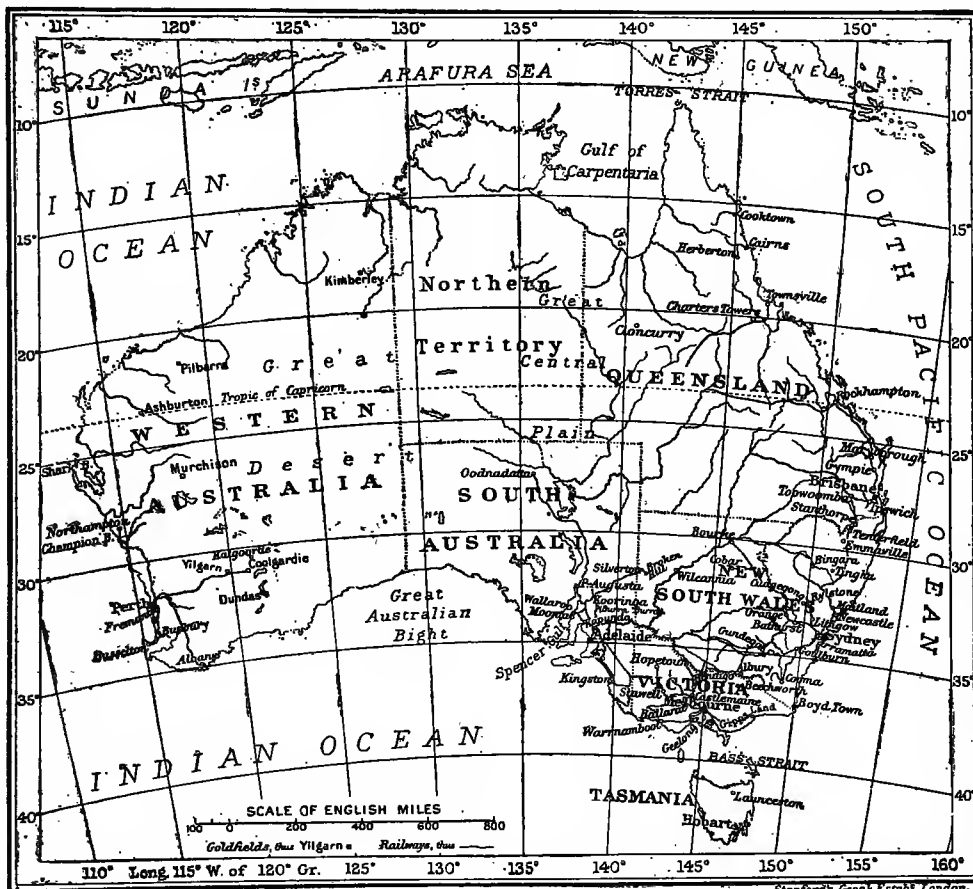

Lead is found in all the Australian states, but is worked only

when associated with silver. In West Australia the lead occurs in the form of sulphides and carbonates of great richness, but the quantity of silver mixed with it is very small. The lodes are most frequently of great size, containing huge masses of galena, and so little gangue that the ore can very easily be dressed to 83 or 84 per cent. The association of this metal with silver in the Broken Hill mines of New South Wales adds very greatly to the value of the product. Up to the end of 1899 the quantity of lead in the ores raised is estimated to have been 523,000 tons.

Mercury is found in New South Wales and Queensland. In New South Wales, in the form of cinnabar, it has been discovered on the Cudjogong river, near Rylstone, and it also occurs at Bingara, Solferino, Yulgilbar, and Cooma. In the last-named place the assays of ore yielded 22 per cent. of mercury.

Titanium, of the varieties known as octahedrite and brookite, is found in alluvial deposits in New South Wales, in conjunction with diamonds.

Wolfram (tungstate of iron and manganese) occurs in some of

SKETCH MAP OF THE MINING FIELDS OF AUSTRALIA.

the states, notably in New South Wales, Victoria, and Queensland. Scheelite, another variety of tungsten, is also found in Queensland. Molybdenum, in the form of molybdenite (sulphide of molybdenum), is found in New South Wales and Victoria, associated in the former state with tin and bismuth in quartz reefs.

Zinc ores, in the several varieties of carbonates, silicates, oxide, sulphide, and sulphate of zinc, have been found in several of the Australian states, but have attracted little attention.

Nickel, so abundant in the island of New Caledonia, has up to the present been found in none of the Australian states except Queensland. Few attempts, however, have been made to prospect systematically for this valuable mineral.

Cobalt occurs in New South Wales and Victoria, and efforts have been made in the former state to treat the ore, the metal having a high commercial value; but the market is small, and no attempt has yet been made to produce it on any large scale. The manganese ores of the Bathurst district of New South Wales often contain a small percentage of cobalt, sufficient, indeed, to warrant further attempts to work them. In New South Wales chromium is found in the northern portion of the state, in the Clarence and Tamworth districts, and also near Gundagai. It is usually associated with serpentine. In the Gundagai district the industry

was rapidly becoming a valuable one, but the low price of chrome has greatly restricted the output. In 1899 the production was valued at £17,000.

Arsenic, in its well-known and beautiful forms, orpiment and realgar, is found in New South Wales and Victoria. It usually occurs in association with other minerals in veins.

The Australian states have been bountifully supplied with mineral fuel. Five distinct varieties of black coal, of well-characterized types, may be distinguished, and these, with the two extremes of brown coal or lignite and anthracite, form a perfectly continuous series. Brown coal, or lignite, occurs principally in Victoria. Attempts have frequently been made to use the mineral for ordinary fuel purposes, but its inferior quality has prevented its general use. Black coal forms one of the principal resources of New South Wales; and in the other states the deposits of this valuable mineral are being rapidly developed. Coal of a very fair description was discovered in the basin of the Irwin river, in West Australia, as far back as the year 1846. It has been ascertained from recent explorations that the area of carboniferous formation in that state extends from the Irwin northwards to the Gascoyne river, about 300 miles, and probably all the way to the Kimberley district. The most important discovery of coal in the state, so far, is that made in the bed of

the Collie river, near Bunbury, to the south of Perth. The coal has been treated and found to be of good quality, and there are grounds for supposing that there are 250,000,000 tons in the field. Dr Jack, late Government geologist of Queensland, considers the extent of the coal-fields of that state to be practically unlimited, and is of opinion that the Carboniferous formations extend to a considerable distance under the Great Western Plains. It is roughly estimated that the Coal Measures at present practically explored extend over an area of about 24,000 square miles. Coal-mining is an established industry in Queensland, and is progressing satisfactorily. The mines, however, are situated too far from the coast to permit of serious competition with Newcastle in an export trade, and the output is practically restricted to supplying local requirements. New South Wales still exports coal to Queensland. The production of the state is about 400,000 tons a year, three-fourths of which is obtained in the Ipswich district. The coal-fields of New South Wales are situated in three distinct regions—the northern, southern, and western districts. The first of these comprises chiefly the mines of the Hunter river districts; the second includes the Illawarra district, and, generally, the coastal regions to the south of Sydney, together with Berrima, on the table-land; and the third consists of the mountainous regions on the Great Western Railway, and extends as far as Dubbo. The total area of the Carboniferous strata of New South Wales is estimated at 23,950 square miles. The seams vary in thickness. One of the richest has been found at Greta in the Hunter river district; it contains an average thickness of 41 feet of clean coal, and the quantity underlying each acre of ground has been computed to be 68,700 tons. The coal mines in New South Wales give employment to 10,340 persons, of whom 8220 are employed underground and 2120 above ground, and the annual production is about 4,700,000 tons. Black coal has been discovered in Victoria, and about 250,000 tons are now being raised. The principal collieries in the state are the Outtrim Howitt, the Coal Creek Proprietary, and the Jumbunna. In South Australia, at Leigh's Creek, north of Port Augusta, coal-beds have been discovered. The quantity of coal extracted annually in Australia has now reached 5,250,000 tons, the estimated production of each state up to the end of 1899 being as follows:—

	Tons.
New South Wales	86,000,000
Victoria	1,500,000
Queensland	5,700,000

This industry gave direct employment in and about the mines to the following numbers of persons in the several states:—

	Miners.
New South Wales	10,340
Victoria	900
Queensland	1,100

Kerosene shale (torbanite) is found in several parts of New South Wales. It is a species of cannel coal, somewhat similar to the Boghead mineral of Scotland, but yielding a much larger percentage of volatile hydro-carbon than the Scottish mineral. The richest quality yields about 100 to 130 gallons of crude oil per ton, or 17,000 to 18,000 cubic feet of gas, with an illuminating power of 35 to 40 sperm candles, when gas only is extracted from the shale. From the year 1865, when the mines were first opened, to the end of 1899, the quantity of kerosene shale raised has amounted to 996,000 tons, valued at £1,908,000.

Large deposits of alum occur close to the village of Bulladelah, 30 miles from Port Stephens, New South Wales. It is said to yield well, and a quantity of the manufactured alum is sent to Sydney for local consumption. Marble is found in many parts of New South Wales and South Australia. Kaolin, fire-clays, and brick-clays are common to all the states. Except in the vicinity of cities and townships, however, little use has been made of the abundant deposits of clay. Kaolin, or porcelain clay, although capable of application to commercial purposes, has not as yet been utilized to any extent, although found in several places in New South Wales and in West Australia.

Asbestos has been found in New South Wales in the Gundagai, Bathurst, and Broken Hill districts—in the last-mentioned district in considerable quantities. Several specimens of very fair quality have also been met with in West Australia.

Many descriptions of gems and gem stones have been discovered in various parts of the Australian states, but systematic search has been made principally for the diamond and the noble opal. Diamonds are found in all the states; but only in New South Wales have any attempts been made to work the diamond drifts. The best of the New South Wales diamonds are harder and much whiter than the South African diamonds, and are classified as on a par with the best Brazilian gems, but no large specimens have yet been found. The finest opal known is obtained in the Upper Cretaceous formation at White Cliffs, near Wilcannia, New South Wales, and at these mines about 700 men find constant employment. Other precious stones, including the sapphire, emerald, oriental emerald, ruby,

opal, amethyst, garnet, chrysolite, topaz, cairngorm, onyx, zircon, &c., have been found in the gold and tin-bearing drifts and river gravels in numerous localities throughout the states. The sapphire is found in all the states, principally in the neighbourhood of Beechworth, Victoria. The oriental topaz has been found in New South Wales. Oriental amethysts also have been found in that state, and the ruby has been found in Queensland, as well as in New South Wales. Turquoises have been found near Wangaratta, in Victoria, and mining operations are being carried on in that state. Chrysoberyls have been found in New South Wales; spinel rubies in New South Wales and Victoria; and white topaz in all the states. Chalcedony, carnelian, onyx, and cat's eyes are found in New South Wales; and it is probable that they are also to be met with in the other states, particularly in Queensland. Zircon, tourmaline, garnet, and other precious stones of little commercial value are found throughout Australia.

Commerce.—The shipping trade has expanded very greatly since 1871. In that year the tonnage entered in all the ports of Australia was only 1,679,700 tons; in 1899 it was upwards of 9,998,000 tons. These figures must be taken with qualification, as many of the steamers trading between Europe and Australia call at the principal ports of West Australia, South Australia, Victoria, and New South Wales, and are set down in the returns as entered at all these ports, so that the total tonnage is exaggerated; but when every allowance is made on this score, it will be found that Australia required nearly six times as much shipping in 1899 to carry its trade as it did in 1870. The value of goods imported into the various states in 1899 was £61,801,076; in 1891, £63,505,225; in 1881, £44,094,538; and in 1871, £26,195,760; and the exports during the same period were—1899, £74,488,792; 1891, £61,698,032; 1881, £41,111,798; 1871, £32,360,762. The imports in 1899 represent £17, 11s. 0d. and the exports £21, 3s. 1d. per inhabitant. These figures, however, refer to the gross trade; to arrive at the trade with countries outside Australia a considerable reduction will have to be made, as the value of re-exports in 1899 was approximately £18,636,000, equal to £5, 6s. 10d. per inhabitant; in that year the net imports amounted to £12, 5s. 2d. per inhabitant, and the net exports to £15, 17s. 3d. The bulk of the Australian trade is in British hands, about 35 per cent. of the imports are from Great Britain and about the same proportion of the exports are sent to that country. Australia has long been a favourite place for British investments, and under normal conditions the exports should exceed the imports to the extent of about £10,000,000 or £11,000,000 sterling, which is the amount of income derived from British investments in Australia; but as the state Governments are constantly adding something to their indebtedness and capital is still being sent to Australia for investment, the excess of exports rarely equals the amount named. The principal items of export are wool, skins, tallow, frozen mutton, chilled beef, preserved meats, butter, and other articles of pastoral produce—timber, wheat, flour, and fruits; gold, silver, lead, copper, tin, and other metals. The weight of wool exported was 458,783,000 lb, which is less by 100,000,000 lb than the export in some previous years, the falling-off being due to the effects of the dry seasons which have prevailed throughout Australia for nearly five years.

Railways.—Almost the whole of the railway lines in Australia are the property of the state Governments, and have been constructed and equipped wholly by borrowed capital. There were on the 30th June 1900, 12,448 miles open for traffic, upon which £118,483,048 had been expended. The railways are of different gauges, the standard narrow gauge of 4 feet 8½ inches prevailing only in New South Wales; in Victoria the gauge is 5 feet 3 inches; in South Australia 5 feet 3 inches and 3 feet 6 inches, and in the other states 3 feet 6 inches. Taking the year 1900, the gross earnings amounted to £10,094,431, the working expenses, exclusive of interest, £6,164,402, and the net earnings £3,930,029; the latter figure represents 3·8 per cent. upon the capital expended upon construction and equipment. In two of the states, New South Wales and South Australia proper, the railways yield more than the interest paid by the Government on the money borrowed for their construction; in Victoria the return is equal to 2·8 per cent., in Queensland 2·7, New South Wales 3·6, West Australia 5·8, and South Australia proper 3·9 per cent., but in the Northern Territory of the latter colony the working expenses have exceeded the gross earnings ever since the railways were constructed. The earnings per train mile vary greatly; but for all the lines the average is six shillings, and the working expenses about three shillings and sixpence, making the net earnings two shillings and sixpence per train mile. The ratio of receipts from coaching traffic to total receipts is about 40 per cent., which is somewhat less than in the United Kingdom; but the proportion varies greatly amongst the states themselves, the more densely-populated states approaching most nearly to the British standard. The tonnage of goods carried amounts to about 13,091,000 tons, or over 3·7 tons per inhabitant, which must be considered fairly large, especially as no great pro-

portion of the tonnage consists of minerals on which there is usually a low freightage. Excluding coal lines and other lines not open to general traffic, the length of railways in private hands is only 382 miles, or about 3 per cent. of the total mileage open. Of this length, 277 miles are in West Australia. The divergence of policy of that state from that pursued by the other states was caused by the inability of the Government to construct lines, when the extension of the railway system was urgently needed in the interests of settlement. Private enterprise was therefore encouraged by liberal grants of land to undertake the work of construction; but the changed conditions of the state have now altered the state policy, and the Government have already acquired one of the two trunk lines constructed by private enterprise, and it is not likely that any further concessions in regard to railway construction will be granted to private persons.

Posts and Telegraphs.—The postal and telegraphic facilities offered by the various states are very considerable. There are some 5800 post offices supported by the different Governments, or about one office to every 600 persons. The letters carried amount to about 54 per head, the newspapers to 27 per head, and the packets to 10 per head. The length of telegraph lines in use is 42,200 miles, and the length of wire about 2½ times that distance. In 1899 there were about 7,745,000 telegraphic messages sent, which gives an average of two messages per inhabitant. The postal services and the telegraphs are administered by the Federal Government.

Banking.—Depositors in Savings Banks number about one-fourth of the whole population. In June 1900 the sum deposited was £27,111,360 to the credit of 851,000 persons. In the ordinary banks the amount on deposit was £86,959,208, of which £50,562,108 bore interest. In 1871 the deposits in the Savings Banks amounted to £3,003,393; in 1881, £7,524,186; in 1891, £14,982,175; and in 1899, £27,111,360.

RECENT HISTORY.

The history of Australia since 1873 is mainly comprised in its industrial progress, for, with the exception of the advent of the Labour party and the Federation Government, there have been no occurrences of such political importance as to call for special mention. The four eastern states had the privilege of responsible government bestowed on them at various dates between 1855 and 1860. After the establishment of responsible government the main questions at issue were the secular as opposed to the religious system of public instruction, protection as opposed to a revenue tariff, vote by ballot, manhood suffrage, abolition of transportation and assignment of convicts, and free selection of lands before survey; these, and indeed all the great questions upon which the country was divided, were settled before the year 1873. With the disposal of these important problems, politics in Australia became a struggle for office between men whose political principles were very much alike, and the tenure of power enjoyed by the various Governments did not depend upon the principles of administration so much as upon the personal fitness of the head of the ministry, and the acceptability of his ministry to the members of the more popular branch of the legislature. For the most part, therefore, the history of the colonies is a catalogue of their domestic events, such a thing as a foreign policy being quite unknown. The leading politicians of all the states have felt the cramping effects of mere domestic legislation, albeit on the proper direction of such legislation depends the well-being of the people, and to this sense of the limitations of local politics is due, as much as to anything else, the movement towards federation, now happily consummated.

Taking the states as a whole, agrarian legislation has been the most important subject that has engrossed the attention of their parliaments, and every state has been more or less engaged in tinkering with its land laws. The main object of all such legislation is to secure the residence of the owners on the land. The object of settlers, however, in a great many, perhaps in the majority of instances, is to dispose of their

holdings as soon as possible after the requirements of the law have been complied with, and to avoid permanent settlement. This has greatly facilitated the formation of large estates devoted chiefly to grazing purposes, contrary to the policy of the legislature, which has everywhere sought to encourage tillage, or tillage joined to stock rearing, and to discourage large holdings. The importance of the land question is so great that it is hardly an exaggeration to say that it is usual for every parliament of Australia to have before it a proposal to alter or amend its land laws. Since 1870 there have been four radical changes made in New South Wales. In Victoria the law has been altered five times, and in Queensland and South Australia six times. Apart from the settlement of agrarian questions, recent Australian politics have concerned themselves with the prevention or regulation of the influx of coloured races, the prevention or settlement of labour disputes, and federation. The agitation against the influx of Chinese commenced very soon after the gold discoveries, the European miners objecting strongly to the presence of these aliens upon the diggings. The allegations made concerning the Chinese really amounted to a charge of undue industry. The Chinese were hard-working and had the usual fortune attending those who work hard. They spent little on drink or with the storekeepers, and were, therefore, by no means popular. As *Chinese question.* early as 1860 there had been disturbances of a serious character, and the Chinese were chased off the goldfields of New South Wales, serious riots occurring at Lambing Flat, on the Burrangong goldfield. The Chinese difficulty, so far as the mining population was concerned, was solved by the exhaustion of the extensive alluvial deposits; the miners' prejudice against the race, however, still exists, though they are no longer serious competitors, and the laws of some of the states forbid any Chinese to engage in mining without the express authority in writing of the Minister of Mines. The nearness of China to Australia has always appeared to the Australian democracy as a menace to the integrity of the white settlements; and at the many conferences of representatives from the various states, called to discuss matters of general concern, the Chinese question has always held a prominent place, but the absence of any federal authority has made common action difficult. In 1888 the last important conference on the Chinese question was held in Sydney and attended by delegates from all the states. Previously to the meeting of the conference there had been a great deal of discussion in regard to the influx of Chinese, and such influx was on all sides agreed to be a growing danger. The conference, therefore, merely expressed the public sentiment when it resolved that, although it was not advisable to prohibit altogether this class of immigration, it was necessary in the public interests that the number of Chinese privileged to land should be so limited as to prevent the people of that race from ever becoming an important element in the community. The New South Wales parliament was considering a Chinese Exclusion Bill when the conference of 1888 was summoned, and ultimately passed a law which in some respects went much beyond the agreement arrived at. Under the New South Wales law masters of vessels are forbidden, under a heavy penalty, to bring to the colony more than one Chinese to every 300 tons, and a poll-tax of £100 is charged on every Chinese landing. In Victoria, Queensland, and South Australia no poll-tax is imposed, but masters of vessels may bring only one Chinese to every 500 tons burden. West Australian legislation was until recently similar to that of the three last-named states, but has now been superseded by the Coloured Immigrants Restriction Act. Tasmania allows one Chinese passenger to every 100 tons, and imposes a poll-tax of £10. These

stringent regulations have had the effect of greatly restricting the influx of Chinese, but in spite of all precautions there is still some immigration. The only other alien race present in large numbers in Australia are the Polynesians in Queensland, where they number about 9000. Of late years there has been an influx of Hindoos and other Eastern races, sufficiently large to cause a feeling of uneasiness amongst the colonists; and in some of the states the evil has been dealt with by parliament, and restrictive legislation has been passed which meted out to these immigrants somewhat similar treatment to that accorded to the Chinese. But a very large proportion of the Asiatics, whose entrance into the colonies it was desired to stop, were British subjects, and the Imperial Government refused to sanction any measure directly prohibiting in plain terms the movement of British subjects from one part of the empire to another. Eventually, the difficulty was overcome by the application of an educational test to the coloured races seeking admission to the states, whereby they are required to write out in some European language an application for permission to enter the colony in which they propose to reside. This provision is taken from an Act in operation in Natal, which is said to have been effectual in preventing an undue influx of Asiatics. An Act applying the educational test has been in force in West Australia since the beginning of 1898; more recently a similar Act was passed in New South Wales, while the other states have analogous legislation in operation. The agitation which this restrictive legislation caused was promoted and kept alive almost entirely by the trades unions, and was the first legislative triumph of the Labour party, albeit that party was not at the time directly represented in parliament.

The Labour movement in Australia may be traced back to the early days when transportation was in vogue, and the free immigrant and the time-expired convict objected to the competition of the bond labourer. The great object of these early struggles being attained, Labour directed its attention mainly to securing shorter hours. It was aided very materially by the dearth of workers consequent on the gold discoveries, when every man could command his own price. When the excitement consequent on the gold finds had subsided, there was a considerable reaction against the claims of Labour, and this was greatly helped by the congested state of the labour market; but the principle of an eight-hours day made progress, and was conceded in several trades. In the early years of the 'seventies the colonies entered upon an era of well-being, and for about twelve years every man, willing to work and capable of exerting himself, readily found employment. The Labour unions were able to secure in these years many concessions both as to hours and wages. In 1873 there was an important rise in wages, in the following year there was a further advance, and another in 1876; but in 1877 wages fell back a little, though not below the rate of 1874. In 1882 there was a very important advance in wages; carpenters received 11s. a day, bricklayers 12s. 6d., stonemasons 11s. 6d., plasterers 12s., painters 11s., blacksmiths 10s., and navvies and general labourers 8s., and work was very plentiful. For five years these high wages ruled; but in 1886 there was a sharp fall, though wages still remained very good. In 1888 there was an advance, and again in 1889. In 1890 matters were on the eve of a great change and wages fell, in most cases to a point 20 per cent. below the rates of 1885. In 1893 came the bank crisis and great restriction in trade. Almost the first effect of this restriction was a reduction in wages, which touched their lowest in 1895, and fell to a point below that of any year since 1850. Since then there has

Labour movement.

been a marked recovery, and wages stood in 1900 at about the same level as in 1873. During the whole period from 1873 onwards, prices, other than of labour, have been steadily tending downwards, so that the cost of living in 1900 was much below that of 1873. Taking everything into consideration the reduction was, perhaps, not less than 40 per cent., so that though the nominal or money wages in 1873 and 1900 were the same, the actual wages were much higher in the latter year. Much of the improvement in the lot of the wage-earners has been due to the Labour organizations, yet so late as 1881 these organizations were of so little account, politically, that when the law relating to trades unions was passed in New South Wales, the English law was followed, and it was simply enacted that the purposes of any trades union shall not be deemed unlawful (so as to render a member liable to criminal prosecution for conspiracy or otherwise) merely by reason that they are in restraint of trade. After the year 1884 Labour troubles became very frequent, the New South Wales coal miners in particular being at war with the colliery owners during the greater part of the six years intervening between then and what is called the Great Strike. The strong downward tendency of prices made a reduction of wages imperative; but the labouring classes failed to recognize any such necessity, and strongly resented any reductions proposed by employers. It was hard indeed for a carter drawing coal to a gasworks to recognize the necessity which compelled a reduction in his wages because wool had fallen 20 per cent. Nor were other labourers, more nearly connected with the producing interests, satisfied with a reduction of wages because produce had fallen in price all round. Up to 1889 wages held their ground, although work had become more difficult to obtain, and some industries were being carried on without any profit. It was at such an inopportune time that the most extensive combination of Labour yet brought into action against capital formulated its demands. It is possible that the London dockers' strike was not without its influence on the minds of the Australian Labour leaders. That strike had been liberally helped by the Australian unions, and it was confidently predicted that, as the Australian workers were more effectively organized than the English unions, a corresponding success would result from their course of action. A strike of the Newcastle miners, after lasting twenty-nine weeks, came to an end in January 1890, and throughout the rest of the year there was great unrest in Labour circles. On 6th September the silver mines closed down, and a week later a conference of employers issued a manifesto which was met next day by a counter-manifesto of the Intercolonial Labour Conference, and almost immediately afterwards by the calling out of 40,000 men. The time chosen for the strike was the height of the wool season, when a cessation of work would be attended with the maximum of inconvenience. Sydney was the centre of the disturbance, and the city was in a state of industrial siege, feeling running to dangerous extremes. Riotous scenes occurred both in Sydney and on the coal-fields, and a large number of special constables were sworn in by the Government. Towards the end of October 20,000 shearers were called out, and many other trades, principally concerned with the handling or shipping of wool, joined the ranks of the strikers, with the result that the maritime and pastoral industries throughout the whole of Australia were most injuriously disturbed. The Great Strike, as it was called, terminated early in November 1890, the employers gaining a decisive victory. The colonies were, however, to have other and bitter experiences of strikes before Labour recognized that of

The Great Strike of 1890.

all means for settling industrial disputes strikes are, on the whole, the most disastrous that it can adopt. The strikes of the years 1890 and 1892 are just as important on account of their political consequences as from the direct gains or losses involved.

As one result of the strike of 1890 a movement was set afoot by a number of enthusiasts, more visionary than practical, that has resulted in a measure of more or less disaster. This was the planting of a colony of communistic Australians in South America.

Political consequences.

After much negotiation the leader, Mr William Lane, a Brisbane journalist, decided on Paraguay, and he tramped across the continent, preaching a new crusade, and gathering in funds and recruits in his progress. On the 16th of July 1893 the first little army of "New Australians" left Sydney in the *Royal Tar*, which arrived at Monte Video on the 31st of August. Other consignments of intending settlers in "New Australia" followed; but though the settlement is still in existence it has completely failed to realize the impracticable ideals of its original members. The Queensland Government has assisted some of the disillusioned to escape from the paradise which has proved a prison; some managed to get away on their own account; and those that have remained have split into as many settlements almost as there are settlers. Another effect of the Great Strike was in a more practical direction. New South Wales was the first country which endeavoured to settle its labour grievances through the ballot-box and to send a great party to parliament as the direct representation of Labour, pledged to obtain through legislation what it was unable to obtain by strikes and physical force. The principle of one-man one-vote had been persistently advocated without arousing any special parliamentary or public enthusiasm until the meeting of the Federal Convention in 1891. The convention was attended by Sir George Grey, who was publicly welcomed to the colony by New Zealanders resident in Sydney, and by other admirers, and his reception was an absolute ovation. He eloquently and persistently advocated the principle of one-man one-vote as the bed-rock of all democratic reform. This subsequently formed the first plank of the Labour platform. Several attempts had been made by individuals belonging to the Labour party to enter the New South

New South Wales.

Wales parliament, but it was not until 1891 that the occurrence of a general election gave the party the looked-for opportunity for concerted action. The results of the election came as a complete surprise to the majority of the community. The Labour party captured 35 seats out of a House of 125 members; and as the old parties almost equally divided the remaining seats, and a fusion was impossible, the Labour representatives dominated the situation. It was not long, however, before the party itself became divided on the fiscal question; and a Protectionist Government coming into power, about half the Labour members gave it consistent support and enabled it to maintain office for about three years, the party as a political unit being thus destroyed. The events of these three years taught the Labour leaders that a parliamentary party was of little practical influence unless it was able to cast on all important occasions a solid vote, and to meet the case a new method was devised. The party therefore determined that they would refuse to support any person standing in the Labour interests who refused to pledge himself to vote on all occasions in such way as the majority of the party might decide to be expedient. This was called the "solidarity pledge," and, united under its sanction, what was left of the Labour party contested the general election of 1894. The result was a defeat, their numbers

being reduced from 35 to 19; but a signal triumph was won for solidarity. Very few of the members who refused to take the pledge were returned, and the adherents of the united party were able to accomplish more with their reduced number than under the old conditions.

The two features of the Labour party in New South Wales are its detachment from other parties and the control of the caucus. The caucus, which is the natural corollary of the detachment, determines by majority the vote of the whole of the members of the party, independence of action being allowed on minor questions only. So far the party has refrained from formal alliance with the other great parties of the state. It supports the Government as the power alone capable of promoting legislation, but its support is given only so long as the measures of the Government are consistent with the Labour policy. This position the Labour party has been able to maintain with great success, owing to the circumstance that the other parties have been almost equally balanced.

The movement towards forming a parliamentary Labour party was not confined to New South Wales; on the contrary, it was common to all the colonies except West Australia, and its greatest triumphs have been achieved in New Zealand and South Australia. Like the organization in New South Wales, the Labour party of South Australia owes its origin to the failure of the Great Strike of 1890. In that year the Trades and Labour Council of Adelaide summoned a conference of Labour representatives, at which a proposal for the formation of a parliamentary party was drawn up and adopted. The political programme of the new party was comprehensive and popular, and almost immediately on its adoption three representatives of Labour won seats in the Second Chamber (Legislative Council), and at the ensuing general election of 1893 the party secured 8 seats in the assembly out of a total of 54, and 6 out of 24 in the council, thereby gaining a controlling vote in both Houses. Two general elections have since taken place, and at each the party has maintained its position. In 1900 it controlled 12 votes in the popular House and 8 in the council. The members of the South Australian Labour party differ in one important respect from those of New South Wales. They are all persons who have worked for their living at manual labour, and this qualification of being an actual worker is one that was strongly insisted upon at the formation of the party and strictly adhered to, although the temptation to break away from it and to accept as candidates persons of superior education and position has been very great. The South Australian Labour party has maintained the unity of its ranks, notwithstanding the fact that several of its members hold very diverse views on important questions of political reform, and it recently showed its power by displacing the Government of the Right Honourable C. C. Kingston, and almost immediately afterwards ousting that of Mr V. L. Solomon, who succeeded Mr Kingston in the premiership. In Victoria the Labour party has not been so conspicuous as in New South Wales and South Australia. The members of the Victorian Assembly are not divided into such distinct parties as are the members of the popular houses of the other colonies, and the Labour party has therefore not been able to determine the real balance of power. Nevertheless it wields an influence that is very much respected, as is evidenced by the large amount of advanced democratic legislation which has been proposed by the various governments that have held office since 1890, even by governments with strong Conservative leanings. In Queensland the Labour party numbered, in 1900, 21 out of 72 members in the elective branch of parliament, a larger proportion than in any other state; but only for a brief period have parties been so evenly divided as to give the Labour party the balance of power.

Other colonies.

The brief period mentioned was towards the close of 1899, when dissatisfaction had spread amongst the supporters of the Government of Mr Dickson. That Government was displaced on a motion moved by the leader of the Labour party, Mr Dawson, supported by the Opposition and by a number of members usually voting with the Government. Mr Dawson was called on to form a Government. He did so, and his ministry held office for only two days, giving place to a government including all the leading members of the previous administration, as well as the leader of the former Opposition.

Australian Federation.—The question of federation was not lost sight of by the framers of the original constitution which was bestowed upon New South Wales. In the report of the committee of the Legislative Council appointed in 1852 to prepare a constitution for that colony, the following passage occurs:—"One of the most prominent legislative measures required by the colony, and the colonies of the Australian group generally, is the establishment at once of a General Assembly, to make laws in relation to those intercolonial questions that have arisen or may hereafter arise among them. The questions which would claim the exercise of such a jurisdiction appear to be (1) intercolonial tariffs and the coasting trade; (2) railways, roads, canals, and other such works running through any two of the colonies; (3) beacons and lighthouses on the coast; (4) intercolonial gold regulations; (5) postage between the said colonies; (6) a general court of appeal from the courts of such colonies; (7) a power to legislate on all other subjects which may be submitted to them by addresses from the legislative councils and assemblies of the colonies, and to appropriate to any of the above-mentioned objects the necessary sums of money, to be raised by a percentage on the revenues of all the colonies interested." This wise recommendation received very scant attention, and it was not until the necessities of the colonies forced them to it that an attempt was made to do what the framers of the original constitution suggested. Federation at no time actually dropped out of sight,

**History of
federation
movement.**

but it was not until thirty-five years later that any practical steps were taken towards its accomplishment. Meanwhile a sort of makeshift was devised, and the Imperial Parliament passed a measure permitting the formation of a Federal Council, to which any colony that felt inclined to join could send delegates. Of the seven colonies New South Wales and New Zealand stood aloof from the council, and from the beginning it was therefore shorn of a large share of the prestige that would have attached to a body speaking and acting on behalf of a united Australia. The council had also a fatal defect in its constitution. It was merely a deliberative body, having no executive functions and possessing no control of funds or other means to put its legislation in force. Its existence was well-nigh forgotten by the people of Australia until the occurrence of its biennial meetings, and even then but slight interest was taken in its proceedings. The council held eight meetings, at which many matters of intercolonial interest were discussed. The last occasion of its being called together was in 1899, when the council met in Melbourne. In 1889 an important step towards federation was taken by Sir Henry Parkes. The occasion was the report of Major-General Edwards on the defences of Australia, and Sir Henry addressed the other premiers on the desirability of a federal union for purposes of defence. The immediate result was a conference at Parliament House, Melbourne, of representatives from each of the seven colonies. This conference adopted an address to the Queen expressing its loyalty and attachment, and submitting certain resolutions which affirmed the desirability of an early union, under the Crown, of the Australasian colonies, on principles just to all, and provided that the

remoter Australasian colonies should be entitled to admission upon terms to be afterwards agreed upon, and that steps should be taken for the appointment of delegates to a national Australasian convention, to consider and report upon an adequate scheme for a federal convention. In accordance with the understanding arrived at, the various Australasian parliaments appointed delegates to attend a national convention to be held in Sydney, and on the 2nd March 1891 the convention held its first meeting. Sir Henry Parkes was elected president, and he moved a series of resolutions embodying the principles necessary to establish, on an enduring foundation, the structure of a federal government. These resolutions were slightly altered by the conference, and were adopted in the following form:—

1. The powers and rights of existing colonies to remain intact, except as regards such powers as it may be necessary to hand over to the Federal Government.
2. No alteration to be made in states without the consent of the legislatures of such states, as well as of the federal parliament.
3. Trade between the federated colonies to be absolutely free.
4. Power to impose customs and excise duties to be in the Federal Government and parliament.
5. Military and naval defence forces to be under one command.
6. The federal constitution to make provision to enable each state to make amendments in the constitution if necessary for the purposes of federation.

Other formal resolutions were also agreed to, and on the 31st of March Sir Samuel Griffith, as chairman of the committee on constitutional machinery, brought up a draft Constitution Bill, which was carefully considered by the convention in committee of the whole and adopted on the 9th of April, when the convention was formally dissolved. The Bill, however, fell absolutely dead. Not because it was not a good Bill, but because the movement out of which it arose had not popular initiative, and therefore failed to reach the popular imagination. Even its authors recognized the apathy of the people, and parliamentary sanction to its provisions was not sought in any colony.

Although the Bill drawn up by the convention of 1891 was not received by the people with any show of interest, the federation movement did not die out; on the contrary, it had many enthusiastic advocates, especially in the colony of Victoria. In 1894 an unofficial convention was held at Corowa, at which the cause of federation was strenuously advocated, but it was not until 1895 that the movement obtained new life, by reason of the proposals adopted at a meeting of Premiers convened by Mr G. H. Reid of New South Wales. At this meeting all the colonies except New Zealand were represented, and it was agreed that the parliament of each colony should be asked to pass a Bill enabling the people to choose ten persons to represent the colony on a federal convention; the work of such convention being the framing of a federal constitution to be submitted to the people for approval by means of the referendum. During the year 1896 Enabling Acts were passed by New South Wales, Victoria, Tasmania, South Australia, and West Australia, and delegates were elected by popular vote in all the colonies named except West Australia, where the delegates were chosen by parliament. The convention met in Adelaide on the 22nd of March 1897, and, after drafting a Bill for the consideration of the various parliaments, adjourned until the 2nd of September. On that date the delegates reassembled in Sydney, and debated the Bill in the light of the suggestions made by the legislatures of the federating colonies. In the course of the proceedings it was announced that Queensland desired to come within the proposed union; and in view of this development, and in order to give further opportunity for the consideration of the Bill, the convention again adjourned. The third and final session

was opened in Melbourne on the 20th of January 1898, but Queensland was still unrepresented; and, after further consideration, the draft Bill was finally adopted on the 16th of March and remitted to the various colonies for submission to the people.

In its main provisions the bill of 1898 followed generally that of 1891, yet with some very important alterations. It proposed to establish, under the Crown, a federal union of the Australasian colonies, to be designated the Commonwealth of Australia. A federal executive council was created, to be presided over by a governor-general appointed by the Sovereign. The legislature was to consist of two houses—a Senate, in which each colony joining the federation at its inception was conceded the equal representation of six members; and a House of Representatives, to consist of, as nearly as possible, twice the number of senators, to which the provinces were to send members in proportion to population, with a minimum of five representatives for each of the original federating states. The principle of payment of members was adopted for the Senate as well as the House of Representatives. The nominative principle for the upper house was rejected, both houses being elective, on a suffrage similar to that existing in each colony for the popular chamber at the foundation of the Commonwealth. The House of Representatives was to be elected for a period of three years, the term of office of senators was twice that period, but half the Senate was to retire every three years. The capital of the Commonwealth was to be established in federal territory. To the federal authority was assigned power to deal with a large number of matters, with the provision that in case of conflict between federal and state law the former should prevail. Customs and excise were to be taken over on the establishment of the Commonwealth, and posts and telegraphs, naval and military defence, lighthouses and lightships, beacons and buoys, and quarantine, on dates to be proclaimed, but without further legislation. A uniform tariff of customs and excise was to be imposed within a period of two years, intercolonial trade then becoming absolutely free. Besides these were many subsidiary provisions usually found in federal constitutions, and provisions of a special character such as were needed to meet the peculiar conditions of the Australian states.

The constitution was accepted by Victoria, South Australia, and Tasmania by popular acclamation, but in New South Wales very great opposition was shown, the main points of objection being the financial provisions, equal representation in the Senate, and the difficulty in the way of the larger states securing an amendment of the constitution in the event of a conflict with the smaller states. As far as the other colonies were concerned, it was evident that the Bill was safe, and public attention throughout Australia was fixed on New South Wales, where a fierce political contest was raging, which it was recognized would decide the fate of the measure for the time being. The fear was as to whether the statutory number of 80,000 votes necessary for the acceptance of the Bill would be reached. This fear proved to be well founded, for the result of the referendum in New South Wales showed 71,595 votes in favour of the Bill and 66,228 against it, and it was accordingly lost. In Victoria, Tasmania, and South Australia, on the other hand, the Bill was accepted by triumphant majorities. West Australia did not put it to the vote, as the Enabling Act of that colony only provided for joining a federation of which New South Wales should form a part. The existence of such a strong opposition to the Bill in the mother colony convinced even its most zealous advocates that some changes would have to be made in the constitution before it could be accepted by the people; consequently, although the general election in New South Wales, held six or seven weeks later, was fought on the federal issue, yet the opposing parties seemed to occupy somewhat the same ground, and the question narrowed itself down to one as to which party should be entrusted with the negotiations to be conducted on behalf of the colony, with a view to securing a modification of the objectionable features of the Bill. The new parliament decided to adopt the procedure of again sending the Premier, Mr Reid, into conference, armed with a

series of resolutions affirming its desire to bring about the completion of federal union, but asking the other colonies to agree to the reconsideration of the provisions which were most generally objected to in New South Wales. The other colonies interested were anxious to bring the matter to a speedy termination, and readily agreed to this course of procedure. Accordingly a Premiers' conference was held in Melbourne at the end of January 1899, at which Queensland was for the first time represented. At this conference a compromise was effected, something was conceded to the claims of New South Wales, but the main principles of the Bill remained intact. The Bill as amended was submitted to the electors of each colony and again triumphantly carried in Victoria, South Australia, and Tasmania. In New South Wales and Queensland there were still a large number of persons opposed to the measure, which was nevertheless carried in both colonies. New South Wales having decided in favour of federation, the way was clear for a decision on the part of West Australia. The Enabling Bill passed the various stages in the parliament of that colony, and the question was then submitted by way of referendum to the electors. The result of the voting (in five colonies in 1899, and in West Australia in 1900) was as follows:—

		1899.
New South Wales	{ for	107,420
	{ against	82,741
Victoria	{ for	152,653
	{ against	9,804
Queensland	{ for	35,181
	{ against	28,965
South Australia	{ for	65,990
	{ against	17,053
West Australia (1900)	{ for	44,704
	{ against	19,691
Tasmania	{ for	13,437
	{ against	791

In accordance with this verdict, the colonial draft Bill was submitted to the Imperial Government for legislation as an Imperial Act; and six delegates were sent to England to explain the measure and to pilot it through the Cabinet and Parliament. These delegates were—Mr Barton (New South Wales), Mr Deakin (Victoria), Mr Kingston (South Australia), Mr Dickson (Queensland), Mr Parker (West Australia), and Sir Philip Fysh (Tasmania).

Under an Act of the British Parliament, dated 9th July 1900, passed under the auspices of Mr Chamberlain, Secretary of State for the colonies, a proclamation was issued, 17th September of the same year, declaring that, on and after 1st January 1901, the people of New South Wales, Victoria, South Australia, Queensland, Tasmania, and West Australia should be united in a Federal Commonwealth under the name of the Commonwealth of Australia. The Act which gave authority for the issue of this proclamation embodied and established (with such variations as had been accepted on behalf of the colonies) the constitution agreed to at the Premiers' conference of 1899. It was cordially welcomed in the mother country, and though its passage was marked by certain difficulties, finally became law amid signs of general approval. The difficulties arose with regard to the right of appeal to the Queen in Council. By Clause 74 of the original Bill this right was very seriously curtailed; Mr Chamberlain wished to preserve it as in the case of Canada, while, in order to disarm colonial opposition, he suggested that the judicial committee of the Privy Council should be strengthened by the appointment of four colonial members with the rank of lords of appeal. But after privately conferring with the Australian delegates he withdrew this suggestion,

Premiers' conference, 1899.

Commonwealth Act, 1900.

and when the second reading of the Bill came on he announced that a compromise had been agreed upon. The final form of the disputed clause provided that in cases which involved non-Australian interests the right of appeal should be fully maintained, and that in questions between the Commonwealth and a single state, or between two states, leave to appeal might be given by the High Court of Australia. Mr Chamberlain indicated that this matter might receive further development at a future time, and that it was possible that after consulting with the colonies the Government might propose the establishment of a permanent court of appeal for the whole empire. Soon after the passage of the Bill the choice of governor-general of the new Commonwealth fell upon Lord Hopetoun, who had won golden opinions as governor of Victoria a few years before; Mr Barton, who had taken the lead among the Australian delegates, became first Prime Minister; and the Commonwealth was successfully inaugurated at the opening of 1901.

The six colonies entering the Commonwealth were denominated original states, and new states might be admitted, or might be formed by separation from or union of two or more states or parts of states; and territories (as distinguished from states) might be taken over and governed under the legislative power of the Commonwealth. The legislative power is vested in a federal parliament, consisting of the Sovereign, a senate, and a house of representatives, the Sovereign being represented by a governor-general. The Senate was to consist of the same number of members (not less than six) for each state, the term of service being six years, but subject to an arrangement that half the number would retire every three years. The House of Representatives was to consist of members chosen in the different states in numbers proportioned to their population, but never fewer than five. The first House of Representatives was to contain seventy-five members. For elections to the Senate the governors of states, and for general elections of the House of Representatives the governor-general, would cause writs to be issued. The Senate would choose its own President, and the House of Representatives its Speaker; each house would make its own rules of procedure; in each, one-third of the number of members would form a quorum; the members of each must take oath, or make affirmation of allegiance; and all alike would receive an allowance of £400 a year. The legislative powers of the parliament have a wide range, many matters being transferred to it from the colonial parliaments. The more important subjects with which it deals are trade, shipping, and railways; taxation, bounties, the borrowing of money on the credit of the Commonwealth; the postal and telegraphic services; defence, census, and statistics; currency, coinage, banking, bankruptcy; weights and measures; copyright, patents, and trade marks; marriage and divorce; immigration and emigration; conciliation and arbitration in industrial disputes. Bills imposing taxation or appropriating revenue must not originate in the Senate, and neither taxation Bills nor Bills appropriating revenue for the annual service of the Government may be amended in the Senate, but the Senate may return such Bills to the House of Representatives with a request for their amendment. Appropriation laws must not deal with other matters. Taxation laws must deal with only one subject of taxation; but customs and excise duties may, respectively, be dealt with together. Votes for the appropriation of the revenue shall not pass unless recommended by the governor-general. The constitution provides means for the settlement of disputes between the houses, and requires the assent of the Sovereign to all laws. The executive power is vested in the governor-general, assisted by an executive council appointed by himself. He has command of the army and navy, and appoints federal ministers and judges. The ministers are members of the executive council, and must be, or within three months of their appointment must become, members of the parliament. The judicial powers are vested in a high court and other federal courts, and the federal judges hold office for life or during good behaviour. The High Court has appellate jurisdiction in cases from other federal courts and from the supreme courts of the states, and it has original jurisdiction in matters arising under laws made by the federal parliament, in disputes between states, or residents in different states, and in matters affecting the representatives of foreign powers. Special

provisions were made respecting appeals from the High Court to the Sovereign in council. The constitution set forth elaborate arrangements for the administration of finance and trade during the transition period following the transference of departments to the Commonwealth. Within two years uniform customs duties were to be imposed; thereafter the parliament of the Commonwealth had exclusive power to impose customs and excise duties, or to grant bounties; and trade within the Commonwealth was to be absolutely free. Exceptions were made permitting the states to grant bounties on mining and (with the consent of the parliament) on exports of produce or manufactures—West Australia being for a time partially exempted from the prohibition to impose import duties.

The constitution, parliament, and laws of each state, subject to the federal constitution, retained their authority; state rights were carefully safeguarded, and an inter-state commission was given powers of adjudication and of administration of the laws relating to trade, transport, and other matters. Provision was made for necessary alteration of the constitution of the Commonwealth, but so that no alteration could be effected unless the question had been directly submitted to, and the change accepted by, the electorate in the states. The seat of government was to be within New South Wales, not less than 100 miles distant from Sydney, and of an area not less than 100 square miles. Until other provision was made, the governor-general was to have a salary of £10,000, paid by the Commonwealth. Respecting the salaries of the governors of states, the constitution made no provision.
